were few in number, and limited in their operation. They had no arms in their hands, like Mahomet and his warlike followers; it was not at the head of a devoted soldiery that they preached the gospel; they were utterly destitute of wealth or influence; and, except in the case of the apostle Paul, they had no pretensions to learning. The current of popular opinion and of popular feeling ran strongly against them; and they knew very well, that they were "hated of all men" on account of the religion which they professed. It is to other and higher causes, to a mightier machinery, and to a power more than human, that we must ascribe the extraordinary rapidity with which Christianity was propagated. The apostles and evangelists were endowed with miraculous gifts: they healed the sick, they cleansed the lepers, they restored the dead to life. And what fitted them, in a remarkable degree, for the important work which they had undertaken, they spoke to every nation which they visited in its own language, proclaiming the glad tidings of reconciliation and of peace, and supporting and comforting their disciples amidst the sufferings to which they were exposed. "There was in their very words," says a respectable writer, "an incredible energy, an amazing power of sending light into the understanding, and conviction into the heart. To this were added the commanding influence of stupendous miracles, the foretelling of future events, the power of discerning the secret thoughts and intentions of the heart, a magnanimity superior to all difficulties, a contempt of riches and honours, a serene tranquillity in the face of death, and an invincible patience under torments still more dreadful than death itself; and all this accompanied with lives free from every stain, and adorned by the constant practice of the sublime virtue." They were enabled likewise to communicate the same extraordinary powers to others, of which they themselves possessed. The evidences of their commission were multiplied on every side; the temples of idolatry began speedily to be forsaken, the number of ages was broken and dissipated, the eye was filled with the prospect of immortality, and the world, awakened and active, pressed forward to everlasting life. Churches were quickly established in almost every portion of the Roman empire; in Phrygia and Galatia, provinces of Asia Minor, and in Ethiopia; at Corinth, at Philippi, at Thessalonica, and in the capital itself. In a short time, nations and cities more remote, heard of Jesus and of his doctrine. The Gauls received the knowledge of Christianity from the immediate successors of the apostles; and during the course of the second century, the Germans, the Spaniards, and the Britons, were added to the multitudes in other places, who made open profession of the Christian faith.

Fortunately for the cause of Jesus, and the best interests of mankind, our holy religion had acquired a considerable degree of stability before any laws were enacted against it. The Christians were at first almost universally regarded as a sect of the Jews, and they escaped from persecution under the general toleration which had been extended to the Hebrew people. The distinction, however, between Christianity and Judaism, came in time to be known. The followers of Jesus made such open and zealous attacks upon the Paganism with which they were surrounded, that the populace considered them as atheists; and this opinion, most incorrect and injurious in itself, having been once entertained, speedily gained strength and currency, because it was perceived that the Christians had no temples, altars, or sacrifices. They held likewise their meetings in secret; they often assembled in the night; and it was sagaciously inferred that they withdrew from the public eye, in order to practise some abominable rites, which they were afraid or ashamed to disclose.

In these circumstances, the Emperor Nero set fire to the city of Rome, and reduced a great part of it to ashes. This wanton act excited the indignation of the people. The emperor, anxious, as it seems, for his popularity, laid the guilt, and all the odium connected with it, to the charge of the Christians. He commenced a very severe persecution against them. He inflicted upon them the most cruel punishments. Some of them were crucified, others were impaled, some were thrown to the wild beasts; and not a few, having been wrapped in clothes smeared with pitch and sulphur, were burnt during the night, and made to serve as torches for illuminating the gardens of the emperor. In the meantime, this prodigy of inhumanity, entertained the people with Circensian games, and was himself an unblushing spectator of the whole; sometimes walking about in the dress of a charioteer, and mingling with the crowd, and at other times viewing the exhibitions from his car. But all his attempts were without effect; neither his largesses, nor his concern for the honour of the gods, nor his merciless severity towards the unhappy followers of Christ, were sufficient to remove from him the imputation of having given orders to set the city on fire. And accordingly he has been transmitted to us, by the pen of Tacitus, in the double character of an incendiary and a persecutor; and his very name is proverbial for all that is tyrannical, cruel, and brutal, and for all that is malignant, perfidious, and mean. After this persecution, which took place about the year 64, and during which St Paul was beheaded at Rome, the churches had rest for a time. Under many of the succeeding emperors, however, they were exposed to the resentment of their enemies. In the reign of Domitian, the apostle John was banished to the island of Patmos, where he wrote his Apocalypse. And a countless multitude of individuals, whose names no history records, and who have long ago passed away out of the memory of man, boldly avowed their attachment to the faith "once delivered to the saints," and rejoiced that they were counted worthy to suffer or to die in the cause of Christianity.

Even the Emperor Trajan, who has been described as a mild and accomplished prince, is to be numbered among the persecutors of the church; and mild and accomplished as he undoubtedly was, when compared with his predecessors, he appears to have meditated nothing less than the extinction of the Christian name. There has come down to us a correspondence between this emperor and the younger Pliny, who was governor of Bithynia, and it refers to the very subject which now occupies our attention. The correspondence in question is deserving of particular notice, both because it shows us how the Christians were treated in those modes of investigation to which the name of trial has been given, and because it affords us the testimony of a Roman magistrate, to the purity and simplicity of their manners. After expressing to the emperor his doubts with regard to the plan of conduct which he ought to follow the procurator of Bithynia, the enlightened and philosophic Pliny, thus declares what he had already done; (Pliny's Epistles, vol. x. p. 97, 98.) "In the mean time," says he, "this has been my method with respect to those who were brought before me as Christians... I
asked them if they were Christians: if they pleaded guilty, I interrogated them twice afresh, with a menace of capital punishment. In case of obstinate perseverance, I ordered them to be executed. For of this I had no doubt, whatever was the nature of their religion, that a sullen and inflexible obstinacy called for the vengeance of the magistrate.

Strange conduct this for a judge, and a very extraordinary mode of trial indeed! Yet such was the treatment of the Christians at the tribunal of the younger Pliny; a man whose character for benevolence, and even for justice, is perhaps the most unexceptionable of any which pagan antiquity can furnish. The testimony, however, given by the same distinguished person to the simplicity and purity of the Christian manner, must not be hastily passed over.

"And this," says he, "was their account of the religion which they professed, whether it deserves the appellation of a crime or an error, namely, that on a stated day, they were accustomed to assemble before sunrise, and to repeat among themselves a hymn to Christ in the character of a God, (Christo quasi Deo,) and to bind themselves, by an oath, not to commit any wickedness, but, on the contrary, to abstain from thefts, robberies, and adulteries; not to violate their promise or deny a pledge: after which," continues the judge, "it is their custom to separate, and then to meet again, sitting down to a harmless meal, of which all are invited to partake."

We are proud of this testimony: it comes from one who evidently believed the statement to be correct; it comes from a man of education and discernment, and it is to be found in a confidential letter from this man to the emperor, acknowledging his incompetence, and begging to be informed how he should act in so peculiar a case. And it puts to flight, for ever, all the accusations which interest and malice have brought against the tendency of the Christian doctrine, and the purity of the Christian assemblies. The persecution, however, with some restrictions, went on. "The Christians," says the emperor in his reply, "are not to be sought for; but if any are brought before you, and convicted, they are to be punished.

Indeed the human mind revolts at the sufferings which the followers of Christ were doomed in many places to experience. They were publicly whipped till their bones and sinews appeared; their flesh was torn from them with pincers; they were consumed in a slow fire, carefully prevented from reaching the vital parts; they were tortured in iron chairs, made red hot, and kept glowing to receive them. The aged and venerable Polycarp was put to death; the excellent and learned Justin obtained the crown of martyrdom. In the beginning of the third century, Irenæus, bishop of Lyons, sealed his testimony with his blood. Pantamiæna, a woman of great beauty, was condemned to suffer on account of her religion, and, with Marcella her mother, was burnt to death, melted pitch having been poured over their naked bodies. The time would fail us should we attempt to enumerate the victims of superstition. Neither age nor sex was spared. The arm of power was lifted up; the genius of man was exhausted in the invention of tortures; and, to a hasty observer, it might seem, that the hour was at length come when Christianity, subdued and worn out with sufferings, would resign her name and her place among men.

This conclusion, however, would be the very reverse of the truth. The Christians had multiplied in a most extraordinary degree. They filled the senate-house and the army, and they were to be found in all situations and employments. Persecution had produced upon them its usual effects,—it had not only united them more closely together, but it had inflamed their zeal and quickened their activity. Their opinions soon became general; a very great majority of the people embraced and avowed them, till at length, in the year 325, Constantine the Great was invested with the purple, and the government of Jesus became the religion of the empire. From this time Christianity was not only tolerated, but protected and cherished. The number of the edifices consecrated to the worship of God was increased, and the emperor himself was not ashamed to be seen engaging in the exercises of religion, or in the devout observance of the ceremonies ordained by the church. It has been said, that when Constantine was about to engage in battle with his rival Maxentius, he saw in the heavens a luminous cross, with the following inscription, "by this overcome," and that in consequence of the vision and the success which attended his arms, he embraced Christianity. We are aware that the story has been suspected, and perhaps not without reason; but whatever truth or falsehood there may be in it, we have no hesitation in ranking the Emperor Constantine among the sincere professors of the Christian faith.

The doctrine of the primitive church is to be learnt with the utmost certainty from the books of the New Testament. These books were received by the leading men in the Christian assemblies, and approved of by the people at large; they were publicly read, and carefully preserved and transmitted; and having been collected into a volume, towards the end of the first century, they became, to all the followers of Jesus throughout the world, the only standard of faith, and the only rule of righteous conduct. The primitive church believed that there is one God, uncreated and everlasting: that the Logos, or word of God, "who was in the beginning with God, and was God," became "bone of our bone and flesh of our flesh," and dwelt upon this earth: that he gave himself for us, "an offering and a sacrifice," and that, "being justified by faith in him, we have peace with God." That our present state is a state of condemnation, corruption, and suffering: that, by the transgression of our first parent, we are enetered into the world, and death by sin; and that "death hath passed upon all men, for that all have sinned." That the soul of man shall exist in a future and unchangeable state of happiness or misery: that, by the influence of the Holy Ghost, our understandings are enlightened in all heavenly knowledge, and our hearts changed from all evil dispositions: that Jesus Christ, having risen from the dead, will appear in the end of all things as the judge of the whole world; and that in the great day of trial and of retribution, he will receive his followers into "mansions" of happiness, where they shall abide forever, beholding his glory, the glory which he had with the Father, before the world was." Such is the sum of the doctrine maintained by the early churches; and it is this doctrine alone which they agreed in considering as "the faith once delivered to the saints."

From the doctrine of the primitive church, we are naturally led to the consideration of the heresies with which it was infested. Some of these heresies appear to have arisen very soon after the first promulgation of Christianity; nor is our religion, even at this moment, and in the countries where it is professed, in its greatest purity, entirely free from their influence. Most of the heresies in question derived their origin from the union of philosophical speculation, or what was called philosophical speculation, with the doctrine of the sacred books. This was particularly the case with the
Heresy of the Gnostics.

The history of the Gnostics, a heresy which must be considered as the fruitful parent of many others, we have almost said of every error which has corrupted and disfigured the simplicity of the primitive faith. At the bottom of this predominating heresy, lay the eastern dogma of the two principles, the one the source of good and the other the source of evil. To the good principle, the Gnostics gave the titles of the Supreme Divinity and the Everlasting Father; while they considered matter as the evil principle, and represented it as independent and active, the antagonist, and, in some instances, the successful rival of the beneficent power. To the evil principle, they attributed the creation of the earth, and the disposition or arrangement of the habitable globe. They held, too, that the soul, which, according to their idea of it, was naturally ethereal and pure, was clogged and depressed by the material body, that its inherent energies were restrained, and its progress towards heavenly happiness obstructed. They contended, that a great Messenger and Deliverer was expected from above, who was to put an end to all such restraints and obstructions, to emancipate the imprisoned and shackled spirit, and to relieve the whole intellectual world from the dominion of matter. They believed in Jesus Christ as the messenger and deliverer, by whom those mighty revolutions were to be accomplished. They spoke of him as the Son of the Supreme Divinity, and, consequently, possessed and dispatched from the habitations of the Everlasting Father. They regarded him as a created existence; and maintained, that though to the eye of man he appeared to be invested with a real body, and exposed to actual pains and privations, he was, in point of fact, destitute of all corporeal organs, and incapable of suffering. In a perfect consistency with their own opinions, they denied the resurrection of Christ, and that of the body in general. They believed, moreover, in a great pléonome, or space above the visible heavens; and this pléonome they sometimes represented as the immediate residence of the benevolent divinity, and at other times as filled with inferior existences, called genii. To the higher genii were added the genii, whose abode was chiefly upon the earth, and whose business and delight it was to thwart the purposes, and disturb the enjoyments of the human race. And in addition to all these jarring particulars, they denied the authority of the Jewish scriptures, and, with an unaccountable and repulsive absurdity, held the serpent in high estimation as the author of sin.

From the motley and incoherent system which we have now attempted to describe, certain practical consequences arose. First of all, it led the Gnostics to the incessant study of magic, in order to avert the influence, or weaken the power of the malignant genii. And, secondly, they were taught by it to practise all the varieties of mortification and modes of austerity. The body was the source and centre of evil, and it was not to be supported or cherished, lest the soul, the ethereal part, should be still further degraded and enslaved. Hence the more rigid of the sect abstained from the most innocent gratifications; they rejected marriage and the society of women, and spent their whole lives in a complete abstraction from the world, in penitence, obnubilance, and prayer. Who does not see that the celibacy of the Romish clergy, and the penances which the Romish church enjoins upon her votaries, may be traced to the heresy of the Gnostics, and especially to that part of it which respects the malignity of matter? Monastic institutions had their origin in the same error. Simon Stylites must be regarded as a practical disciple of the Gnostic school. St Dunstan, if there be any truth in the history which is given of him, may be classed with Simon Stylites; and the race of pilgrims and flagellants will complete the catalogue of deluded individuals, and the triumph of philosophical speculation over the simplicity of genuine Christianity, and the obvious application of its precepts. What we have stated above was the practice of the more numerous and rigid of the Gnostics; others of them, however, made a different use of their favourite notion, the malignity of matter; for they regarded the soul as utterly unaffected by the actions of the body, asserted the innocence and the propriety of yielding to every dictate of nature, and indulged themselves in every species of vice. This division of the Gnostics could not possibly have any great respect for the decalogue or the authority of Moses; and we may not perhaps be very far mistaken, if we suppose them to have been the chief admirers of the serpent.

The tenets of the later Platonists were scarcely less pernicious than the reveries of the Gnostics. Besides their philosophical opinions, which were those of the Eclectics, they maintained that the morality of the sacred scriptures was of two sorts, one more gross, for the multitude, and another more refined, for Christians of superior merit and sanctity. Hence the counsels of our religion were distinguished from its precepts; the former being meant for those who, by contemplative abstraction, aspired to an immediate intercourse with the Divinity, and the latter for such as were disposed to satisfy themselves with discharging the ordinary duties of life. They maintained likewise the pernicious dogma, that the end, if good, justifies the means which are employed in order to attain it, of whatever description those means may be. It is true, this sentiment was propagated at first with great caution, and with many explanations; but it soon spread abroad, and was generally received, and it gave birth to all that train of imposture, and all those pretended miracles and legends, which, in succeeding ages, brought disgrace upon the Christian church. Alexandria was the chief seat of the later Platonists. Ammonius Saccus is regarded as the founder of the sect; and it ranks among its adherents no less a man than the respectable Origen himself.

For an account of the primitive order and government of the church, the reader may consult the History of the following period, where the rise and progress of the papacy is traced.

d

CHAP. II.

The History of the Christian Church from the time of Constantine, A.D. 325, to the Year 755, when the supremacy of the Pope was acknowledged, and his temporal Dominion established.

The order established and recognized in the primitive church, was exceedingly simple. The care of each congregation was entrusted to its pastor or bishop, along with a certain number of assistants; and these last were particularly consulted in matters of government and discipline. To the pastor or bishop, and his assistants, were added the deacons, whose business it was to take charge of the poor. The office of pastor continued for life, unless it was forfeited by some instance of misconduct on the part of him who enjoyed it. He was commonly styled the bishop or overseer, and sometimes the angel of the congregation to which he belonged: (See Bishop.) In the first age, the ecclesiastical functions were supported by the voluntary contributions of the
people attached to them. The whole society was joined together in one principle of love, and its members were distinguished by a "simplicity and godly sincerity," which we shall look for in succeeding ages of the church.

Out of this primitive simplicity, the hierarchy and the papacy arose; but they arose by gradual steps, and consecutive and sometimes imperceptible deviations, from the apostolical pattern. *Nemo fit repepte irrisimus,* is a maxim which applies not only to individuals, but to societies. "The interest and the splendour of an order of men may be promoted and secured by unjustifiable means, as well as the interest and the splendour of any one man. But in both cases, the changes are commonly slow, and the encroachments gradual and successive. Let us trace, as shortly and distinctly as we can, the steps by which the usurpations of the hierarchy reached their unwarrantable and criminal height.

First of all, the distinction between the bishop and his assistants was rendered more obvious and considerable. Next, an idea began to prevail, that these assistants were only the representatives of the bishop, deriving their powers exclusively from him, and subject, in the exercise of those powers, to his superintendence, inspection, and control. He ordained the functionaries in question to the clerical office, and they were tried in what may be called, even at this early period, his consistory court. The property of the church, arising from the liberal donations of the Christian brethren, was now regarded as belonging, in a great degree, to the bishop, and in the disposal and use of it, he not infrequently consulted his own importance and splendour. This property was sometimes in land; but whether in land, or in money, or in cups and vestments, when once consigned to the church, it remained for ever in her possession. She could acquire property, but she could not lose it; no individual could deteriorate it to the injury of his successor; no deed or settlement could alienate it, to the injury of the community.

The next step seems to have been taken by the bishops residing in large towns. In those towns, the ecclesiastical assemblies were usually held; the bishop, always on the spot, and growing daily in wealth and influence, was commonly chosen president of these assemblies. When once chosen, he would not easily be prevailed upon to resign his place. In a short time, he would claim it as his right. Prescription would sanction what usurpation had begun. And thus the bishop, once upon a level with his presbyters, or at most upon a level with his brethren of the episcopate, would be established in precedence and splendour, as the metropolitan of the province to which he belonged. His powers were then extended and confirmed; new claims were made and allowed; the civil polity of Constantine afforded an example; the ecclesiastical constitution was made to approximate to the political; the rulers of the church corresponded to the high officers and governors of the state; their provinces were of similar extent, and though their functions were different, their authority was nearly the same. The metropolitan now became a patriarch, and in process of time the patriarch became a pope.

This change, however, the completion of sacerdotal absolutism, was the result of other circumstances and considerations, besides those which we have mentioned above. It had been observed, that in the enumeration of the apostles, given by the sacred writers, Peter held the first place, probably of his age, and personal respectability. "Now the names of the twelve apostles," says St Matthew, "are these, first, Simon, who is called Peter, επίσκοπος Σίμων ἐκ Παλαιστινῆς;" first Peter, that is, as Dr Campbell seems to think, "Peter, occupying the first place." It had been remarked likewise, that this apostle is represented by Christ himself as the rock on which the church was to be founded. "Thou art Peter," says he to him, "and on this rock, (alluding to the name,) will I build my church," that is, in consequence of his ministry and apostolical labours, shall the religion which I am commissioned to teach, be introduced into the world, and finally established. Accordingly, the apostle Peter was the first who preached to the Jews the doctrine of our Saviour's resurrection as a tenant of the Christian faith; and he was the first also who announced to the Gentiles, that they were admitted into the covenant of Abraham, and entitled to all its privileges and blessings. By the bishop of Rome, however, and his adherents, these passages of holy writ were understood in a very different sense. In their apprehension, St Peter occupied the first place, not on account of his years, and his personal respectability, but solely on account of those powers and dignities which were conferred upon him by Christ. He was the rock, they affirmed, on which the church was built, the foundation and support of the whole. And in their zeal for their own aggrandizement and interest, they forgot the declaration in which we are assured that the church is built on "the apostles and prophets" generally, "Jesus Christ himself being the chief corner-stone."

But it would be of no consequence to invest St Peter with powers and dignities, unless the bishop of Rome could prove himself to be the legitimate successor of that venerable apostle. This, of course, he attempted. It was given out, and very soon believed, that the see of Rome was founded by the apostle alluded to; though it does not appear from any historical document, that he ever visited the capital of the Roman world. There was a prevalent tradition, however, that such had been the case. The claim once made, was not to be abandoned. It was affirmed more loudly than ever, that St Peter, the first and chief of all the apostles, was the founder of the holy see. And it was no less pertinaciously maintained, that the powers originally conferred on this distinguished individual, had descended by regular devotion upon his successors in office. The inference was plain. The bishop of Rome, like St Peter himself, was the rock on which the church was built, the foundation and basis of the whole superstructure, without which it could not stand together for a moment, but must instantly fall into ruins. The powers of the church were invested in him alone, laid up as it were, and condensed in his sacred person. If others were the branches, he was the root; if others might be permitted to call themselves the streams, he was the inexhaustible fountain which supplied the whole. In one word, he was constituted by Jesus Christ himself the supreme legislator and judge of the universal church; and all bishops, metropolitans, and patriarchs, were subject to his authority, and dependent on his sovereign will.

This it must be owned was a sweeping conclusion; the patriarch of Constantinople the rival of the pope. The patriarch of Constantinople in particular was extremely dissatisfied with it. There were other churches, he said, which were founded by the apostle Peter, as well as that of Rome. By the consent of all antiquity, the church of Antioch was one of these. And he insinuated in a way which could not be misunderstood, that as Constantinople was the seat of empire, the place where...
the Master of the world condescended to reside, the bishop of that city was clearly entitled to the first voice in point of authority, and to all precedence in point of rank. He had his claims as well as Rome; his footing was good, and his assurance strong; and so satisfied was he of his right and privilege, and so jealous of his rival, that he was the first who took the title of universal bishop. But whatever might be the claims of the Byzantine church, these claims were not ultimately established. The bishop of the West was at one time too powerful, and at another too cunning, for the Eastern prelate. The Latin churches likewise united more cordially and effectually, in supporting the pretensions of their ecclesiastical head. And at length, Felix the Second, a bold and resolute pontiff, summoned the patriarch of Constantinople before himself, and a synod of his Italian clergy, and after due consultation, solemnly degraded him from his rank, and deposed him from his office. It is true, the Eastern bishop laughed at the impotent attempt of his lofty antagonist, and anathematized him in his turn. But the Byzantine pontiff gradually sunk into the second place; and though his claims were not relinquished, he found it necessary to urge them only at favourable seasons, and with great prudence.

We are not to suppose that, even in the first century, the power of the Christian bishops was limited to matters of doctrinal decision, or of ecclesiastical polity. It comprehended a very great proportion of those questions which now belong exclusively to the jurisdiction of the civil magistrate. There is some countenance given to this extension of the episcopal power in the sacred writings, and especially in the epistles of St Paul; and it was perhaps necessary, in the early and unsettled state of the Christian communities. "If thy brother," says Jesus, (Matth. xviii. 15.) "tresspass against thee, go and tell him his fault between thee and him alone: if he hear thee, thou hast gained thy brother; but if he will not hear thee, then take with thee one or two more, that at the mouth of two or three witnesses every word may be established. And if he neglect to hear them, tell it to the church, but if he neglect to hear the church, let him be to thee as a heathen man and a publican. Verily I say unto you, whatsoever ye shall bind on earth, shall be bound in heaven, and whatsoever ye shall loose on earth shall be loosed in heaven." And in conformity with what has now been quoted, the apostle Paul enquires of the Corinthian Christians, why they went to law "before the unjust, and not before the saints? Is it so," says he, (1 Cor. vi. 5.) "that there is not a wise man among you? No, not one that shall be able to judge between his brethren; but brother goeth to law with brother, and that before the unbelievers. Now therefore there is utterly a fault among you, because ye go to law one with another."

We do not stop to enquire whether these passages were rightly interpreted or not. It is sufficient for our purpose to state, that these and similar passages were long supposed to sanction, in the most authoritative manner, and to the utmost extent, those encroachments on the civil power, which characterize the ambition, and dishonour the annals of the popish church. By a little management, almost every question was made to put on an ecclesiastical aspect, and as such it was tried in the episcopal courts. The parties concerned might indeed belong to the laity, and not to be the clergy; but the Church was regarded as distinct from the parties, was pronounced to be of a different nature. Of justice had been denied by the civil magistrate: and where had the poor man, injured and oppressed as he was declared to be, an opportunity of making his complaint, unless before the rulers of the church, the constituted guardians of innocence, and the delegates of heaven? Or the case was from the beginning of a mixed nature, and belonged in its substance and character to the bishop as well as to the magistrate. Or the feudal officers were too fond of their amusements, too careless, or too illiterate to interfere. From these causes, it grew into a maxim, "that except in places bordering on the infidels, a good lawyer makes a better bishop than a good divine." Enroachment followed encroachment. The clergy, while they exercised their functions as judges, and in civil questions too, proceeded also to legislate. The principles of the canon law gave an aspect and colouring to those of the civil; and the supremacy of the Roman pontiff, in ecclesiastical matters, being acknowledged, the ambition of the papal see appeared to look forward to nothing less than a despotism over the whole Christian world, in all its interests and concerns. In addition to this, the pope was now raised to the dignity of a temporal prince. About the year 755, Pepin king of France, made over to him twenty-two cities of Italy; and in one part of Europe, at least, the successor of the poor and humble Peter reigned uncontrolled in the exercise of the civil as well as the ecclesiastical authority, and united in his own person the highest offices of king and of priest. In a succeeding age he laid claim to infallibility; and in the proclamation of the human understanding, and presumptuous plentitude of apostolical power, he disposed of crowned and governments at his pleasure.

No sooner had Constantine the Great ascended the throne of the Caesars, than his attention was directed to the Arian heresy. This heresy, which long divided and afflicted the church, had many patrons and supporters. It gave rise to many personal disputes, and it broke and disturbed the peace which Christianity might have enjoyed under the imperial protection.

The heresy alluded to was propagated by Arian, a presbyter of the church of Alexandria; He was a man of considerable learning, acuteness, and eloquence, and his natural abilities were sharpened and improved by the opposition which he met with, and the controversies in which he was engaged. He maintained, in the assembly of the Alexandrian presbyters, and against the opinions of his bishop, that in the sacred Trinity, the Son was essentially different from the Father; that there was a time hid in the depths of eternity, when he did not exist; or, in other words, that he was really a creature, produced or brought into being by the supreme volition of the true God. He contended farther, that though a creature thus produced, the Father had impressed upon him the effulgence of his glory, and transmuted into him his ample Spirit;" that he was the former of the world, and that he governed the universe as the representative of the eternal and unchangeable Divinity. In consequence of these tenets, Arius was publicly condemned and excommunicated by Alexander, his bishop. He retired, however, into Palestine, where he was received and protected. The number of his followers increased. The angry passions were awakened, and the controversy was agitated with the utmost violence. Distant provinces and churches engaged in the dispute. The combatants became every day more and more warm: reproach took place of argument; and the sacred scriptures themselves, and even the very subject of the discussion, were forgotten amidst personal quarrels and mutual reviling. The contests of the
schoolmen, in the dark ages, may have been violent, but they must have exceeded all common measures of asperity, if they surpassed, in malignant zeal and fierce recrimination, the dispute which now roused and dishonoured the church.

In these circumstances, Constantine, with a laudable concern, but perhaps with little knowledge of human nature, wrote first of all to the bishop of Alexandria, and afterwards to Arians himself, reprimanding them for their indecent hostility, and exhorting them to peace. But it soon appeared, that the paternal advice of the emperor might have been spared. Neither of the parties was willing to yield, because each of them, of course, believed his antagonist in the wrong. The subordinate agents likewise in the dispute, had their victories to gain, their enemies to crush, and their interests to serve: In reality, the letter of the emperor had no other effect than that of magnifying the controversy in the public estimation, and of inducing those, who, from indolence or prudence, had hitherto been silent, to range themselves with the one party or with the other; to resist the heretick or to abandon the church. Something more decisive, therefore, was to be done. Accordingly, the imperial summons was issued, and an ecumenical or general council convoked: And in the year 325, the representatives of the whole Christian world assembled at Nice in Bithynia, to ascertain the Catholic doctrine, and provide for the tranquillity of future generations.

The appearance of the assembly was venerable in the highest degree. No fewer than two thousand ecclesiastics, according to some accounts, had risen from their retirements in obedience to the imperial summons, and of these three hundred and eighteen were bishops. The emperor himself presided in the council, "exceeding," as Eusebius says, "all his attendants in stature, gracefulness, and strength, and dazzling every eye with the splendour of his apparel." And the question to be decided related to nothing less than the peculiar distinctions which may be predicated of the divine essence, and the honour which belongs to the Son of God. Impartiality, however, obliges us to declare, that the conduct and deportment of the fathers did not exactly correspond, either with the respectability of their appearance, or the solemnity of the occasion. They seemed to think, that they had met together, rather with a view to settle their private disputes, than to ascertain the Catholic faith. Numerous complaints were made, and loads of memorials transmitted to the emperor. These memorials were little else than accusations of parties or of individuals, each man libelling his antagonist, and representing him as an enemy to the church. It is said that the emperor, having collected the libels in question, threw the whole of them into the fire; advising the fathers, according to the precept of our Saviour, to forgive one another as they themselves expected to be forgiven, and modestly hinting, (as Sozomen observes,) that it did not belong to him to decide the differences of Christian bishops. Having proceeded so far, he requested the immediate attention of the council to the weighty matter which lay before them. Upon this subject, however, there was a very great and unexpected unanimity. The doctrine of the church appears to have been so completely separated from the heresy of Arius, that no private dissensions, or remaining rancour among the members of the synod, could prevent them from agreeing upon the question at issue. The tenets of the disputatious presbyter, as he was called, were solemnly condemned; and, by the order of the emperor, he was banished into Illyria. The Homousian doctrine, or the doctrine of Consubstantiality, was pronounced to be the faith of the church; and though there were certain differences of opinion with regard to the correct meaning of the term ὑπὸστάσεως, and though it was for some time disputed, whether this term applied to the nature of the Godhead, or to the persons (ὑποστάσεων) in the blessed Trinity, still it was finally declared, with scarcely a dissenting voice, that Jesus Christ, the Son of God, was not, in substance or essence, distinct from the Father. Arians himself was present in this assembly, the most numerous which the Christian world had ever witnessed before. He was supported by Eusebius of Nicomedia, Maris of Chalcedon, and Theognis of Nice. These ecclesiastics, who seem to have been persons of considerable ability, attempted to explain or to qualify the heretical opinions; but Eusebius alone persisted in refusing to subscribe the sentence of the council. Among the orthodox, the chief speaker was the famous Athanasius, then only a deacon in the church of Alexandria.

The following may be considered as a summary of The Nicene council, the second in the order of time, and the Heavenly Trinity, at the period to which our observations refer. It is a version of the Nicene creed, as it appears in the Epistle of Eusebius to the Cæsareans, &c.

"We believe in one God, the Father Almighty, maker of all things, visible and invisible. And in one Lord Jesus Christ, the Son of God, the only begotten; begotten of the Father, that is, of the substance of the Father. God of God, Light of Light, true God of true God; begotten, not made; consubstantial with the Father, by whom all things were made, both things in heaven and things on earth: who, for us men, and for our salvation, came down, and was incarnate, and became man, suffered and rose again the third day, and ascended into the heavens, and comes to judge the quick and the dead: and in the Holy Ghost. And the Catholic and Apostolical church doth anathematize those persons, who say, that there was a time when the Son of God was not; that he was not before he was born; that he was made of nothing, or of another substance or being, or that he is created, changeable, or convertible."

To the Arian controversy succeeded the Pelagian, in which St Augustine distinguished himself; but as the heresy of Pelagius is nearly allied to that of Arminius, we shall afterwards have occasion to treat of it, in giving our account of the Synod of Dort.

Our attention must now be directed to another quarter. About the commencement of the seventh century, a new religion began to spread itself in Arabia; and Christianity received a blow, nearly fatal, from the doctrines and the conquests of Mahomet. In whatever light we view the prophet of Mecca, we cannot hesitate to pronounce him an extraordinary man. Without that learning which is to be derived from books, he was far from being ignorant; of great natural acuteness, he employed that talent in distinguishing between human characters, and in ascertaining the motives by which they are influenced or formed; and prudent and dextrous, he rarely let slip an opportunity of increasing his knowledge, or establishing his reputation. While yet in the service of Cadijah, a rich widow, whom he afterwards married, he travelled into Egypt, Syria, and Palestine; comparing the manners of the people, noting their genius, and marking the defects or the excellencies of the governments under which they lived. Though originally poor, he was born of an illustrious race. His person was beautiful, his forehead large and liberal, and
Ecclesiastical History.

In the depths of solitary retirement, and in the cave of Mecca, about three miles from Mecca, the impostor of the East appears to have conceived the first idea of his prophetic mission. His visions were many, and his intercourse with heaven is said to have been frequent and beatific. For a while, he confined his exertions and his teaching to his own family and kindred. Success, however, soon emboldened him to take a more ample range, and to display himself upon a wider field. Being constrained to fly from Mecca, in order to avoid the rage of his enemies, the citizens of Medina, who had already heard of his name and his pretensions, received him with open arms. Here he erected his standard, and declared his commission; with consummate art, he touched the predominating feelings of his countrymen, and filled their imaginations with the prospect of riches and glory. The effect exceeded his utmost expectation. Multitudes from every quarter enlisted themselves under his banners, anxious and zealous to propagate the faith, and longing to share the possessions of those who should call in question the authority of their leader. The fanaticism of the prophet now became more furious, and his artifice more profound; and his plans being at length mature, he proclaimed to the whole world the great dogma of Islamism, "That there is one true God, and that Mahomet is his prophet."

The system adopted by Mahomet was eminently calculated to ensure success. His mode of proselytism, though not extremely novel, was remarkable for its efficacy. Whoever refused to acknowledge his mission, was instantly put to death. It was with a naked sword in his hand, and with uplifted arm, that this military apostle preached the Koran. A logic so powerful was not easily resisted. After completing the conquest of Arabia, the leader of the faithful burst like a torrent into the Roman territories, and soon convinced the Christians, that whatever they might think of his arguments or his eloquence, his sword was not to be despised. Christianity, indeed, was now very different from what it once had been. The pure worship, the zeal of attachment, and the magnificent devotion of the early times, had in a great measure disappeared; and the church, torn with dissensions, enfeebled and listless, became an easy prey to its ferocious invaders. The means by which the disciples of Mahomet were retained and secured, were not less effectual than his decisive way of propagating the faith. The rewards of Islamism were neither remote nor spiritual; neither distant in the period of enjoyment, nor at all unintelligible to the sense. A fifth part being reserved for pious and charitable purposes, the spoil of the conquered nations was divided in equal portions among the soldiers. The true and faithful servant of the prophet was permitted to indulge in all sensual gratifications; he was allowed a plurality of wives, and he was assured that in the paradise of the blessed above, to which of course he was admitted, he should be attended by females (houries) of resplendent beauty, whose sole employment it should be to execute his commands, or minister to his pleasures. And it was declared to him, that his capacity for enjoyment would be enlarged and perfected, according to his means of gratification. The effect of all this upon a gross and voluptuous people, may easily be conceived. This, however, is not the whole matter. While by one part of the system, the love of pleasure was stimulated and gratified, by another part of it the fear of death and of danger was completely destroyed. The prophet of Mecca taught the doctrine of unbroken and immovable fatality. The world, he said, stood secure by the unalterable appointment of him who created it. The lot of man was fixed; no courage or dexterity could change it. To our destiny we must come. Why should we distress ourselves about future dangers, when these dangers cannot be prevented? Why should we harass ourselves with the fear of death? No concern of ours can stop the progress of dissolution. The fate of the world is not to be reversed; the glory of the prophet and of his followers is decreed; victory is on our side, and our names are enrolled in the records of the blessed.

The successors of Mahomet, not only propagated his doctrine, but imitated his example. Their arms were everywhere victorious; and such was the rapidity of their progress, that in little more than half a century, the whole of Persia, Syria, and Egypt, and a great part of Africa and Spain, had yielded to their irresistible valor, and acknowledged the dominion of the prophet.

CHAP. III.

The History of the Church of Christ, from the year 755, when the Supremacy of the Pope was acknowledged, and his Temporal Dominion established, to the era of the Reformation, about the year 1545.

This period may justly be denominated the period of darkness. It comprehends in it more instances of false opinion and elaborate folly, than all the other portions into which the history of the church may be divided. In this melancholy period, the religion of Jesus seems to be very nearly extinct, and imposture and fanaticism are dignified with its name. The historian finds himself lost amidst the aberrations of the human understanding, and the expressions of mistaken piety; and has to grope his way through the monastic institutions, and reliques, and canonizations, and indulgences, and to conduct his reader safe, amidst the interdicts of the popes, the battles of the crusaders, and the wrangling of the schools. To expatiate on all these topics, would carry us far beyond our limits; we shall only touch upon a few of them, and refer our readers to the accounts which are given, under the different titles, in other parts of the work.

In the beginning of the ninth century, the passion for accumulating the relics of the saints, appears to relics, have reached an extraordinary height. A respect for holy men when alive seems to have been extended to their corrupted remains after their death; and the more so, as every year brought new accounts of the miracles performed by these exuviae of the faithful. In consequence of his abstinence and his penances, the anchorite is supposed to have overcome the malignity of matter, and to have purified and refined it, by infusing a portion of his spiritual excellence into its native depravity. And matter, once believed to be the origin and the seat of all evil, is now represented as effectual in healing the sick, and in restoring the dead to life. Many persons, some of whom were in eminent stations, and others, distinguished by the learning which was prevalent at the time, travelled into Judea for the express purpose of obtaining relics. The bodies of the apostles and first martyrs are said to have been dug up, and innumerable fragments, bones, or pieces of bones, legs,
ECCLESIASTICAL HISTORY.

arms, toes and fingers, skulls, jaw-bones and teeth, were brought into Italy. Very large sums of money were often paid for them; they were incased in gold, surrounded with precious stones, and worn as amulets about the neck. In some instances, the purchaser does not appear to have been extremely nice or scrupulous in his enquiries. If the bone presented to him was reported to have been dug up in Judea, or if it only looked like an old bone, or was in reality a rotten bone, he seemed content to buy it. Hence the knavery of the Greeks led them to substitute the remains of other animals for those of human beings, and particularly for those of the saints. And he who records the fulness of human credulity, will not fail to state, that many a devotee has wept over the leg or the spine of a dog or a jackass, and pleased himself at the same time with supposing that he had before him a relic of St Mark, St Bartholomew, or St James. Sometimes the remains in question were found in consequence of an immediate revelation from heaven; a holy monk, or female renowned for chastity, being directed to the place where they lay dispersed or interred. Many real crosses and fragments of them were obtained; and, last of all, the thirty pieces of silver with which Judas Iscariot was bribed, and which, by some confusion among the historians, are now called thirty pieces of gold, were discovered and known; and, passing through several hands, are still (it seems) possessed by the curious in relics, in different parts of the world. There is one of them "as large as an English noble," which is shown in the entrance to St Peter's at Rome. "But though the veneration for the remains of celebrated persons," observes an elegant writer, "when carried to such an extreme as to be converted into a species of religious worship, is certainly culpable; and though the miracles which were attributed to these remains, must be considered either as delusions of the fancy, or as forgery of priestcraft; still we are not to suppose the passion itself, without a foundation in the principles of human nature. It is impossible to confine the human affections in their operation; it is impossible not to connect the objects of our regard and our veneration, with every thing which was originally connected with them. The axe, which terminated the existence of the innocent and beautiful Anne Bullen, is still contemplated with some sensations of sympathy; and were it possible to survey the real cross on which the Saviour of mankind had been suspended, the person who did not consider it as more than an object of curiosity, must be destitute of all the most amiable feelings of the human heart."

Monastic institutions kept pace with the passion for relics. The monk (monk's) was originally a hermit or anchorite, who withdrew from society, and spent his time in solitary devotion. St Anthony the Egyptian is usually considered as the founder of monachism. He was ignorant in the very highest degree, and boasted of his ignorance; regarding learning as useless at least, if not pernicious. He was a severe ascetic and flagellant, lived much with the wild beasts, and supported himself upon fruits and herbs, the spontaneous productions of the earth. From Egypt and the East, monachism passed over into Greece. The Latins received it from the Greeks; and so highly was it valued in Italy, that, in the beginning of the ninth century, multitudes of persons, in all ranks and situations, withdrew from the world, and wasted their days in celibacy and solitude. The madness spread from province to province, and from one country of Europe to another; and even kings, dukes, and great lords of the court, forgot their true dignity as well as their duty to society, and joined with the poorest of their subjects or dependents, in all the severities of the monastic life. There is reason to believe that monachism, in its first institution, was the result of a sincere, though mistaken piety. Like the passion for relics, it unquestionably has a foundation in the principles of human nature. Beyond all doubt, it is wise and profitable to retire occasionally at least from the world, from its business and its allurements, and to prepare ourselves for an everlasting separation. In process of time, however, it was found convenient and desirable to relax the severity of the primitive institution. The fervour of fanaticism evaporated; mankind, too, became at length familiar with the tale of voluntary infatuation, and were less prompt to approve, and less vociferous in their praise; and the monks, in the course of a few centuries, contrived to join abstinence with the gratification of the appetites, to unite society with retirement, and the appearance of poverty with the possession of much wealth. The very nature of the monastic institutions afforded a solvo for the conscience. As individuals, the recluse were poor, but as a community they were rich; no one could boast of his acquisitions, yet the society grew daily in wealth and splendour. The monasteries were magnificent and commodious; to the eye of a stranger, they would have appeared rather as the palaces of princes, fully stored with all the luxuries of life, than as the cells of the anchorite, or the retreats of penitence. They were often not merely liberally, but profusely endowed. Many large estates had been conferred on some of them; legacies and bequests formed the riches of others. At one time a prince of the blood, having spent a long life in oppression and profligacy, made a liberal gift to some religious house, and conceived, that in this way he secured the forgiveness of his sins; and at another, a rich merchant, able to retain his wealth no longer, bestowed a portion of it upon the church. And by the invariable maxim of an artful priesthood, property once given to the church becomes ever after the property of God. It is sacrilege to touch it; a loud anathema is pronounced against him who shall convert it to any secular use.

Nothing appears too gross in the eyes of an ignorant and credulous people. The very dress of the monks was held to be possessed of peculiar and extraordinary virtues; and men of rank and eminence, when they found themselves about to die, often directed their servants to clothe them with the monastic vestments, "thinking that the sanctity of the garment would protect them against a condemnationary sentence of the omniscient Judge." False miracles, legends, and lies, were produced on every side. The multitude heard and believed. New followers of the apostles and evangelists were found out, each of them with a name and a history attached to it. Egypt and the East, in all their caves and cells, were peopled afresh: and the worthies lately enrolled and held up to the public admiration, were even more powerful than their predecessors, in protracted prayer, in exorcisms, and in their contests with the devil. The expression is somewhat coarse, but it has been justly said, that when the monks wanted a saint they made one, and when they wanted a miracle they made that too. Indeed it must be owned, that on subjects of this kind the greed of money was of a ready invention; and their facility in contriving is equalled by nothing but the prompt acceptance and capacious faith of those who swallowed the imposure.
Before Manichaeism was corrupted in the highest degree, the friars sometimes discharged the duty of the secular clergy. These last seem almost to have forgotten that they had any duty to discharge: they were, in truth, equally ignorant and remiss, and, in many instances, distinguished by all the vices which characterize the period in which they lived. Even on those rare occasions when they entered the pulpit, they conducted themselves in the most impious and shameless manner. Of this we have a remarkable example in the case of the Grecian Patriarch Theophylact. The prelate alluded to was by no means famous, either for his virtues in private life, or for his public performances as a functionary of the church. He sold, without scruple, every ecclesiastical benefice as soon as it became vacant, and converted the money to his own use. The writers of his times, (the 10th century,) have told us nothing of his dexterity as a patriarch in managing his clergy, of his integrity as a judge in the episcopal courts, of his commanding oratory or persuasive address; but they have given us very particular information about his excellent stud. He was, indeed, the very Nimrod of the middle ages, a mighty hunter; he had no fewer than 2000 horses in his stables, and these he fed with pig-nuts, pistachios, dried grapes, and figs steeped in wine. One Holy Thursday, when engaged in celebrating high mass, a groom brought him the intelligence that a favourite mare had foaled; upon which he instantly stopped short, threw down the liturgy, and running to the stable in an ecstasy of curiosity and dispatch, ascertained, by ocular demonstration, that the joyful news was true. And being now assured that a real and living foal was actually produced, he returned to the altar, took up the liturgy, and finished the service. It must be owned, however, that such flagrant instances were rare. Idleness and luxury, a tendency to political intrigue, and an insatiable ambition, are the vices with which the secular clergy are more justly charged. To these qualities, he added most profound ignorance. They seldom preached, for they could not compose; and they never studied, because they could not read. In the 12th, 13th, and 14th centuries, the sacred scriptures were little known. The volume of the New Testament was rarely to be found; many bishops had never once seen it in their whole lives: what they knew of its doctrines and precepts, they learnt solely from their missals. The people had no learning, and no sense of its value. At first the friars were somewhat more attentive to their duty than the secular clergy, enjoining at least the exercises of fasting and prayer. They even attempted to instruct the people in public; but their discourses had scarcely any relation to the Christianity of the sacred books, being chiefly occupied with the exploits of the saints; their power over the devil, especially in single combat; their watchings, fastings, and flagellations. When these topics failed, they had recourse to the virtues of holy water, crossing, and chrism. By degrees, however, all public instruction was given up; the darkness spread itself, thick and heavy, over the kingdoms of Europe; the intellect was degraded and enslaved; the curiosity asleep; and, at the period of the Reformation, it seems to have been universally held, that to repeat credo and ave mariae, in rapid succession, to undertake pilgrimages, to observe the holidays appointed by the church, and to pay the tithes and perquisites of the clergy, constituted the sum of religious duty, and formed the principal, if not the only excellencies of the Christian character.

Were we required to select any individual out of the whole fraternity of ascetics and recluse, who had influenced, in any remarkable degree, the opinions and the conduct of men, we could not fail to make choice of Peter the Hermit. And should we be asked to specify any one of the religious societies, whose principles and zealous activity have produced the most striking effects, we should be constrained to give, as our example, the society of the Jesuits. Let us now, therefore, introduce a short account of the extraordinary individual whose name we have mentioned, and of this notable society.

Peter, commonly called the Hermit, was born at Peter the Aniens in Picardy. In his youth he had been a soldier, and had served with reputation under the Count of Boulogne. It is not, however, in his military capacity, that we are at present to view him. In truth, he very soon relinquished the sword, and all worldly employments along with it. He made a tedious and painful pilgrimage to Jerusalem; and during his residence in that city and in Palestine, he beheld, with inexpressible concern, the sufferings which the Christians endured, from the tyranny and insolence of the Saracens. Immediately upon his return, he conceived the design of arming the sovereigns, and the people of Europe, in order to rescue the holy sepulchre from the pollution of the infidels. For this purpose he travelled from kingdom to kingdom, representing the sufferings of the pilgrims, and calling aloud for vengeance. He declared that he was willing to lead the armies himself, if no better general could be found: he spoke with confidence of special revelations, and preternatural assurances of success.

As he travelled from place to place, the Hermit exhibited, in his own person, the most complete specimen of monkish abstemiousness and frantic enthusiasm. His body, which was covered with a coarse garment, seemed wasted with fasting; his head was bare, his feet naked; he bore aloft in his hand a large and weighty crucifix, and his prayers were frequent, long, and loud. He accosted every person whom he met; and entered, without hesitation, both the palaces of the great and wealthy, and the cottages of the poor. If the power of eloquence is to be estimated by the effects which it produces; it certainly did not expire with Demosthenes and Cicero. The exhortations of the Hermit to repentance and to arms, roused the people from their lethargy: he painted the sufferings of the pilgrims in such glowing colours, that every heart was melted into compassion; and touching, with the hand of a master, the chivalrous spirit of the age, he challenged the brave to rescue their brethren from oppression, and to protect the holy earth in which their Saviour had been interred. Every eye kindled with indignation as he spoke, and the sword was already drawn to carry into effect the purpose of vengeance. Nor were these the only arts which were practised by this enthusiastic preacher. We have already hinted, that he built his hopes of success upon the assurances of heaven. He affirmed that Jesus Christ, and the holy Virgin his mother, had both appeared to him; and he mentioned the names of many saints with whom he had personally conversed. He even produced a letter, which he assured the people was written in heaven: it was addressed, he said, to all true Christians residing upon the earth, and its only object was to rouse their courage, and to animate their zeal, in the great and pious work which he urged them to undertake. This letter was...
ECCLESIASTICAL HISTORY.

The crusade under Godfrey.

In consequence of the zeal and the labours of the Hermit, a very considerable sensation was produced in many parts of Europe. It seemed to be just and reasonable that the pilgrims should be relieved; and it was acknowledged as the will of heaven, that the holy sepulchre should no longer be defiled. Urban II. the reigning Pope, availed himself of the predominating feeling. He assembled a council at Clermont, in Auvergne. The prelates, great lords, and princes of Europe, with their numerous retainers, hastily obeyed the summons. No house could be found large enough to receive the multitude that were met together, and the deliberations took place in the open air. The pope himself, the head of all the churches, and representative of the true God, addressed the council: he made a powerful and deep impression upon the audience, especially the French who were present, and whose character, naturally susceptible and impetuous, rendered them the most proper subjects for the papal oratory. The hermit in his turn was not deficient. Plenary indulgence, and full absolution, were proclaimed to all who should devote themselves to the service of the cross. And such was the effect, that the whole assembly, as if moved by some divine impulse, cried out with one voice, "It is the will of God! it is the will of God!" Nor were these, by any means, words without import or consequence. An incredible number enlisted themselves in the sacred cause: peasants and artisans, nobles with extensive domains, and sovereigns renowned for their romantic valor, eagerly pressed forward, and requested permission to fight under the consecrated banner. Early in the year 1096, no fewer than 300,000 men, under the orders of Peter the Hermit, and Gautier or Walter the Moneyless, set out from the confines of France and Lorraine, and marched through Hungary and Bulgaria, to the capital of the Grecian empire. These, however, were an undisciplined rabble; laborers, indolent tradesmen, malefactors let loose from prison, monks and slaves; all, in short, to whom warfare was an amusement, or plunder was desirable. Many of them were partially armed, others were utterly unprovided with any military weapon. Behind this promiscuous and noisy assemblage, more like the collected banditti of Europe than a constituted soldiery, the regular troops advanced. These were men properly trained and appointed; conducted by the leaders of their respective nations or provinces, eager for the combat, as well as experienced in the field. By universal consent, the supreme command was conferred on the illustrious Godfrey of Bouillon, duke of Lorraine. He was supported by Baldevin his brother; Robert, duke of Normandy; Hugh, count of Vermandois; Raymond, count of Thoulouse; and Stephen, count of Blois. When the troops were numbered on the plains of Asia, they amounted to 700,000 fighting men. The fortune of the crusaders was various. Many of the soldiers died in battle, or perished through fatigue, and the diseases incident to the climate. In the end, however, the holy city was taken, and purified from infidel pollution; and Godfrey was saluted "King of Jerusalem" by all the troops under his command. The expedition itself has formed the subject of the well known epic poem of Tasso, a work inferior only to that of Milton, in modern times, if it be at all inferior; and ever to be named with those of Homer and Virgil, among the ancients, when we are verifying, by examples, the extent of the human genius.

If Peter the Hermit was remarkable, as an individual, for the effects which he produced on the opinions and conduct of men, the Jesuits were not less so as a society. The order now mentioned was founded by Ignatius Loyola, a Spanish gentleman, about the year 1540. It differed in many respects from all the other monastic institutions; its form of government, or ecclesiastical rule, was peculiar to itself; a great proportion of its members were trained to business, as well as to literature; and, instead of cultivating retirement, it was, from the beginning, a chief part of their duty to mingle with the world.

Loyola was equal to any of his predecessors in monkish austerity. He suffered his hair to grow, and cherished his nails to an extraordinary length; he begged from door to door—fasted, according to the statement of his biographer, six days in the week—whipped himself often—lay upon the ground without bedding—and spent seven hours of each day "in vocal prayer." To the austerity of the monk, he added the usual portion of fanatical zeal. He undertook a pilgrimage to Jerusalem—a circumstance which seems to have been necessary, in those days, to form the character of a perfect saint; and, in the course of his journey, he had many visions and miraculous adventures. Some say he had more than the requisite number of personal conflicts with the devil. His chief ambition, however, was to become the founder of a religious community. For this purpose, he produced a plan, or order, suggested, as he affirmed, by immediate inspiration; and hastening to Rome, presented it to the pope for his acceptance. Paul III., who at that time filled the chair of St. Peter, appeared at first inclined to reject the proposal of the zealous monk. Loyola, however, recommended his plan by an offer too powerful to be resisted. Besides the three monastic vows, of poverty, chastity, and submission to the rules of the order, he engaged, that all his followers should swear fealty and devoted obedience to the see of Rome—that they should acknowledge themselves the servants of the Pope, ready, upon the earliest signification of his wishes, to execute his commands, and to support his authority. The advantages to be derived from such an offer were instantly perceived. Paul III. immediately confirmed the institution, endowed the society with ample privileges, and appointed Loyola himself the first general of the order.

Among the Jesuits, the ecclesiastical rule put on the appearance of a simple and unlimited monarchy. The most implicit obedience was required from all the members of the society to the will of the superior. They were bound to yield up to him the very faculties and sentiments of their minds. "They were to listen to his injunctions as if they had been the commandments of Christ. Under his direction, they were to be mere passive instruments, like clay, to the hands of the potter, or like dead carcases incapable of resistance." The general himself was responsible to none but the Pope. In him were vested all the revenues and funds belonging to the society. He nominated, without partner, and without control, the provincials, rectors, and other functionaries of the order, and could remove them at pleasure. To him every novice was obliged to manifest his conscience; that is, to confess his sins and strongest propensities, and to lay open the inner recesses of the soul. And to him also, or to a person...
whom he should choose to appoint, the reports of the subordinate societies were regularly transmitted. These reports were minute and circumstantial in the highest degree, containing exact information respecting the characters of the novices and professed members, their talents, dispositions, and prevailing tendencies, and, above all, their knowledge of human nature, and experience in affairs. And thus the general, placed at the head of the whole institution, could issue his orders with the most perfect propriety; could appoint to each man his station, and to each man his reward; could allot the chief duties to the highest abilities; could elevate or degrade, exclude or retain.

By the fundamental principles of their constitution, the Jesuits were connected with the world, and almost necessarily involved in its business and troubles. Whatever tended to promote the instruction of the ignorant; to disseminate the true religion, either in countries already professing Christianity, or among Heathen nations,—and whatever contributed, or might be supposed to contribute, to the increase of the holy see, formed their province and care. Hence their chief study was human nature, and their chief art lay in managing and directing it. Hence they allowed no public transaction to take place without observation, for public transactions have much influence upon religion; and hence they attached themselves to the great and the powerful, for the time might come when their alliance and aid would be serviceable to the pope. They cultivated learning, because they perceived its use in governing mankind; and were not only theologians, but grammarians, critics, mathematicians, philosophers, and poets. Within fifty years after the institution of the order, they had obtained the chief direction in the education of youth throughout all the Catholic countries of Europe. The books "in usum Delphini," form a portion of the proofs which remain to us of their unwearied labour, and skill in the critical art. Nor were they satisfied with biasing the mind in early life; they were at the same time the spiritual guides of those more advanced in years. Every prince had his confessors, and that confessor was a Jesuit. In weak reigns, this functionary was superior in influence and authority even to the chief minister himself; and the politician, with all his foresight and address, was frequently constrained to yield to the intriguing skill and more successful activity of the monk. The whole society were closely united in promoting the interests of the order; to this paramount object all their efforts were directed; they corresponded with one another usually in cypher, and gave the earliest information; they were always upon the spot, and always attentive, dextrous, and persevering. Ambition was their fault, and the cause of their ruin; they had made large acquisitions of territory and of Indian subjects in South America, and unwise growing at independence, they provoked the jealousy of the European princes, and precipitated their fall. After a keen controversy with the Jansenists, and a considerable variety of fortune, the order was suppressed by Clement XIV. in the year 1773.

For an account of the inquisitorial tribunals, see Dominicans and Inquisition.

During the period which extends from the year 755 to the reformation by Luther, many strange and novel doctrines were introduced into the church. It would be altogether improper to call them heresies; for they were either propounded by the pope himself, and delivered from the chair of infallibility, as existing articles, or integral parts of the catholic faith; or they were generated in the schools, and growing into notice, were at length confirmed by the authority of the holy see. Of the doctrines alluded to, there is none more worthy of a place in ecclesiastical history, than that which relates to the presence of Christ's body and blood in the sacrament of the supper. Even so early as the 11th century, an opinion began to be entertained, that the bread and wine, when consecrated by the priest, were not mere symbols or representations. In the year 1201, the pope's legate enjoined the people of Cologne to prostrate themselves at the elevation of the host. The eucharist was no longer regarded as a commemorative rite; it was held to be sacrificial and propitiatory; the consecrated bread was represented as the victim, (hostis,) the Saviour himself was declared to be actually and substantially present, and to be really offered up to God as a sacrifice for the sins of the world; and the people were commanded to adore. But last we should err in giving our account of this monstrous doctrine, let us state it in the language of one of its most zealous defenders: "The bread and wine," says Humbert, on the confession prepared for Berenger, archbishop of Angers, who had maintained the opposite doctrine, "the bread and wine, after consecration, are not only a sacrament, but also the real body and blood of Jesus Christ; and this body and blood are handled by the priests, and consumed by the faithful, and not in a sacramental sense, but in reality and in truth, as other sensible objects are." This undoubtedly is broad and plain enough. It was regarded as no sufficient objection to the doctrine in question, that it contradicted the senses; it was a mystery, and mysteries, by their very nature, are difficult to be understood. Nor was it held sufficient to say, that the body of Christ was in heaven, and that, if we suppose it to be a real body, tangible and visible, it could not retain its qualities of length, breadth, and thickness, and yet be present in many places at the same time. The answer was easy, "we allow that the doctrine is mysterious." The words of Jesus likewise were quoted, as putting an end to the controversy, "this is my body, broken for you;" and though these words might have been considered as opposed to, and reduced in their signification by such expressions as the following: "I am the door, I am the vine, I am the way," &c. the doctrine of the real presence was believed, and with certain modifications, not very easy to be discerned and understood, it remains to this hour the doctrine of the Romish church.

Another of the doctrines which prevailed during the period above alluded to, was that of purgatory, or a temporary state of punishment in the world to come. Something resembling this doctrine, appears to have been taught in very early times; there are traces of it in the writings of Origen; and Gregory Nazianzen and Ambrose speak still more decisively concerning it. It may be inquired whether the intimations of a hades, or separate state, which are given to us in the scriptures themselves, ought not to be regarded as the foundation, on which the doctrine of purgatory was afterwards raised.

"In the tenth century, the fear of purgatory was carried to an extraordinary height, excelling even the apprehension of final judgment, and everlasting misery. And in later times, prayers and masses were continually offered up for the souls of those who had passed into this preparatory state; all the saints in heaven were supplicated, in order to shorten or mitigate the punishment, and rich gifts were bestowed upon the church. Some of the largest bequests which the clergy ever in-
Ecclesiastical

The season of sickness and the hour of death were the times when such donations, "for the good of the soul," were usually made. The dying transgressor readily parted with his possessions to secure the mediation of the saints; and all antiquity had declared, that the mediation of the saints was not to be secured without proper benefactions to the clergy. The following are the arguments by which the doctrine of purgatory is maintained: 1. As every sin, however inconsiderable, is an offence to God, it is deserving of punishment. 2. Many sins are so inconsiderable, as not to deserve everlasting punishment. 3 There must be a place or state of existence, where these inconsiderable transgressions are punished according to the measure of their enormity; and to this place, or state of existence, (say the Catholics,) we give the name of Purgatory. 4. There is no man who is altogether free from the stain of sin at the period of his dissolution. 5. There must, of consequence, be an intermediate state, a state of purification, where the soul is cleansed from all defilement, and the stain of corruption is completely washed away. And, (say the Catholics again,) we do nothing more than apply the name of Purgatory to this intermediate state.

The doctrine which relates to absolution and indulgence, must be mentioned in the third place. These two varieties of imposture have been joined together by the ecclesiastical historians, and with sufficient reason; for the tendency of both was to produce on the minds of men, one great and pernicious effect, namely, that of substituting the pope in the room of Almighty God, and establishing our title to the happiness of heaven, without the cultivation of personal virtue. While such doctrines and practices degrade the understanding, by subjecting it to the opinion and the authority of an individual, they relax at the same time the ties of all moral obligation. The power of absolution is one of those numerous consequences which result from what is technically called "the possession of the keys." We trust we need not repeat the arguments by which the Catholics attempt to support the exercise of this power. The extraordinary gifts which were conferred upon St Peter, were transmitted, (as they affirm,) to his successor the pope. And to Peter it is distinctly said, "I give unto thee the keys of the kingdom of heaven; and whatsoever thou shalt bind on earth shall be bound in heaven; and whatsoever thou shalt loose on earth, shall be loosed in heaven." It is more proper to observe, that the power of absolution was exercised in all its presumptuous and blasphemous extent, during the period of the crusades. In the course of these expeditions, few sins were left unpardoned. Simply to enrol the name in the lists of the sanctified soldiery, was held sufficient to secure the high blessing of unlimited forgiveness. The gates of paradise were opened wide to receive the consecrated battalions. The warriors of the cross were washed and cleansed by one deed of the pope, from all their iniquities. And in the thick darkness of the age, there were few who were able to search into the foundations of the papal authority, and few who were willing to expose its absurdity, even if they had had the penetration to detect it. Some planet seems to have struck the nations, or some fatality to have depressed the faculties of the human mind.

Indulgences, though producing nearly the same effects with absolution, may be considered as somewhat different in their description and history. And they are deserving of more particular notice, as it was the indiscrimet use of indulgences that provoked the opposition of Luther, and gave rise to the reformation in Germany.

The doctrine respecting this branch of the papal imposture, seems to be merely an extension of that which relates to penances. It was universally admitted, that it belongs to the church, upon sufficient considerations, to relax the severity of her discipline, to shorten the period of probation, and to lessen the number of penitentiary infictions. And it was granted likewise, that the church is the only judge of those considerations which she may hold to be sufficient. To allow therefore certain sins to be committed, without subjecting the individual to the usual penances, was supposed to be within the legitimate range and just exercise of the ecclesiastical power; and when the permission was signified in writing, the document alone, or the fact and the document taken together, constituted what, in the primary acceptance of the term, was called an indulgence. But the matter did not remain long in this situation. An additional import was given to the word; the practice was extended; and the remission of penances prepared the way for the remission of sins. If the individual was freed from all penitentiary infictions, in the former case, in the latter he was exempted from all punishment whatever; and if the indulgence was plenary, he might transgress with impunity every statute in the decalogue, and every ordinance of the church. To this favoured individual, purgatory, and even hell itself, were divested of their terrors; in the prospect of the last judgment, he was already acquitted. Nor were arguments wanting to support the doctrine and the practice which we have thus cursorily described. Indulgences were purchased; the error was lucrative, and a lucrative error never fails to find its champions in the schools, ready to arm themselves, and to sail on in its defence. "There actually exists," says St Thomas, "an immense treasure of merit, composed of the pious deeds and virtuous actions which the saints have performed, beyond what is necessary for their own salvation, and which are therefore applicable to the benefit of others; the guardian and dispenser of this precious treasure is the Roman pontiff; and of consequence he is empowered to assign to such as he thinks proper, a portion of this inexhaustible source of merit, suitable to their respective guilt, and apply the revenue to deliver men from the punishment due to their crimes."

From the tumult of the crusades, the blasphemous impiety of absolution, and the corruption of morals arising from indulgences, let us turn for a moment to the abodes of literature, and the retreats of philosophy. Here, perhaps, we may find something to rest upon with satisfaction; some light, however scanty, to diversify the scene; some straggling ray to prove to us that the darkness may yet be broken and dispelled. We must own, however, that we are far from being relieved or glorified by the change. The literature of the middle ages is occupied chiefly with the miracles of the saints; and the combats of the crusaders are surpassed in every thing, except the shedding of human blood, by the warfare of the schools. The Nominalists gave keen battle to the Realists, and the Realists, no less valorous than they, maintained the conflict. John the Sophist and the famous Roscelin led on the bands of the former, while the latter marched under the banner of Thomas Aquinas, and of Albert the Great. The doctors, subtle, irrefragable, seraphic, angelic, all mingled in the fray, and augmented the noise by very large accessions. The great question among these fierce disputers was,
whether the universals were things actually existing in nature, or whether they were merely words, that is, things existing only by designation. We trust our readers will see that this question was much more easily proposed than answered. In fact of point it proved to be so; but on that very account, it formed the better subject of discussion. Argument was held upon it after argument, and syllogism tried after syllogism; objections were made and rejoinders tendered, divisions took place, and deadly feuds were established. The learned every where engaged in the dispute, and all Europe rung again with the momentous controversy. Books were published; numerous and heavy comments were written, and annotations upon comments. Nor do we believe that this abstruse and subtle question is determined even at the present day. Our latest philosophers range themselves on opposite sides; Dr Reid embracing the opinion of the Realists, and Dr Berkeley and Professor Stewart attaching themselves to that of their more popular antagonists.

The question above referred to was one of breadth and generality. There were others, however, of a more particular nature; and some, if not very important in the result, were sufficiently amusing in the enumeration. Of these last the following are instances: "Can an angel pass from one extreme to another, without travelling through the middle space? When a man leads a pig to market, by means of a rope, is the pig led by the man or by the rope? (This question was propounded in a dispute about causes.) Is a Negro black or white? (answer, he is white accudum quid, that is, in relation to his teeth.) Other questions entertained in the schools were impious and blasphemous in the highest degree. We shall mention a few of these in the language in which they were originally proposed. An possible fiiit habere Mariam, placere filios, unica generatione, quid generetur verbum? An Maria dormiendo, habuerit umum rationem? An fuerit apostolus apostola, et omnium artium mechanicarum perita? An in statu innocentiae, aquilus numerius futurae fusilis, viroarii mulierem? An passere, el alia brevis ecclesiam fadantia licet ezcomunicare? An possitis baptizari aliquit, in lazioso, mulo, jure carnium, brodo piscium, urin? An tenet baptismus, si conferatur in nomine Diaboli? Utrum naturum mulieris, asini, serpenis, vel columbae? Christus deberet aut potuerit assumere? An haec similis propositiones, Deus est ujus, est scaramuzia, quae sint possibilis atque illa, Deus est homo? An pontifex Romanus, sit Deus, an homo, an ex utroque unum? From these questions, it will appear, that a reformation was no less necessary in the schools than it was in the church.

CHAP. IV.

The History of the Church of Christ, from the Era of the Reformation (inclusive) about the Year 1545 to the present Time.

In the year 1517, John Tetzel, a Dominican friar, began to publish indulgences in Germany, and to offer them for sale. He was employed by Albert, elector of Metz and archbishop of Magdeburg; and Albert himself was the immediate agent of Leo X. whose profuse munificence had exhausted the papal treasury, and induced him to replenish it by the most unjustifiable means. The indulgences in question were plenary, in the highest sense of the word; for Tetzel proclaimed the complete remission of sins, whether past, or present, or future, to all who could pay the stipulated sum. He who had money, or who had interest enough to borrow it, might transgress with impunity every precept of the decalogue, and set the justice of heaven at defiance. With an absolution already in his possession, nothing but the punishments of the civil magistrate could restrain him from committing the most atrocious wickedness; and, by the usurpations of the ecclesiastical courts, the number even of heinous crimes which fell within the jurisdiction of the civil magistrate was exceedingly small. The church, or, more correctly speaking, the pope, reigned triumphant; the prerogative of the Supreme Judge was violated and destroyed; and the thunderbolt of the divine wrath smote from the hand of Omnificence. All morality was relaxed—all government weakened—and all subordination and obedience appeared likely to cease; and the pernicious tendency of the doctrine was surpassed by nothing but the shameless impudence of Tetzel, and his associates, who published the indulgences, and magnified their value. The lives, too, of these unblushing apostles, corresponded with the nature of their mission; they often squandered, in low debauchery, the money which had been given by the pious and the simple, in the hope of obtaining everlasting happiness; and such was the perception of their worthlessness, and general opinion of their character, that even those who purchased the indulgences were ashamed to be seen in the company of the persons who sold them. The princes and great lords were provoked to find their subjects drained of their wealth, in order to supply the profusion of the sovereign pontiff; men of reflection, superior to the times in which they lived, marked the deep ignorance of the age; and men of learning anticipated a brighter era, or hailed the indications of its approach.

In these circumstances, it seemed good to the providence of Almighty God, to scatter the darkness, to put a stop to the accumulating corruption, to awaken inquiry, and restore the intellect of man to its original size and strength. The dominion of imposture, and the despotism of Rome, were now to be shaken. At the juncture of affairs which we have described above, there arose in Germany, the celebrated Martin Luther, a man of humble extraction, but endowed with penetration, with learning, and with courage, far beyond the proportion which falls to the lot of ordinary mortals. He was a native of Eisleben in Saxony, and in early life had entered a convent of the Augustine friars. Being speedily distinguished, on account of his piety, his love of knowledge, and unwearied application, he was appointed by Frederic the Wise, Elector of Saxony, to teach philosophy and theology in the university of Wittenburg. The prince just mentioned had lately founded the university, and was anxious to fill it with men who were celebrated for their learning.

Nothing is more certain, than that he who teaches others must first be taught himself. When knowledge is disseminated through the world, it is taken for granted, that some individual mind has previously been instructed. It would be gratifying, therefore, if we had it in our power to ascertain the endeavours and approximations, in consequence of which Luther's own sentiments were formed. It would be interesting as a philosophical inquiry, and it would be most satisfactory to the readers of ecclesiastical history, could we trace the steps by which this extraordinary individual was led to call in question the truth of the prevailing opinions,
ECCLESIASTICAL HISTORY.

— to resist the authority of the pope— and to expose the insufficiency of his pretensions. But, whatever other helps Luther might have used, there is reason to believe, that his sentiments were formed, in a very great degree, by the perusal of the holy scriptures themselves. He drew his knowledge from the original source, pure and living; he sought Christianity in her first estate, and discovered her in all her native simplicity and beauty. There lay in an obscure corner of his monastery a neglected copy of the New Testament, to which his attention was casually directed; and having once begun to read in it, he commenced the study of the inspired volume, with all the eagerness and perseverance which belonged to his character. What must have been his emotions, when he contrasted the simplicity of the primitive institute, with the presumptuous pomp of the hierarchy and the papacy; and placed in opposition to one another, the humble follower of Jesus, and the mighty monarch, who reigned uncontrolled over the understandings and the consciences of men? What must have been his feelings, when he marked the terms of acceptance with God, as these terms are proposed to us in the sacred books, and bethought himself, for a moment, of the penances, and relics, and the intercession of the saints, and works of supererogation, and indulgences, and all the solemn trifling and elaborate mummery, by which the Church of Rome directed her votaries to the way to heaven! How different the language of inspiration, "believe on the Lord Jesus Christ and thou shalt be saved," and the language of the papal bulls, and even of the councils of Christendom!

At first, Luther contended himself with a bold and vehement opposition to Tetzel and the Dominicans. He declared against indulgences, in all the power of his eloquence, from the pulpit of the great church at Wittenburg; pointed out, with bitter reprehension, the vicious lives of the monks, their injustice, extortion, and vulgar debauchery; and, adopting already the first principle of Protestantism, he warned the people of their danger, in trusting for pardon and acceptance with heaven, to any other means than those which God had appointed in his word. The pope, he said, might unquestioningly remit the penances which he had himself imposed, or dispense with the ceremonies ordained by the church; but it belonged to the Supreme Judge, and to him alone to forgive the trespasses of the moral law. To the pope, he acknowledged that he owed all submission; and he even spoke of referring the question at issue between him and his antagonists, to the decision of the sovereign pontiff. From this, it is evident, that the sentiments of Luther, with regard to the powers of the papacy, were not yet mature; and had Leo X. conducted himself on the present occasion with the prudence often displayed by the successors of St. Peter, the dispute might either have been terminated among the combatants themselves, or left undecided altogether; and historians would have handed it down to us as nothing more than a contest between certain ecclesiastics in Germany, scarcely deserving of particular notice. But the temper of Leo appears to have been violent, and his cause was radically bad: by threats and ferocious dogmatism, he roused the courage and sharpened the acuteness of the reformer, induced him to prosecute his inquiries, and in the end gave occasion to that memorable rupture, which has rent asunder the Christian church, and shaken, even in its own estimation, the supremacy of the holy see.

If ever there was a time when threats and dogmatism were improper to be used, it was the time of the controversy between Luther and the agents of the Pope. The era of ignorance was now hasteing towards its close. The human mind was quickened and stimulated, the intellectual eye began to open, learning had revived, books were printed and circulated, inquiries were made, and investigations pursued. The reverence for antiquity was already much abated; and mankind now looked for argument in the decision of theological as well as philosophical questions; or if authority was referred to, they proceeded to examine the grounds on which the authority was built. Reformations were talked of; abuses specified; the names of Wickliffe and Huss were mentioned with respect; whispers were abroad unfavourable to the honour of Rome, and the security of the papal power.

At this most auspicious time, Leo X. and his agents proceeded against Luther, wholly in the way of despotic authority and simple recantation. The reformer was summoned to appear at Augsburg, before Cardinal Cajetan, a Dominican monk, at once the friend of Tetzel, and the undisguised enemy of the new opinions. The cardinal, who had the reputation of learning, and was at the same time the pope's legate in Germany, was imprudently nominated sole arbiter in the cause. Luther, though he perceived from the beginning, that little was to be expected from the impartiality of the judge, repaired to the place appointed, ready to defend the sentiments which he had published, and animated with a courage which nothing could resist. The event corresponded exactly with the anticipations of the reformer. The cardinal stood high upon his dignity, refused to enter into a dispute with an Augustine monk, would listen to none of the reasons with which Luther endeavoured to support his opinions, and required him, "by virtue of the apostolic powers with which he was clothed, to retract his errors in regard to indulgences and the nature of faith, and to abstain, for the future, from the publication of new and dangerous doctrines." Nor was this all. The reformer was not only commanded to retract and to abstain,—he was also commanded to believe. And for the accommodation of his understanding, and as the subject of his belief, the cardinal pronounced to him, in consequence of the apostolic powers which he has just allowed, to the following authoritative dogma: "That one drop of Christ's blood being sufficient to redeem the whole human race, the remaining quantity, which was shed in the garden and upon the cross, was left as a legacy to the church, to be a treasure, from whence indulgences can be drawn and administered by the Roman pontiff." The answer of Luther was temperate, yet firm. He declared, in direct asseveration, that he could not renounce those opinions which he held to be entirely consonant with the sacred scriptures; and that nothing should ever induce him to do what he conceived to be so unworthy in itself; and so dishonourable and offensive to God. He expressed his willingness, at the same time, either to reason the matter to an end with the cardinal himself, or to refer it to the decision of certain universities which he named. He even went so far as to engage that he would abstain, in all time to come, from preaching or writing against indulgences, provided his enemies were enjoined to observe a similar silence with respect to them. This equitable and moderate conduct, however, and those concessions, had no effect upon the cardinal. He still insisted upon a simple and unqualified recantation. He branded Luther with the name of a schismatic, and stigmatized him, as indeed the pope himself had already done, in several of
his briefs and letters, under the characters of a child of
iniquity, and a man given up to a reprobate sense. And
such was the tyrannical violence of this lofty prelate,
that the reformer, after solemnly appealing from his
judgment, to the more mature deliberation and decision
of the holy see, complied with the earnest intreaties of
his friends, and withdrew himself privately from Augs-
burg.

From what we have stated, however, our readers will
easily perceive, that an appeal to the pope was both un-
wise and unnecessary. The dispute respecting indul-
genesis affected not only the authority of the papal chair,
but the revenues of the pontiff. The cultivated magni-
ficence and the splendid liberality of Leo, required ex-
tensive funds. By diminishing the value of indulgences,
the profits of the sale were lessened. One country of
Christendom would imitate another; the resources of
the church would be impaired; and who does not know
that the power of the pope has always been intimately
connected with the resources of the church? But the
appeal in question was unnecessary, as well as unwise.
The court of Rome had already decided against Luther
and his followers. The sovereign pontiff had declared
the new doctrines heretical; and a bull was in agitation,
to cut off the schismatic monk, and to cast him out from
the bosom of the church. The document, if it may be
called so, was very solemnly pronounced. The whole
college of cardinals were consulted upon the occasion,
and were repeatedly assembled, in order to select the most
objectionable passages from the writings of the reform-
er; and the schools were ransacked to procure some able
canonists, that the sentence might be expressed with
unexceptionable formality. At length, on the 15th day of
June, A.D. 1520, the bull, so fatal to the
papal interests, was issued. "Forty-five propositions,
extracted from Luther's works, are condemned in it as
heretical, scandalous, and offensive to pious ears; all
persons are forbidden to read his writings, upon pain
of excommunication;" such as had any of them in their
custody, are commanded to commit them to the flames;
he himself, if he did not, within sixty days, publicly re-
cant his errors, and burn his own books, is pronounced
an obstinate heretic, is excommunicated, and delivered
over to Satan for the destruction of his flesh; and all
secular princes are required, under pain of incurring
the same censure, to seize his person, that he might be
punished, if his crimes deserved punishment. The whole
college of cardinals were consulted upon the occasion,
and were repeatedly assembled, in order to select the most
objectionable passages from the writings of the reform-
er; and the schools were ransacked to procure some able
canonists, that the sentence might be expressed with
unexceptionable formality. At length, on the 15th day of
June, A.D. 1520, the bull, so fatal to the

and were repeatedly assembled, in order to select the most
objectionable passages from the writings of the reform-
er; and the schools were ransacked to procure some able

This famous bull had no other effect upon the mind
of Luther, than that of exciting him to keener opposi-
tion, and more systematic hostility. He had perseve-
red with habitual diligence, and with humble prayer
to God, in the study of the sacred scriptures. He had
read of the "man of sin," the antichrist who was to
come in the latter days of the church; that power
which was to oppose itself to the interests of true reli-
gion, and the dominion of the everlasting God. He
marked the resemblance between the descriptions of
this power given to us in the sacred books, and the un-
justifiable pretensions and blasphemous arrogance of
the holy see. He noted the distinguishing circumstances
alluded to in the particulars, of "sitting in the temple
of God, (referring to the man of sin,) and showing him-
self that he is God, of "lying wonders," and the " de-
ceivableness of unrighteousness," of " forbidding to
marry," and "commanding to abstain from meats," and
rewriting the whole matter in his mind, he next
boldly pronounced the Pope to be the man of sin, and
the power of the Romish church to be the deadly power,
which should raise itself, in the latter days, against
the sovereignty of Christ. Amidst a vast assemblage of
people in the town of Wittenburg, he threw the papal
bull, and the volumes of the canon law, into the flames;
appealing to a general council, which he declared to be
the only tribunal where his case could be judged, and
to which, in the opinion of Christendom, the pope him-
self was subject. He warmly exhorted the princes of
Europe to shake off the yoke which they had too long
borne, and too ignominiously borne; and offered thanks-
givings to Almighty God, that he had been selected as
the advocate of true religion, and, according to the mea-
sure of his abilities; as a friend to the liberties of man-
kind.

Nor was the voice of the reformer lifted up in vain. The Re-
formation found supporters in almost every
kingdom of Europe. In Switzerland, Ulric Zwingli,
a man of a republican spirit, attacked the ancient su-
perstition, with a courage by no means inferior to that
of Luther himself. The elector of Saxony was the pa-
tron of the Reformation. Most of the Prussian princes
joined with the elector. The edict of Worms, which
was unfavourable to Luther, could not be executed.
At the same diet in which the edict alluded to was pro-
nounced, it was resolved, that every secular prince
should manage the ecclesiastical affairs of his own do-
minions, as he himself should judge to be most proper,
till the meeting of a general council. We must own,
however, that at a subsequent diet, this wholesome
resolution was reversed; but we must not fail to state,
that against the sentence of reversal, the elector of
Saxony, the landgrave of Hesse, the marquis of Bran-
denburgh, together with the princes of Luneburgh and
Anhalt, and the representatives of fourteen Imperial
cities, entered their most solemn protest. They decla-
red the sentence to be unjust as well as impious.
From the circumstance of protesting on the part of the
princes and representatives, mentioned above, the name of Pro-
testants had its origin; a name since applied to all
the variety of sects which have withdrawn, upon any
account, from the communion of Rome. The sacred
scriptures were translated into the German tongue, and
were read with astonishing avidity. Melanchthon, who
had assisted Luther in the translation, drew up the
conciliatory creed, entitled the "Confession of Augs-
burg." The league of Smalcalde was formed, and the
Protestant states were united into a regular body.
The Helvetic cantons, under the auspices of the famous
John Calvin, proclaimed aloud their determined hosti-
ity to the rites and ceremonies of the papal institu-
tion.
The secret friends of the Reformation abounded in
France, Spain, Hungary, Bohemia, and the Nether-
lands. And to crown the whole, King Henry VIII. of
England, after writing in defence of the papacy, and
obtaining from the holy see the title of "Defender of
the Faith," suddenly deserted the cause which he had
espoused, and commenced a rough and hasty, but ef-
fectual reformation throughout his dominions, dethron-
ing the pope, and with blustering magnanimity, sub-
stituting himself in his place.

Still, however, the enemies of the Reformation were
both numerous and powerful. A very great proportion
of the European princes remained attached to the an-
cient system; some of them from religious considera-
tions, and others from motives of interest or policy.
Among the last class we must reckon the Emperor
Charles V. It was in opposition to this monarch that
the league of Smalcalde was formed; and during a
considerable part of his reign he was engaged in open
war with the Protestant leaders. The sovereigns of
France, Spain, and Portugal, continued to acknow-
ledge the powers of the holy see. All the Italian states
remained submissive to the pope. The numbers on both sides were great; the interests jarring, yet weighty; but the strength of argument, and the power of eloquence and of truth, belonged chiefly to the Protestants. They rejoiced in the exercise of their faculties, emancipated and enlarged; they published their opinions, and challenged a investigation. True religion is ever friendly to inquiry; it is error alone that hastens to hide itself in darkness. Every new discovery which was made in the arts, or in the sciences, and every copy of the holy scriptures that was printed, conveyed additional light to the understanding, and gave additional vigour to the champions of reformation.

In this situation of affairs, and when religious disputes were about to be settled by an appeal to arms, the council of Trent was unexpectedly convoked. It was summoned by the authority of the pope, and sat down, at the place from which it takes its name, in the year 1545. Strange as it may appear, the Catholics were now the most forward in demanding a general council; and those ecumenical assemblies, which in the preceding ages were the terror and the abhorrence of the popes, were at length convoked, if not with greater alacrity, at least with fewer objections. The weakness of human nature had been duly estimated. The court of Rome, always intriguing in its character, and rendered dextrous by long practice in affairs, perceived that general councils might be influenced and managed as well as other bodies of men. It was easy to throw difficulties in the way, and make it disagreeable or inconvenient for the Protestant leaders to attend; some of the members might be flattered into acquiescence, and others overawed. Bribes were to be tried in the first instance, and if these were found to be unavailing, threatenings might be employed.

But the cause of Protestantism, identified as we must conceive it to be with that of true religion, suffered about this time in a very different way. Luther, the great father of the Reformation, died at Eisleben in Saxony, on the 18th of February 1546. His health had for some time been declining, and his constitution, naturally strong, was exhausted with incessant study, and that agitation of mind to which controversy almost necessarily gives rise. To a zealous regard for truth, he added an apostolical intrepidity in its defence. His manners were pure, perhaps even austere; his diet was plain; his whole mode of living characterized by a primitive simplicity. He knew nothing, and wished to know nothing, of the elegancies which belong to cultivated society; he was satisfied with the emoluments of his professorship, and left the preferments and honours of the church entirely to his disciples. Upright in his intentions, and fair and direct in all his conduct, man could justly charge him with duplicity; he disdained the crooked artifices of little minds; but his zeal was often excessive, his temper inflexible and haughty, and his language, especially in controversy, contumacious and coarse. Yet there was, in this coarseness, a barbaric strength; and such was the power of his opposition, that it was not safe for any one who valued himself upon his literary reputation, to awaken him into rage. His piety was very great and sincere; and, in his last moments, he discoursed to his friends of the happiness of heaven, with a fervour and delight which could result from nothing but a well-grounded hope of immortality. He left a character to be imitated almost in every thing but the excess of his zeal: nor will the friend of genuine Christianity, of literature, or of liberty, ever mention his name, but with the gratitude and reverence which are due to the benefactors of mankind.

We return, however, to the narrative of events. When the council met, in obedience to the papal mandate, it was found to consist almost entirely of the Italian and Spanish prelates. In the first session, there were present only the Pope's legates, who presided, four archbishops, and twenty-two bishops; yet a considerable number immediately declared themselves to be a general council, and proceeded to determine controversies, and to enact laws for the benefit of the church. The subsequent sittings were better attended; but still the Italian and Spanish clergy formed by far the greater part; and, even of these, some who were refractory, and who spoke of abuses and reformations, were awed into silence by the overbearing authority of the papal legates. The Protestant leaders had long ago declared the jurisdiction of the council; they would not allow it to be a synod properly convoked; and far less would they acknowledge it as an ecumenical assembly of the Christian church. Everything, of course, was transacted according to the despotic will of the holy see. The case of St Peter, whom the Protestants have justly described as the most blundering of all the apostles, was introduced, and argued at large. In the eye of Catholic interpretation, St Peter was the shepherd, and the Christian world were the sheep. —"... silly animals," as Lainez, the general of the Jesuits, expressed it, "which have no part or choice whatever in conducting themselves." St Cyprian, too, (observed the general), compares the apostolic see to the root, the head, the fountain, the sun; shewing, by these comparisons, that the supreme jurisdiction resides in her alone; and that it exists in others only by derivation and participation. And this is the meaning (continued he) of the ancient language, when it is said, that St Peter and the Pope possess the plenitude of power, while others do nothing more than participate in the cure. To the arguments of the general, no effectual reply was made. The authority of the Pope was confirmed in all its extent and latitude. The French ambassador alone appears to have spoken in favour of the Protestants, declaring that, so far from being the cause of the troubles which existed in France, they were the injured party. He plainly stated, that abuses had crept into the church; that reformations were necessary; and that his most Christian majesty, and the whole French people, expected nothing less than certain very considerable changes. And he requested, in the name of his master, that the council should not satisfy themselves with enacting laws, but that the Pope and the clergy should make use of their power, in order to carry them into execution. "If the "father," said he, "should ask, why France is not in peace?—no other answer can be given, than that which Jehu gave to Joram of old, What peace (can there be) so long as the whoredoms of thy mother Jezebel and her witchcrafts are so many?"

But if the council were unwilling to reform abuses, or to acknowledge their existence, they were sufficiently attentive to the security of their own rights and privileges. They enacted many statutes, the tendency of which was, to secure the ecclesiastical orders from all interference on the part of the civil powers. By the spirit, and even by the letter of these statutes, no clergyman could be tried in any secular court. He was responsible, indeed, in matters of civil delinquency; but, with the exception of a few cases, peculiarly aggravated, he was responsible only to the judicatories of the church. And, even in the excepted cases, it was
determined that the trial of an ecclesiastical before the secular judge must be preceded by a declaration or permission from the episcopal court. The property of the church is pronounced to be sacred: the clergy cannot be compelled to pay taxes, even under the name of loans or free gifts, whether those taxes, loans, or free gifts apply to their patrimonial possessions, or to the goods belonging to the community. The mandatory letters, sentences, or citations, of the ecclesiastical judges, are to be executed without inquiry or delay. From the enactments now alluded to, as well as others of a similar description, which our limits prevent us from specifying, we may form some idea of the height to which sacerdotal presumption was carried in the sixteenth century, and of that independence upon the civil authorities to which the exertions of the Roman church were so long and so unjustly directed.

But while the council were at all pains to secure their own rights and privileges, they found it necessary to put forth a statute, "concerning the rule which should be held as supreme and decisive, in matters of faith." An ordinance relative to this important particular, was imperiously demanded by the progress of the Reformation; and it was chiefly with a view to ascertain the opinion of the church with regard to it, that the council had been convened. Accordingly, at their fourth sitting, and when only forty-nine members were present, they promulgated their famous decree respecting the canon of scripture, and the value of the apostolical traditions: a decree which pronounces the apocryphal books to be of the same authority with those which are genuine, and which places the traditions of the fathers on a level with both; an enactment which declares, that the Vulgate Version of the Sacred Scriptures, though not written, as its very title implies, either in the ancient language of the prophets, or in that of the apostles and evangelists, is nevertheless to be received and used throughout the church, as authentic and canonical. Of this notable decree, the following is a short account. It is solemnly determined, "that the books to which the designation of apocryphal hath been given, are of equal authority with those which were received by the Jews and the primitive Christians into the sacred canon; that the traditions handed down from the apostolic age, and preserved in the church, are entitled to as much regard as the scripture and precepts which the inspired authors have committed to writing; and that the Latin translation of the Scriptures made or revised by St Jerome, and known by the name of the Vulgate Translation, shall be read in the churches, and appealed to in the schools, as authentic and canonical;" and all persons who refuse to subscribe these tenets, are anathematized, and cut off from the communion of the church. Upon this decree, which has occupied so much attention, and been the topic of so much discussion since the era of the Reformation, we shall make only one or two additional remarks. First of all, when the council were employed in concocting it, they seem to have felt very indignant that pedants and grammarians (petits maîtres de grammaire) should presume to contend about the meaning of scriptures with doctors in theology. And, secondly, while they pronounced the Vulgate Version to be authentic and canonical, they appointed, at the same time, a committee of six persons, apparently the whole number present that were acquainted with the original languages, to revise and correct it.

The statute concerning the rule of faith.

Such is the well known decree of the Tridentine council, with regard to the rule of faith. It had passed with some difficulty, and not without considerable argumentation, even among the small number of members who were present. No sooner, however, was this famous decree promulged, than the pope, representing himself as superior to the council, and ultimate in decision, confirmed it by his apostolical authority, prohibiting at the same time all Christians, in communion with the holy see, from writing notes or comments upon it. They were not even allowed to illustrate or to defend it, without the permission of the sovereign pontiff.

Having confirmed the decree respecting the rule of faith, as well as the other acts of the council, the next step, on the part of the pope, was to procure the formal and implicit acknowledgment of the whole, by the different nations of Europe. The Venetians, with a dutiful submission to the supreme ecclesiastical authority, readily acquiesced. The Poles likewise expressed their willingness to abide by the decisions of the council. The Spaniards, too, manifested a considerable promptitude of comprehension and compliance; though in some provinces the Tridentine decrees were received with certain murmurs, doubts, enquiries, and reservations. It was thought that the episcopal order was too much reduced, and the powers of the papacy extended too far. Among the German Catholics, there were many who objected. But the most refractory of all the papal subjects were the French. No commanding attitude on the part of the holy see, nor stratagem of ecclesiastical dexterity on the part of its devoted agents, could induce the Gallican church to accept of the Tridentine decisions. They specified no fewer than twenty-three articles which, as they affirmed, were directly opposite, even in the very letter of the enactments, to the ancient usages of the realm; and they pronounced them to be equally destructive of civil and of religious liberty. "In all which particulars," says the celebrated Pasquier, alluding to certain portions of the twenty-three articles, "we have found such a repugnance and contravention to our ancient liberties, that we can never be induced to receive this council. For, first of all, it takes away from the bishops the power of reforming the churches which are situated within their own dioceses; and grants them only such a measure of power as the holy see shall think proper to allot them; a procedure which we believe to be contrary with the ancient canons approved of by the Gallican church. And besides this, the council seems desirous of establishing a new empire over kings, princes, barons, and every civil jurisdiction; which, in plain language, is to introduce old abuses which we have long ago reformed. Whereas, I can demonstrate, that our national privileges, and the liberties of the Gallican church, are such as the authority of neither pope nor council can abrogate, being founded on the broad and sacred reason of things (sur une raison auteur et générale.) By the admission of such decrees, (continues he), instead of securing order, we should bring in disorder, and introduce at the same time a monarchy, a thing which we have never hitherto beheld, into the middle of our own. Wisely, then, has this council never been received in France, by which, with a single stroke of the pen, the pope would acquire more authority than he has been able to do since the commencement of our common Christianity. I have no intention, (observes the same writer,) to deprecate the good Fathers of Trent; but I cannot help wishing that their zeal and devotion had been accompanied with a little more wisdom and discretion; and that in guarding the pretended
privileges of the holy see, they had not furnished its real enemies with the fittest weapons to overthrow it."

From the short account which we have just given of the Council of Trent, our readers will easily perceive, that we have no means likely to put any stop to the progress of the Reformation. It was considered by the patrons of the new opinions, as the exertion of a power which felt itself to be unstable. Its authoritative decisions were ridiculed by the Protestants, and even the Catholics have ceased to regard and to observe them with their wonted veneration. The revolutionary spirit appeared, by indications not to be questioned, in many of the kingdoms of Europe. In England, the changes were both numerous and radical. The reformation of Henry VIII. were no less effectual than hasty and tumultuous. He was declared by his parliament to be "the supreme head, on earth, of the church of England;" and he proceeded, not only to secure the property belonging to the monasteries which he had suppressed, but to fabricate, with all his royal diligence and skill, a suitable creed for the English people. History may record him as the first layman who took to himself, in the ecclesiastical sense of the expression, the title of supreme head of the church. The rough reformation of Henry, were succeeded by the more deliberate and steady measures pursued by the government, during the minority of Edward VI. The Bible, which had been translated into English, was allowed to be more generally read; a new liturgy was composed; and the service was performed in the vernacular tongue. The persecutions under Mary, in the course of which the virtuous Ridley, and the aged Latimer, were put to death, terminated with the reign of that inatuated princess, Elizabeth, her successor, openly avowed and protected the new religion. The sacred scriptures, together with the liturgy and the homilies, were freely circulated. The efforts of Spain and of Rome to restore the dominion of the papacy, were crushed by the defeat of the celebrated armada; the Scottish Catholics in the interest of their beautiful and unfortunate queen, were no less unsuccessful; the parliament united with the sovereign and her ministers; a very great majority of the nation supported the measures of the executive; and the reign of Elizabeth, though its full brightness is shaded by some acts of cruelty, must ever be regarded as that illustrious period, when truth and genuine Christianity secured for themselves a place, and established their abode among the English people.

In Scotland, the Reformation was effectuated by different means. Here we are constrained to look, not to the ruler, but to the subject. In the country alluded to, the Reformation could not, with any measure of propriety, be denominated a contest between the sovereign and the holy see, about the possession and the exercise of unlimited power: At the commencement of the changes, the civil and ecclesiastical authorities were not opposed. In this country, the Reformation took its rise from beginnings almost imperceptible. It was a poor man who achieved the mighty work in our native land. We hail the father of Scottish independence, the magnanimous Knox; at once the champion of truth and of liberty; stern, indeed, in his aspect, and fierce in his opposition, but stern only towards those whose iniquities he reproved, and fierce only when summoned by the mandate of heaven to arouse his courage, and to "wax valiant in fight." To his unwearied exertions, we owe our emancipation from an enslaving superstition, our successful system of education, the intelligence of our people, the discipline of our ecclesiastical polity, and whatever remains of genuine piety in the remoter provinces and sequestered vales of the country to which we belong. We venerate his honored name, and rejoice that a biographer has at length appeared, who has done justice to the character of the Scottish reformer, and, at the same time, has secured for his own performance an abiding place among the literature of the nation.

With the exception of the miraculous powers, the weapons used by Knox were the very same weapons with those which were employed by the apostles in the early period of the church. It was chiefly by the "preaching of the word" that the Scottish reformer accomplished the great work which he had undertaken. Though of an inferior stature, and of an appearance little engaging, his eloquence was efficacious in the highest degree. During the circuit of the country which he made soon after his return from the continent, he produced an extraordinary change upon the sentiments and feelings of the people. Multitudes from every quarter of the kingdom attended him, and eagerly listened, while he proposed and explained to them the doctrines of the Reformation. Every eye was fixed upon him, and every heart throbbed with emotion, as he prayed for deliverance to the enslaved land. The mind sprang forward, rejoicing in its liberty, and the courage even of the fearful arose. "Come out of her, my people," was the divine command; and never was it pronounced in allusion to a church so gross and festering with corruption, and never, since the times of inspiration, was it pronounced with greater energy, or with more important results. No speech uttered even by Demosthenes himself, in all the mighty fierceness of his declarations, was ever followed by such effects as the sermons of Knox. With the irresistible power of truth and of heaven, he took possession of the understanding, and captivated the affections. Undismayed by opposition, and not fearing the face of man, he overlooked all distinctions between the rich and the poor, the great and the humble; and addressing them indiscriminately in the character of guilty and condemned creatures, he proclaimed to them, with apostolical energy, the "glad tidings" of pardon and of peace. The sinner trembled under the denunciation of punishment, and the desponding were comforted and established in their most holy faith.

It is to be regretted that the zeal excited by the discourses of Knox could not uniformly be restrained within the limits which he himself would have prescribed for it. The multitude, animated and inflamed by the eloquence of the reformer, and moved likewise in a very considerable degree, by the imprudence of the Catholic party, proceeded, with ungovernable fury, to destroy the objects and the monuments of the papal worship. The images, relics, and altars, were broken in pieces; some of the religious houses shared a similar fate: the barriers were removed; the waters were out; and in the overwhelming tide and fierceness of the inundation, the superstitions of ancient times were swept away from the land. We are not aware that the destruction of the images and relics is to be lamented with extraordinary sorrow; but antiquaries and architects have wept, and perhaps not without sufficient reason, over the fate of the monasteries. Let it be remembered, however, that when the machinery of superstition was broken, the superstition itself was annihilated. The doctrines of popery, considered as distinct from the authoritative enactments of the holy see, had no possession and no...
place in the public mind; it was a system of external observances; and when the tools by which the work was carried on were destroyed, the work itself could no longer be performed. To remove the means of iniquity, is, in many instances, to put an end to its existence.

But it was not only on the minds of the people, that the eloquence of Knox produced its effects. Many of the nobility attached themselves to the cause of the Reformation. There is reason to believe, that a considerable number of these were actuated by a sincere regard for the interests of religion, and the welfare of their country. With others, the motives were of a mixed and doubtful nature; and not a few appear to have adopted the new opinions, because the success of the Reformation afforded them the immediate prospect of seizing and appropriating the ample possessions of the church. The meetings of the Protestants, were attended by the great lords and their retainers, in arms. The Earl Marischal and Glencarn were at once the disciples and the protectors of Knox. A powerful party, variously composed, existed in the country; and, by uniting themselves in the articles of covenant, for mutual support and defence, they at once assuaged their number, and concentrated their strength. The political events, so well known to every reader of Scottish history, facilitated the progress of the reformers. The inauspicious marriage of the young and beautiful queen, the murder of Darnley, the infamous conduct of the Earl of Bothwell, the zeal, the valour, and the prudence of Murray, all conspired with the labours of the preachers, and the increasing intelligence of the people; till at length the public voice became nearly uniform, and whenever the public voice becomes uniform or nearly uniform, the experience of ages will tell us, that it is neither to be trifled with, nor resisted. The parliament of the nation supported and confirmed the sentiments of the people. The Papacy was abolished; even the order of bishops was completely subverted; and Presbyterianism, a system, the leading principle of which is, that every teacher of religion, shall employ himself in the work of instruction among the people committed to his care, was established and acknowledged throughout the country. This wholesome system has ever since been fondly cherished by the Scottish nation; nor could all the efforts of the English court in later times, a court professing a regard for Episcopacy indeed, but secretly and slavishly devoted to the cause of Rome, induce them to swerve, even in the slightest degree, from the doctrine and the institute of the great reformer of their church. More than twenty years of cruel persecution, and of military apostasy, were tried in vain. Their attachment remained unbroken; and Presbyterianism, continues to this day the object of sacred estimation, in the eyes of the Scottish people.

For an account of the progress of the Reformation in France, the massacre of St. Bartholomew, and that which followed the revocation of the edict of Nantz, see France.

The doctrine of the Protestant churches is the next topic which demands our attention. This doctrine, as it is, in many important and prominent particulars, to the articles of the Romish faith, is detailed at considerable length, in the creeds and confessions, which have at different times been published by the chief persons and societies of the Reformation. The "Confession of Augsburg," which is understood to represent the Lutheran tenets, has been mentioned above. The doctrine of the English church is contained in her XXXIX Articles; and that still adhered to in Scotland, is to be found in the Confession of Faith, and in the Larger and Shorter Catechisms of our national church. In the Scottish formularies, the peculiar doctrines of the Holy Scriptures are supposed to be more amply and distinctly set forth. It is worthy of notice, however, that in all the creeds and confessions above alluded to, there is a very remarkable agreement; a harmony so conspicuous indeed, as well as gratifying, that the reader, by carefully consulting any one out of the whole number, may arrive at a sufficient degree of information, respecting the doctrine professed and maintained by the reformed communities. To one or other of these formularies, therefore, we refer our readers; and shall proceed to offer a short account of the most important controversies which have been agitated among the Protestants, since the time of Luther to the present day.

When the leaders of the Reformation withdrew from the communion of Rome, they separated from her by different stages of removal, and with different degrees of aversion. Of all the distinguished individuals among the Protestants, Melancthon appears to have retained the greatest attachment to the ancient church. He was a person extremely gentle in his dispositions, and he seems to have thought that by mutual concessions and approximations, the peace of the church might be restored and established. In one particular, the doctrine maintained by Luther himself, appears to have been removed only a short way from the corresponding article of the Romish faith; and, with regard to this one particular, the Father of the Reformation was long engaged in controversy, even with those who agreed with him in the general system of his belief. The particular to which we allude, is that very mysterious one, respecting the body and blood of Christ in the sacrament of the supper. It is true, that Luther denied and rejected, with abhorrence, the doctrine of transubstantiation, and would by no means allow, that the sacramental bread was converted into the real body of Christ. But while he denied any conversion of this nature, he strenuously maintained, that though the eucharistic bread continued, after the solemnity of consecration, to be nothing more than bread, the real body of Jesus, distinguished of course, as we should be inclined to think, by the usual material qualities, extended, visible and tangible, was present along with the bread. In short, he held the doctrine of consubstantiation, or what was afterwards described by the still more barbarous term of impanation. It was the age of minute and evanescent distinctions, and of scholastic refinement; a taste for subtle discrimination among kindred or similar ideas prevailed; and neither arguments nor illustrations were wanting. "As in red hot iron," said Luther, "two distinct substances, viz. iron and fire, are united, so is the body of Christ joined with the bread in the eucharist." To such an argument or illustration, if it deserve the name of either, was a man even of Luther's sagacity reduced, when he set himself to maintain, what he felt to be absurd. But while the Saxon reformer was zealously employed in maintaining the incomprehensible tenet of consubstantiation, a more plain and accessible doctrine was proposed by Zwinglius, his cotemporary. We have already mentioned the name of this distinguished person, as the first reformer of Switzerland; and have stated, that he commenced his career with an activity equal or superior to that of Luther himself. Zwinglius rejected at once both the doctrine of the Romish church, respecting the eucharist, and the notion of consubstantiation, maintaining, certainly with a
greater appearance of reason, "that the body and blood of Christ were not really present in the eucharist; and
that the bread and wine were no more than external
signs or symbols, intended to excite in the minds of
Christians the remembrance of the sufferings and death
of the divine Saviour, and of the benefits which result
from his heavenly intercession." Besides the names of
Luther and Zuinglius, as leaders in this mysterious con-
troversy, we must not fail to mention that of the cele-
brated Calvin. This last reformer was not a whit be-
hind the greatest of his contemporaries in activity and
zeal. He maintained, however, a doctrine apparently
intermediate between that of Luther and the opinion of
Zuinglius; though it is not to be denied, that, upon
this subject, he expressed himself with such an extra-
ordinary diversity, and even ambiguity of phrase, as
renders it difficult or impossible to ascertain what his
real sentiments were. Upon the whole, the opinion of
Calvin seems to have been, that Christ was "spiritually
present" in the eucharist; or, in other words, that as
our blessed Saviour, according to the promise which
he made to his disciples, is present with them, when-
ever two or three of them are met together, so he is
more immediately and effectually present, when they
approach him in the solemn service of the Supper.

About the middle and towards the close of the six-
teneth century, the heresy of the Socinians began to
appear in different parts of Europe, and especially in
Poland. This heresy derives its name from its chief
patrons, Lachius and Faustum Socinus; the former, a
man of considerable learning as well as acuteness; the
latter, distinguished by his resolution and his prudence.
The heresy in question may be regarded as an exten-
sion of the Arian doctrine, respecting the nature and the
person of Christ, his inherent dignity, and the wor-
ship which is paid to him. Arian, indeed, went no fur-
ther than maintaining, that there was a time hid in the
depths of eternity, when the Son of God did not exist;
Socinus and his followers contended, that he had no ex-
istence at all, previous to his miraculous conception in the
womb of the virgin. Arian regarded our Saviour as the creator of the visible world; Socinus acknow-
ledged him only as a messenger from heaven, and a true prophet. In a word, the Polish sectaries main-
tained, that Christ, in his nature or essence, was a
man, and nothing more, (φυσις ανθρωπως); but, with a
strange inconsistency, they allowed that he was pro-
duced by extraordinary and heavenly generation; and
that it was incumbent on all Christians to address him
as an object of worship. They denied the pious in-
spiration of the sacred books, and rejected the person-
ality of the Holy Ghost. The tenets of the Socinians
are fully set forth in the Raccoian catechism; and their
interpretations of Scripture are to be found at large in the
complete collection of their writings, entitled the
Bibliotheca Fratrum Polonorum. "The ancient cate-
chism," says Mosheim, "which was no more than a
rude and incoherent sketch, was laid aside, and a new
form of doctrine was drawn up by Socinus himself.
This form was corrected by some, augmented by others,
and revised by all the Socinian doctors of any note;
and, having thus acquired a competent degree of accu-
racv and perfection, was published under the title of the
"Catechism of Racow," and is still considered as
the Confession of Faith of the whole sect.

In later times, a certain modification of the Socini-
an doctrine was proposed by Dr. Priestley, and repre-
sented, in his numerous writings, as the only doctrine
contained in the sacred books. More daring than the
first patrons of the cause, the modern heresiarch de-
clares that Jesus Christ is a man in every sense of the
word, born of Joseph and Mary, in the way of ordi-
nary generation; that he was put to death, as some of
the apostles and early Christians were, in consequence
of the hatred and power of his enemies; and that he is
to be distinguished from the primitive preachers of
our religion, only by the circumstances of rising
from the dead, and of presiding at the general judg-
ment. Dr. Priestley likewise contended, and with per-
fected consistency, that every act of worship addressed
to Jesus is an act of idolatry; disregarding, as it ap-
pears, the prayer of the holy martyr Stephen, when
expiring under the fury of his persecutors. In con-
junction with their predecessors, the patrons of the
new doctrine deny the pious inspiration of the sac-
red writings; find out, with a discernment not very
easily communicated to their disciples, what passages
we are to reject, and what portions we are bound to re-
ceive; and even venture to affirm, without awe or con-
cern, that they have detected the great apostle of the
Gentiles "in reasoning inconclusively." The modern
system, too, is coupled with certain philosophical and
recondite speculations, about the materiality of the hu-
mansoul, and the necessity of moral actions; and,
when its parts are taken together, or put into juxtapo-
sition, it forms, beyond all question, the most extra-
ordinary phenomenon which the theology of the eight-
teneth century can produce. The antagonists of Dr.
Priestley, were, Dr. Price, in the philosophical depart-
ment, and Dr. Horsley, bishop of St Asaph, in the
critical and historical; and the latter, in particular, is
understood to have established the primitive or Niece
faith, with singular and tremendous ability, and
with triumphant success.

The third and last heresy which we shall mention, is
that which derives its name from Arminius. It is mere-
ly a less repulsive form of the doctrine proposed in the
fifth century by Pelagius, a man once famous in the
estimation of the learned, but now so far moved from
his place, and clouded in the lustre of his reputation,
that no country of Europe contends with our native
island, for the honour of his birth. He is the father of
the sect denominated Pelagians. Arminius, whom we
have just mentioned as adopting, with some variety,
the tenets of this sect, was a disciple of Beza, and
professor of divinity at Leyden. In a controversial
point of view, he is to be considered as the antagonist
of Calvin; and he is justly recorded as the first who
attacked the theology of Geneva with any measure
of success. The tenets of Arminius were solemnly con-
demned in a synod, which met at Dort in the
year 1618. They are usually called the "five Armi-
ний points;" and the doctrine contained in them is
expressed in the following propositions. The Armi-
nian sectaries hold. 1. That God, from all eternity,
has determined to bestow salvation on those only, with
regard to whom he has foreseen, that they will persevere
unto the end in their faith in Christ Jesus; and to in-
fect everlasting punishments upon those who shall con-
tinue in their unbelief, and resist unto the end his di-
vine succours; so that election is conditional, and re-
probation, in like manner, the result of foreseen infide-
licity and persevering wickedness. 2. That Jesus Christ,
by his sufferings and death, has made an atonement for
the sins of all mankind in general, and of every individ-
ual in particular: but that none, excepting those who
believe in him, can be partakers of this divine benefic.
3. That true faith cannot proceed from the exercise of

Arminian.
our natural faculties and powers, nor from the force and operation of free will; since man, in consequence of his natural conception, is incapable either of thinking or of doing any good thing; and that therefore it is necessary to his conversion and salvation, that he be regenerated and renewed by the operation of the Holy Ghost, which is the gift of God, through Jesus Christ.

4. That this divine grace, or energy of the Holy Ghost, which heals the disorder of our corrupted nature, begins, advances, and brings to perfection, every thing that can be called good in man; and that, consequently, all good works, without exception, are to be attributed to God alone, and to the operation of his grace: that, nevertheless, this grace does not force the man to act against his inclination, but may be resisted and rendered ineffectual, by the perverse will of the impenitent sinner.

5. That they who are united to Christ by faith are furnished with abundant strength, and with success sufficient to enable them to triumph over the seductions of Satan and the allurements of the world; but that the question, "Whether such may fall from their faith, and forfeit finally this state of grace?" has not yet been resolved with sufficient perspicuity; and must therefore be yet more carefully examined by an attentive study of what the holy scriptures have declared, in relation to this important point. This is the fifth article as it was originally propounded by Simon Episcopius and the other Arminians in the Synod of Dort. "It is to be observed, however," says Mosheim with regard to this article, "that it was afterwards changed by the Arminians, who in process of time declared their sentiments with less caution, and positively affirmed, that the saints might fall away from a state of grace. For a full account of the Arminian controversy, the reader may consult the works of Arminius himself, together with those of Episcopius and Grotius, Brandt's History of the Reformation in the United Provinces, vol. ii. and iii.; Whitley's Treatise on the Five Arminian Points; and a work of great pretensions, lately set forth by Dr Tomline, Bishop of Lincoln. On the other hand, may consult the volumes of Calvin and Gill, and a very profound and masterly Treatise on Free-will, by the celebrated Dr Jonathan Edwards of America.

Conclusion.

In a work like the present, the article Ecclesiastical History must, of course, be a very general one. Having, therefore, now given a short account of the most important controversies which have been agitated among the Protestants since the time of Luther to the present day, we shall bring our labours to a close. And in looking around us, we cannot contemplate the existing state of Christianity without the sincerest emotions of gratitude and joy. Not many years ago, the security of our holy religion was shaken by the torrent of infidelity, which threatened to overspread, with its mighty force, every country of Christendom. The fanaticism which prevailed, had its origin in France. In this unhappy kingdom, the superstitions of Rome had been so confounded with genuine Christianity, that they were completely identified in the estimation of the people. An erring philosophy, that failed to distinguish between things unquestionably different, had gained possession of the public mind; the chief authority was put into the hands of the multitude, ever captivated with the novelty and the acquisition of power, and ever ready to abuse it; the whole system of Christianity was ferociously overthrown; the observance of the Sabbath was abolished:—the human understanding seemed to be perverted beyond the hope or the possibility of recovery, and the human character, as exemplified among the revolutionists of France, appeared to become every day, more and more degraded and brutal. The convulsions of the state kept pace with the downfall of the church. The madness heightened, and was exasperated; the hearts of men, who looked on and witnessed the scene, failed them through fear: other nations felt the shock of dissolving empire, or were engulfed in its ruins. But better days have at length arrived. The contending elements have found their balance and their proper place. We rejoice in the cessation of a protracted warfare, and would record in our pages too, and with no little or feigned satisfaction, that the captains and the mighty men have met together, each of them with "the green branch" in his hand. A reputable, and, as we trust, a permanent peace has at last been attained. But we know not ourselves at all, if this be the only cause of our joy. The human mind has returned to a sense of religion, and the acknowledgment of a God. The throne of the Redeemer has again been erected. From England a light is gone forth which shall illuminate the most distant lands. Christian benevolence has multiplied her children. A society has been formed and established for the printing and the circulation of the holy scriptures; differences are laid aside, dissensions are forgotten; the lofty churchman unites with the humble Presbyterian, or still humberl Methodist; one feeling bounds in every breast, and every prayer which is breathed to heaven is breathed for the accomplishment of the prophecy, which assures us, "that the knowledge of the Lord shall cover the earth as the waters cover the sea." In point of fact, this prophecy, through the exertions of the British and Foreign Bible Society, has already, in part, been fulfilled: and it is now true with a peculiar significance in the statement, and extent in the application of the language, "that the heathen is given" to Christ Jesus "for his inheritance, and the uttermost parts of the earth for a possession." See Mosheim's Ecclesiastical History, passim; Lardner's Works, passim; Du Pin's Church History; Campbell's Lectures on Ecclesiastical History; Histoire Ecclesiastique par Fléury, edit. Bruxelle; Father Paul Sam's History of the Council of Trent, translated from the Italian into French by De la Houssaye; Jortin's Remarks on Ecclesiastical History; Neal's History of the Puritans; M'Crie's Life of John Knox; and Reports of the British and Foreign Bible Society, passim. ECHINUS. See MOLLUSCA.

ECHO, from the Greek word σφων, a sound. In the article Acoustics, we have already treated the subject of echoes, as connected with the general doctrines of sound, having reserved for the present article, brief notices of some of the most celebrated echoes.

Dr Plot, in his Natural History of Oxfordshire, mentions an echo in Woodstock Park, in Oxfordshire, which repeats 17 syllables in the day-time, and 20 in the night. This effect he ascribes to the superior density of the air during the night, which diminishes the velocity of the sound.

Harris describes an echo on the north side of Shipley church, in Sussex, as repeating 21 syllables distinctly, under favourable circumstances.

Dr Birch informs us, that there was an echo at Rosebank, in Argyllshire, in Scotland, which distinctly repeated, three times, a tune played on a trumpet. When a person, placed at a proper distance, plays eight or ten notes, they are correctly repeated, but a third lower; after a short silence, another repetition is heard, in a still lower tone; and, after another short interval, there is a third repetition, in a still lower tone.
Addison describes an echo at the palace of Simonetta, near Milan, as returning the sound of a pistol 56 times. The palace has two wings; and, when a pistol is fired from a window in one of the wings, the sound is reflected from a dead wall in the other wing, and is heard from a window in the back front. The following account of it, however, from Keysler, is more minute and interesting.

"At the Marquis Simonetta's villa is a very extraordinary echo; it is occasioned by the reflection of the voice between the opposite parallel wings of the building, which are fifty-eight common places from each other, and without any windows or doors, by which the sound might be dissipated or lost. The repetition of the sound dwells chiefly on the last syllable, which might have been altered by allowing a greater distance between the two wings; but possibly it was apprehended, that the number of the repetitions would be diminished by that means. Two or more bodies placed opposite each other, at different distances, are requisite to form a multiplied echo; or the wall at which the speaker stands, must have another wall opposite to it, so as to form two parallel planes, which will alternately reflect to each other the sound communicated to them, with as little dissipation as possible. This last circumstance is found in the two parallel wings of this seat, which, forming right angles with the main body of the building, have a very surprising effect. A man's voice is repeated above forty times, and the report of a pistol above sixty, by this echo: but the repetition is so quick, that it is difficult to tell them, or even to mark them down, unless it be early in the morning, or in a calm still evening: when the air is rather too moist or too dry, the effect is found not to answer so well."

Southwell mentions a building, similar to the palace of Simonetta, which had projecting wings, and produced 60 repetitions of every sound.

The Abbé Guynet describes an echo on the road from Rochepot to Chalons, which repeats, in the day-time, 14 syllables well articulated, and, during the night, 16 syllables.

About three leagues from Verdun, there is a singular echo, occasioned by two towers projecting from the body of a house, and distant 26 toises, or about 50 metres. When a person stands in the line between the two towers, and pronounces a word in a pretty high tone, he will hear it repeated 12 or 13 times at equal intervals, and always more feebly. If he places himself at a certain distance out of this line, the echo is no longer heard. One of these towers has a low apartment vaulted with hewn stone, while the other has its vestibule vaulted. See Hist. Acad. Par. 1710.

In the Memoirs of the French Academy of Sciences for 1792, there is described a curious echo, at Genefay; in the neighbourhood of Rouen. A person who sings, does not hear the repetition of the echo, but merely his own voice; whilst those who listen hear only the repetition of the echo, though with singular variations. Sometimes the echo seems to approach, and at other times to recede. One person hears a single voice, and another several voices: one person hears the echo on the right, and another on the left; the echo always varying with the position of the person who hears it.

M. Quesset has described another singular echo near Rouen, in the Memoirs of the Academy for 1664.

In the neighbourhood of Coblenz, on the banks of the Rhine, there is a very remarkable echo, which is described by Barthius, in his notes upon the Thebaid of Statius. He has heard it repeat words seventeen times, and it produces exactly the same effects as that at Genefay, near Rouen.

At Lochielair, a lake in Inverness-shire, and the property of J. P. Grant, Esq. of Ruthemuckethrach, there is a very fine echo. The wall of an old castle, in the middle of the lake, repeats several syllables with great distinctness; and when a pistol is fired, the sound is repeated about thirty times, from the numerous and lofty hills with which the lake is circled.

In the neighbourhood of Edinburgh, in the King's Park, there is a place called the Echoing Rock. A person standing in front of this, will hear repeated with great distinctness several syllables which he may utter. The sound is in this case reflected from a circular wall at a great distance, and the rock to which the property is ascribed merely happens to be near the centre of the circular wall.

In erecting the baptistery of the church of Pisa, the architect, Giovanni Pisano, disposed the concavity of the cupula in such a manner, that any noise from below is followed with a very loud and long double echo. The repetition, however, is not so distinct as that of Simonetta. Two persons whispering, and standing opposite to each other, with their faces near the wall, can converse together without being overheard by the company between. This arises from the elliptical form of the cupula, each person being placed in the focus of the ellipse.

In the cathedral church of Gloucester, there is a whispering gallery above the eastern extremity of the choir, and which extends from one end of the church to the other. If two persons, placed at the distance of 22 toises, speak to one another in the lowest voice, it is distinctly heard. A similar effect is produced in the vestibule of the Observatory of Paris, and in the cupola of St Paul's in London. Mr Southwell informs us, that, in Italy, on the way to Naples, and two days journey from Rome, he saw in an inn, a square vault, where a whisper could easily be heard at the opposite corner; but not at all on the side corner that was near to you. This property was common to each corner of the room. He saw another on the way from Paris to Lyons, in the porch of a common inn, which had a round vault. When any person held his mouth to the side of the wall, several persons could hear his whisper on the opposite side.

ECLECTICS, a name given to certain ancient philosophers, who endeavoured to form a system of opinions by selecting from every sect those doctrines which seemed to approach nearest to the truth. Hence their denomination, derived from 

"Echo," as "I choose," may be considered as referring either to themselves or their tenets; and may signify either "one that chooses," or "that which may be chosen." They were also denominised "philologici," but generally called themselves "philosophers," i.e. "lovers of truth," or rather never assumed any distinct name, but wished to be considered as chiefy followers of Plato, whose philosophy they made the foundation of their system. The notion of such a philosophical selection had been adopted by several of the leaders among the Grecian sects, even by Plato, Zeno, and Aristotle; had been sufficiently con-
mon among the Alexandrian philosophers, from the commencement of their schools, had particularly prevailed, (as appears from Philo, who was himself an eclectic,) about the beginning of the Christian era; and was followed, in a later period, by Plutarch, Pliny, Galen, and many others. Between the endless contests of the dogmatists, and the dark uncertainty of the sceptics, it was by no means an irrational scheme to separate from every former system its purest and best supported tenets, and to form them into a new institute of philosophical and religious truth. The idea was peculiarly acceptable to those Heathen philosophers, who felt the growing ascendency of Christianity; and who endeavoured to support the declining influence of their own schools, by incorporating Christian principles into their new system. The first, however, who attempted to establish a distinct sect upon this scheme, appears to have been Ptolemaeus of Alexandria, who is supposed by some to have flourished during the reigns of Augustus and Tiberius; but, according to others, about the close of the second century. Nothing more is known of his system, but that he endeavoured to reconcile the tenets of Plato with those of other philosophers; and it is generally concluded, that his attempt to found a school upon the eclectic principle proved unsuccessful. The eclectic philosophy received its proper form and establishment from Ammonius, another philosopher of Alexandria, who flourished about the beginning of the third century, and who, from his former profession of a porter, (εστρωτης) was surnamed Sacca. (See Ammonius.) This philosopher, however, and his followers, ought properly to be considered, like their precursor Ptolemaeus, as merely modern Platonists; and there is a gross impropriety in giving them the name of eclectics. Instead of selecting a little from each, he professed to unite all sects in one. He maintained, that the great principles of philosophic and religious truth were to be found equally in all the different systems; that they differed from each other only in their method of expressing their tenets, except a few points of minor importance; and that, by a proper interpretation of their respective sentiments, they might easily be united into one body. He considered the ancient philosophy of the East, preserved in his opinion uncorrupted by Plato, as the primitive standard, and actual substance, of all the religious systems in the world; and affirmed, that to remove the errors which in all nations had been more or less blended with this ancient theology, and thus to restore them to their original purity, was the great design of Jesus Christ in descending upon earth. Upon this principle, as all the sects were fundamentally right, there was no occasion to select any thing from each; and it was even of little consequence which of them was chosen, as the enquirer, by merely removing the supervening errors, was sure to find in any one of them the true doctrine at the bottom. As Ammonius left no writings of his own, and as he taught his more sublime mysteries only to a few select disciples, under a solemn injunction of secrecy, it is scarcely possible to ascertain what he considered as the original and uncorrupted system of truth; and though several of his followers afterwards divulged the secrets of his school, their expositions are so full of obscurity, and so mixed with dogmas of their own, that the real system of their founder cannot be separated with any degree of certainty from so confused a mass. The leading object of the whole was to obstruct the progress of the Christian religion, by forming such a combination of the principal tenets of the Heathen and Christian schools, as might confirm the former in their attachment to the old superstitions, and reconcile the latter to the doctrines of Paganism. Hence, on the one hand, they represented Jesus Christ as the friend of God, who came not to abolish, but to purify the ancient religions; incorporated into their system many of the peculiar doctrines of revelation, and even adopted, on many occasions, the language of the Christian Fathers. On the other hand, they endeavoured to conceal the absurdities of Paganism under the veil of allegory; and represented the numerous train of Heathen divinities, as celestial ministers emanating from the Supreme Deity, who was himself worshipped in the adoration which they received. The philosophy of Plato, already united with that of Pythagoras, formed the basis of the new system; and with these doctrines they attempted to blend those of Aristotle, of the Stoics, and of almost every system except that of Epicurus, whose mechanical principles of nature could never be made to coalesce with the doctrines of Platonism. Not satisfied with the intuitive contemplation of intelligibles, and especially of the first intelligence, which Plato posited as the summit of human felicity, they aspired after a sort of deification of the human mind; adopted from the Oriental philosophy the system of emanation, one of an indefinite series of spiritual natures derived from the supreme source; and, besides supposing, that the soul of man, by various stages of purification, might at length reach a mysterious union with the divine nature, they conceived, that, even in this life, it might be prepared, by previous discipline, to enjoy, in ecstasy, an intuitive vision of the Deity. Upon such fanciful foundations, they constructed systems of metaphysics, morals, and theology, of which it is impossible to convey any intelligible idea, and which indeed seem never to have been properly fixed or defined in the minds of their authors. Their great principle, also, of producing an apparent harmony among systems essentially different, necessarily compelled them to have recourse to vague expressions, fanciful interpretations, and subtle distinctions, till they at length involved themselves and their readers in endless subtleties and impenetrable obscurity.

After the death of Ammonius, the system was completed by his disciple and successor Plotinus; taught also by Porphyry, and Jamblichus; adopted by Longinus, Eustathius, Julian the apostate, Hecules, Chrysanthus, &c. In the reign of Julian, it was publicly professed at Athens, and, by the emperor's appointment, was taught there by Chrysanthus last mentioned, who was succeeded by Plutarch the son of Nestorius, Syrian, Proclus, Marinus, Isidorus, Zenodotus, &c. It was supported by the celebrated Hypatia, Macrobius, Ammonius Marcellinus, &c, but expired among the Pagans in the 7th century. It received, even from its commencement, the approbation of many eminent teachers among the Christians, especially Athenagoras, Panteus, and Clemens Alexandrinus; and became, through many succeeding ages, a fruitful source of confusion and corruption in the church of Christ. But, in the course of the 17th century, arose the true eclectic philosophy, which admits of no sectarian subdivisions, rejects prejudices of every description, renounces all submission to celebrated names or ancient sects, subjects the opinions of all former philosophers to the strict scrutiny of reason, and admits no conclusions but what may be clearly deduced from principles founded on the nature of things, or discovered by actual experience. Of this method, the principal promoters were Bacon, De Cartes, Leibnitz, Malebranche, Locke, Grotius, Selden, Pufendorf, Copernicus, Kepler, Galileo, Boyle,

328

The Eddystone rocks consist of three principal ridges, which have been distinguished by the relative names of House Reef, South Reef, and East Reef. These rocks, in their greatest extent, lie north and south, and in this direction measure about 600 or 700 feet in length; besides a small rock, seen only in spring tides, called the north east rock, which lies about one thousand feet from the house rock. From the general aspect and appearance of the Eddystone rocks, there is reason to infer that the whole consists of the same kind of stone. The state of the weather did not admit of the writer of this article touching at any of the rocks excepting that on which the lighthouse is built, which he the more regrets, as, from the smallness of the house rock, it would be a kind of sacrilege to mutilate it by breaking off specimens, so that he was left to judge imperfectly of its composition from parts which were worn by the feet of the light keepers. It seems to be either granite or gneiss, called moulstone in Cornwall. The felspar is most abundant in it, and is chiefly of a brownish colour, containing large irregularly shaped white specks. It dips in generally at the rate of one perpendicular to two horizontal, is extremely hard, and has a very rugged appearance. Its greatest horizontal dimensions at low water is about 65 feet, and its least about 35 feet. On the eastern side it is perpendicular to the surface of the water, and at one place may be said rather to over-hang, where the top of the rock is elevated about 18 feet above low water mark of spring tides, and is therefore seldom covered by the rise of the tide, but on the western side it slopes towards low water mark. The lighthouse is of difficult access on all sides, and can only be approached in moderate weather. The gut, or landing place, is formed by the house reef, and the south reef, which afford some shelter for a boat at low water. In this gut there is about one fathom of water at the lowest tides, but in all directions from the rocks the water suddenly deepens to 15 and 20 fathoms, and at greater distances to 45 and 50 fathoms.

On the days of new and full moon, it is high water at the Eddystone at a quarter past five o'clock. The tide of flood sets easterly, or up Channel, and the ebb tide sets westerly. Spring tides rise from 16 to 18 feet, and neap tides from 10 to 11 feet; but in storms, the sea at this place flies to an incredible height. At these rocks, and upon the opposite shores, it is high water about two hours and a half sooner than in the middle of the channel.

The nature of the stone, and the small dimensions of the house rock, are adverse to the growth of marine fungi, or to the habitation of animals. Of the former, only the smaller sorts of sea-weed were observed, as fucus mamilla-losus, fucus palmatus, the common dulse, and conof-a rupestris, which, in continued storms, appears to acquire a growth upon the western side of the lighthouse, about 20 feet upon the building. The only shell-fish seem to be the lepas balanoides, or barnacle, and a few limpets of a small size: these last might perhaps increase both in number and in bulk, were they not apt to be destroyed for bait before they are matured in growth. In very moderate weather, a few young coal fish are caught by the light keepers, and, in the vicinity of the rock, the fish common upon the coasts of Cornwall and Devonshire, are caught in abundance, as hake, John Dorie, cod, conger, cef, dog-fish, haddock, whiting, skate, turbot, holibut, flounder, sole, mackerel, herring, and pilchard. (s)

EDGAR. See ENGLAND.
EDINBURGH.

EDINBURGH, the metropolis of Scotland, is situated in the northern part of the county of the same name, or Mid-Lothian. The centre of the city lies in 55° 57' 58" north latitude, 8° 11' 55" west longitude, and is about two miles from the estuary called the Firth of Forth, where, in Leith harbour, the tide rises nearly 16 feet. But intermediate buildings, which are rapidly increasing, will soon identify Edinburgh with the town of Leith; and, in general calculations, they are even now included together. The following observations, however, are restricted to the former.

The length of Edinburgh, from east to west, is between a mile and a half and two miles; the breadth is about the same; and the circuit is calculated at eight miles. Its general site may be described as on elevations; the centre of the city standing on a high narrow ridge, declining towards the east, from a lofty precipitous rock, on each side of which are two valleys, one entirely occupied by buildings, the other partly so, and chiefly consisting of a marsh, nearly dry in summer. This marsh, which is 200 feet below the top of the rock, is crossed by a bridge 1270 feet long, of five arches; by an immense earthen mound of great breadth and depth; and also by an intermediate mound of smaller dimensions, all to the north. The buildings to the south of the city, independently of other communications, are connected by another bridge of 22 arches, one with more level ground, on which the city is extended. Only one of these arches, 30 feet wide, is visible; the rest being fronted by houses, of which they form a part. The span of the larger arches of the first, or North Bridge, is 72 feet, and the height to the top of the parapet 68; but the arches and piers occupy only 310 feet of the whole 1270, which partly form a street. From thence, the city, to the north, occupies a slight elevation, which soon becomes a gradual declivity down to the sea. Edinburgh is thus divided, by the North Bridge and Earthen Mounds, into two parts, known by the distinguishing apppellations of the Old and New Town: the former has been built from all different periods down to the present day, with little order or regularity; but the latter, being altogether of modern erection, and formed after a certain determinate plan, exhibits an elegant assemblage of edifices, disposed in ample streets and spacious squares. This portion of the city is the residence of the better class of inhabitants, though not exclusively; for some part of the old town, to the south, also consists of modern buildings, equally commodious.

The two principal streets in the Old Town intersect each other at right angles: first, the High Street, which stretches from the castle to the abbey, 5570 feet, under different names; and, secondly, a street, commencing at the Register Office, and terminating in St Patrick's Square, after also passing by different names, of nearly the same extent. From the High Street, which occupies the elevated ridge, numerous lanes diverge on either side down the declivity; and some are so steep as to require steps for the security of passengers. There are three principal streets in the New Town: Prince's Street, George's Street, and Queen's Street uniting with York Place. The first is 4110 feet long by 100 broad; the second 2640 by 115; and the third, 4440 by 100. These principal streets, and others which, now in progress, will soon merit the same denomination, are intersected at right angles in several places, by wide cross streets. George's Street terminates in a square at either extremity; and there are on each side two subordinate parallel streets, Rose Street and Thistle Street, 30 feet in width, and extending half a mile.

There are few squares in this city, considering its magnitude; and of these, the principal are, George's Square, in the Old Town, which measures 665 feet by 510; and St Andrew's and Charlotte Square in the New Town. There are several, however, such as St James's, St Patrick's, and Nicholson's square, of smaller dimensions; but the inequality of the ground, the width of the streets, and the salubrity of the atmosphere, render the want of squares a less sensible defect. From many points of the city, the most varied and delightful prospect is commanded, either in ranges of hills, distant mountains, or verdant fields, bounded by a beautiful river, which is traversed by numerous vessels.

Almost the whole city is built of fair hewn stone, buildings from inexhaustible quarries in the neighbourhood; and the houses are covered with slates. The New Town is invariably so; and the front of all the buildings in the principal and cross streets are fenced with neat iron railing. Here they are less commodious than the exterior would indicate; but the high price of ground-rent obliges the architect to seek that accommodation in altitude which would be more conveniently disposed in surface. Thus two stories are sometimes sunk below the level of the street. Ground-rents are in many places L. 10, L. 20, or even nearly L. 30, for the site of the house and a small plot behind it; and the price of the best houses is L. 2000, L. 3000, or L. 4000. The yearly rent of such is from L. 100 to L. 160, or more. In the Old Town, on the other hand, the houses being for the most part crowded together, their inhabitants are deprived of many conveniences found in more modern edifices. Frequently they rise to a great height, being five, six, or seven stories from the street; and there are even instances of some houses consisting, on one side, of eleven or fourteen stories, each of which is inhabited by a different family. But this uncommon structure is owing to the sudden declivity of the bank on which they are founded.

Edinburgh is a remarkably beautiful city, not only from its situation, but from the width of the streets, particularly of the modern part, the regularity of architecture, and the colour of the stone employed in the buildings. Nor is its general appearance less singular, from lofty edifices on a high ridge, overlooking those which occupy the lower grounds; from the two bridges, without water to either; and the immense mound connecting the different divisions of the city. The magnitude of this may truly be the subject of admiration, especially considering the few years in which it has been produced. The Earthen Mound is 960 feet in length, 188 feet broad at the first opening to the north in the wall traversing it; and, at the same place, about 100 in perpendicular height, but somewhat more at the opposite extremity. It is composed almost entirely of the rubbish excavated from the foundation of the houses.
in the New Town, since the year 1783. An enormous quantity of earth has sunk into the marsh below, and the whole is still yielding, from the accumulated pressure.

The most striking object, on approaching this city, is the Castle, perched on a lofty isolated rock, elevated on three sides from a level plain. Part of it, especially on the north, is absolutely perpendicular, or somewhat overhanging the base, to the height of 150 or 200 feet; but to render the rest still more inaccessible, we read, that the governor who held it for the adherents of Mary, took pains to "pare away the green grass" that had taken a slender root in the fissures of the rock. Of old, the castle was certainly a place of great strength, and it has stood many tedious sieges; but, being commanded by ground within the range of artillery, its importance in modern warfare is much diminished. Etymologists have found equal difficulty in the derivation of Castrum Alatum, the Maiden Castle, or Edinburgh; but it seems more generally admitted to have been from Edwin, the Northumbrian potentate, in the seventh century; and that the town, gradually seeking protection under its walls, thence received the name of Edwinesburg, by which it was anciently known. The castle is now separated from the city by a vacant regular acclivity, 350 feet long, and nearly as broad, which has lately been supported by a strong wall, sunk several feet below the level. Its entrance is by a draw-bridge, which is raised every night, over a wide dry ditch, and guarded by strong palisades without, where the heaviest ordinance on the batteries may be pointed. Different gates within open into a winding way, which ascends to various edifices, for stores, barracks, or other purposes; and the grooves, from which two portcullises descended, still denote the obstacles opposed to an assailing enemy. The surface of the rock, extending to six or seven acres, is disposed in batteries, or for the accommodation of troops, and what is requisite for a garrison; and the highest part, up long flights of stairs, consists of a square, which is used as a parade. A circular draw-well is on the higher part of the castle, but as the water recedes with the firing of cannon, it becomes a precarious resource: and there are instances of the besieged being obliged to resort to a well without the ramparts, which, on one occasion, an enemy poisoned, and thus forced them to surrender. To supply this defect, a capacious cistern has been erected, which is filled by pipes brought into the castle from a reservoir at a distance. There are numerous cannon on the walls, whose signals have long been devoted to festivities only; and there is a small armoury, which, when full, can contain 30,000 stand of arms. It is said that 3000 men can be accommodated in the castle: Part of the barracks are of recent erection, and by an injudicious and inconsistent style of architecture, have materially impaired the grand and imposing aspect which this fortress presented. King James the Sixth of Scotland, under whom the island of Britain became one empire, was born here in a small square apartment in the south-east part of the castle. The date of his birth is painted on the wall, also the royal arms of Scotland in good preservation, and some indifferent verses written under them. In a late examination, no date older than 1565 could any where be observed. At the time of the Union, the Scotch regalia were deposited with much solemnity in a room with strong grated windows; and the door, which enters from a stair-case, is also strongly secured, though not built up. Whether they still remain is uncertain; but most probably prudential reasons have long ago led to their destruction or removal. They were too dangerous insignia of royalty to lie within the reach of the dissatisfied during the rebellions of the preceding century. Towards its close, however, a vague report having arisen, that some of the records of the kingdom were contained in the same room, a warrant to search it was issued from the office of the secretary of state, addressed to several individuals holding high official situations here. Nothing was found but an old chest covered with dust; and doubts being started by one of the deputation, whether the words of the warrant contained authority to go farther than simple inspection of the room, the search was abandoned, and an opportunity of ascertaining the fact, not likely to recur, was lost.

The history of the castle of Edinburgh would be an abbreviated history of the kingdom. Contending factions anxiously sought possession of it, and its fall was usually followed by that of the metropolis. Of old it was a royal residence, more particularly in those unsettled periods, when strength constituted the chief security of individuals.

The Abbey of Holyrood, however, at the opposite extremity of the city, was the principal abode of the kings of Scotland for several centuries preceding the union of the crowns; even during the rebellion, it was occupied by the last descendant of the Stuarts; but it has never been visited by any sovereign of the house of Hanover. This abbey was originally founded in 1128 by David I. in commemoration of his escape from danger, while hunting in the neighbouring forests, and endowed with ample revenues. But we know that he dwelt in the castle, and that it was not until the time of his successor James V. in the sixteenth century, that adjoining buildings rendered it a royal palace. Only the walls of the abbey remain: the eastern window, which was an elegant remnant of Gothic architecture, yielded to an extraordinary tempest in the year 1795. The remainder has long been in a state of progressive decay. James VI. is said to have repaired and embellished the church, at the same time providing it with an organ, a throne for the sovereign, and twelve stalls for the knights of the thistle. But the mob, in abhorrence of popery, immediately afterwards broke in, and, in the fervour of their zeal, committed greater devastation than was wont to be done by a public enemy. Their ravages being repaired at a considerable interval, a new roof of ponderous flag-stones was raised upon the walls, which speedily appeared very insufficient to bear it. The impending danger was communicated to the Barons of Exchequer, but no measures having been taken to prevent it, the roof fell in during the year 1768, since which time the abbey itself has been a total ruin. It was the royal cemetery of old, and also a place of sepulture for distinguished persons. James V., his queen, and several of their children and successors, were entombed here. A vault, containing the body of the king, was visited by some curious and intelligent persons, in the year 1688, when they found it coloured black, from the balsam in the coffin resembling melted pitch. He died in the year 1542, but hair still seemed to be on the head. There was also a coffin containing the body of Queen Margaret, who died immediately on landing in Scotland in 1537. That of James was in wood, encircled by another coffin of lead. But when the roof fell in 1768, the sepulchres were violated, and the chapel again ransacked by the mob. Arnot in his History relates, that between the years 1776 and 1779, the leaden coffin of James V. and some others, were stra-
The head of Queen Magdalen, which was then entire, and even beautiful, and the skull of Darnley, were also stolen. Several bones of enormous size, reputed to be those of this nobleman, the husband of Mary, were lately exhibited, as also a body called that of a Countess of Roxburgh, converted to a mummy. The entrance to the vault containing these relics, was built up within these few years, so that the dead can be disturbed no longer. Most of the area of the church is now covered with rubbish; but on examining parts of the pavement, figured stones, with inscriptions of considerable antiquity, may be discovered. It is still used, though on rare occasions, for the sepultures of different families and their connections. On the exterior, two coats armorial with supporters of great antiquity, are visible, though much defaced by time.

The palace itself is a large quadrangular edifice of hewn stone, with a court within, surrounded by a piazza. The west front, which extends 230 feet in length, consists of two lofty double circular towers at each angle, connected by a lower building, ornamented above by a double balustrade; and in the centre is a porch, which is the principal entrance, with stone columns, "supporting a cupola in form of an imperial crown." Above the entrance are the arms of Scotland, as borne previous to the Union; and within are the same arms as borne after it. A small garden is before the east front, which is of modern architecture.

In this palace, there is a gallery 150 feet long, by 27½ wide, and 18 feet high, containing portraits of all the Scottish kings, from the reputed time of Fergus. But few or none are genuine, although some may be copies of originals; and we are told that a Dutch artist, named De Witt, was employed to make the collection. A great desire that the nation should remount to extraordinary antiquity, has always prevailed in Scotland; and it appears that, amidst the pageantry exhibited to Charles I. by the University of Edinburgh in 1633, at his public entry, there were portraits of 109 kings in Scotland: the number in Holyroodhouse is said to be only 111. Mercury was there represented bringing up Fergus I. in suitable attire, "who delivered to his Majesty a very grave speech, containing many precious advices to his royal successor." This gallery is now used at the election of the sixteen peers of Scotland to represent their order in Parliament; and during the residence of the princes of the house of Bourbon and the French noblesse, mass was sometimes performed in it. There are some other pictures in the palace, particularly one of Charles I. and his Queen, and several old portraits. The bed-chamber occupied by the unfortunate Mary, with her own bed, now advancing to decay, are still to be seen; also a cabinet where her secretary, David Rizzio, was seized in her presence, dragged forth, and assassinated. The credulous are taught to believe that his blood yet stains the floor of the adjoining apartment.

The Duke of Hamilton, who is heritable keeper of the palace, has a considerable part of it allotted for his accommodation, and it is now occupied by his family. Other noblemen have suites of apartments, and also different persons who have interest to procure a dwelling here. A large portion of the whole underwent complete repair about twenty years ago, when the French princes sought an asylum in it after the revolution.

The precincts of Holyrood-house, embracing a circuit of about three miles, including the King's Park, Arthur's Seat, and Salisbury Craig, afford a sanctuary to debtors. Thus there are constantly a number of persons either insolvent, or who have experienced sudden reverses, who hope to retrieve, resident in houses of mean appearance within the boundary. A jurisdiction is exercised over them by an officer, called the bailie of the abbey, who is always appointed from some of the law department; and there is a prison pertaining to the abbey, in which they may be confined for debts contracted there, or offences against the inhabitants. The privilege of sanctuary is strictly limited to civil debts. No protection is afforded for breaches of the peace, or crimes of any description. There is a similar sanctuary in Edinburgh, within the precincts formerly appropriated for the royal mint; but here the period of protection from arrest is understood to subsist only during 24 hours.

The situation of no two edifices in the same city can be more opposite than that of the castle and the abbey; the one on a high precipitous insulated rock, the other on a plain, surrounded in a manner by hills: yet they are equally picturesque, equally denoting their respective purposes of strength for warfare, and retirement for tranquillity.

The metropolitan church is dedicated to St Giles; but history has not preserved the reasons which induced the citizens to choose a Saint of Greek extraction for their patron. Nevertheless, he was held in high veneration; and a person of some consequence, who, in the fifteenth century, presented a relic, part of his arm, to the community, was rewarded with the privilege of bearing it at all public processions. But so versatile are the opinions of men, that the safety of the city was endangered in the subsequent century by the anxiety of the multitude to tear the picture of their tutelar saint from the standards, and demolish his image wherever it could be found. All the relics, the sacred utensils of gold and silver belonging to the church, and the rich vestments of velvet and brocade, serving for the priesthood, were then seized on, and sold for the public behoof. This church is an ancient Gothic building, known to have stood since the fourteenth century, and now forms the north side of the Parliament-square. The dimensions of the fabric are 206 feet in length, 110 feet broad at the west end, 75 at the east, and 123 in the middle. A square tower rises from the centre, surrounded by intersecting arches, forming an imperial crown, with pinnacles from the curvatures, and a spire above the whole, 101 feet in height. Four separate places of worship are contained within, which go by different names, but the eastern is the largest, and best deserving attention, consisting of cloisters with high pointed arches, and a lofty roof. Rude monumental sculptures, almost effaced, may be seen on the pavement below, and on the roof inscriptions of considerable antiquity at the junction of the arches. Here there is a seat for the royal family, which is occupied by the commissioner to the General Assembly of the Church of Scotland, as representing the king. The judges of the Court of Session, the barons of Exchequer, and the magistrates of the city, also sit here, where they appear with their insignia of office. James Earl of Murray, Regent of Scotland, who zealously promoted the Reformation, is entombed within the walls of the church; and also Napier of Merchiston, the celebrated inventor of logarithms. In common with other sacred edifices, it was formerly used as a cemetery, and whole cart loads of bones, disturbed by the successive repartitions which the church fabric has undergone, have been removed to other places of repose. Around it also was a burying-ground,
in which the remains of John Knox, the great Scottish reformer, were deposited.

In the steeple of St Giles, there is a set of music bells, or carillons, which are played during an hour every forenoon; and a family performing the ordinary office of beadle, finds a dwelling somewhere in the recesses on the top of the church.

An aisle of this building is appropriated for the use of the General Assembly, which meets a few days in the month of May; other parts are devoted to a police office, and the accommodation of a sergeant's guard. Its uniformity is greatly impaired by every successive alteration; as in one place is to be seen an attempt to restore or preserve the original architecture, which in another undergoes partial demolition; while a third presents what is altogether discordant with both.

The church of St Giles became a cathedral in 1633, on the restoration of Episcopacy, when Edinburgh was first constituted a bishop's see.

Another church, of which the history can be better traced, was founded by Mary of Gueldres, widow of James II., soon after his decease, and is called the Trinity College Church. It occupies part of the valley on the north of the city, and although unfinished, is an edifice of the most genuine antiquity in Edinburgh. The original object of the pious founder was to endow a collegiate church for "a provost, eight chaplains, two boys; as also an hospital for the maintenance of thirteen paupers, and two clerks, who should be subservient to the direction of the provost." The interior now presents a dull and gloomy aspect: it contains no striking monument of antiquity; and although the foundress lies interred in one of the aisles, her place of sepulture is unmarked by any memorial. The hospital which stood south-east of the church having become ruinous, was transferred to a more convenient situation.

There are no other ancient churches now extant in Edinburgh, of many that were once devoted to religious purposes. Perhaps the oldest of all was St Cuthbert's, near the base of the castle rock, which is mentioned in the earliest records; but it was renewed a few years ago, in a plain modern building, capable of containing a large congregation, and decorated with a spire. It stands on very low ground, amidst an extensive cemetery.

The churches of older erection in the city are the Greyfriars, Canongate, and Tron Church. The first of these stands near a spot that was the site of a monastery of the same name, and contains two places of worship under one roof. A cemetery, equally extensive as the former, environs it, wherein are many monuments, recording the existence of celebrated characters. Although this cemetery was probably used as such by the monks, it was not appropriated to receive the bodies of deceased citizens until the year 1561; and about 1612, the church called Old Greyfriars was erected. The New Greyfriars church adjoining, was built in 1721. Most of the children maintained in public hospitals sit in these churches, under the care of their respective instructors.

In the earlier part of the 17th century, a fund seems to have been raised by voluntary contribution, for the purpose of erecting a church dedicated to Christ, which was founded near the castle, on the site of the present reservoir. But soon afterwards, the materials were transferred to a more convenient situation, and what is now called the Tron Church, founded in 1637. In the year 1614, 16,000 pounds of copper were purchased in Holland to cover the roof; but this design being altered, lead and slates were substituted in its place. The whole exterior was lately renewed, and is at present a neat plain edifice, with a steeple and a clock. It appears that, in 1641, it was dedicated to Christ and the church, by the citizens of Edinburgh.

In the year 1647, Margaret Ker, Lady Yester, daughter of Margaret, late wife of the first Earl of Lothian, founded a church, "erected a chapel in the same, which stands amidst a small cemetery, wherein patients dying in the infirmary are interred. The chapel in the abbey seems to have been resorted Canongate, subsequent to the Reformation in 1560, as a place of public worship. But when King James VII. restored it to its original purpose, for the exercise of the Roman Catholic religion, the Protestants were necessarily excluded. However, the inconvenience was not of long subsistence, for Thomas Moodie, a merchant of Edinburgh, having given £1100 sterling, to be employed in building a church, his design was carried into effect by the royal mandate in 1688, and the Canongate church erected. It is a heavy edifice, has the end fronting the street, and stands amidst a large cemetery.

There are two churches for the established religion, entirely of modern erection, in the New Town; the one dedicated to St Andrew; the other to St George. This relic of Papist superstition, the dedication of every new church to a saint, is singular in a country where nothing but strict Presbyterian forms are recognised by the legislature. The former, St Andrew's church, St Andrew's, is a plain building 87 feet by 64 feet, with a small spire, erected in 1688, and is in a good state of preservation. A handsome portico fronting the street, is supported by four columns of the Corinthian order, from which springs a spire, executed in good taste, 108 feet high. The church is lighted by two rows of windows, and a gallery runs along the upper part of the wall; but the extreme plainness of the whole, which is entirely void of relief or decoration, gives a mean aspect to an edifice which would otherwise have been both elegant and ornamental.

St George's church presents a front of 112 feet to St George's, Charlotte-square, with a portico, supported by four Ionic columns, 35 feet high, including the capitals. They are elevated on an extensive flight of steps, forming the entrance to the church, which is 128 feet in extreme width, and can accommodate 1600 persons. A great dome rises from a basement 48 feet square, behind the portico, above which is a circular row of columns, with their entablature and balustrade, surrounded by the upper compartments of the dome. The whole is crowned by a lantern, with a cross, 160 feet above the ground; and produces a fine effect when viewed from different parts of the city or the avenues approaching it. This church was erected at the expense of above £20,000, and opened for divine service on the 5th of June 1814.

These are the principal churches for exercise of the established religion. There are besides, in connection with the establishment, a chapel of ease, which stands amidst a small cemetery on the south side of the town, belonging to the parish of St Cuthbert's, and erected
Edinburgh. 333

Edinburgh, in 1757; another built by Lady Glenorchy in 1773; and two others connected with the Canongate.

A number of the citizens of Edinburgh are very imperfectly acquainted with the English language, from being Highlanders by birth. Those are chiefly among the lower ranks, and their usual communications are in Gaelic only. Two places are appropriated for public worship in that language; one near the Grassmarket, and the other close to the college.

Dissenting Chapels and Meeting-houses.

But many inhabitants of this city professing other modes of worship, there are various churches and chapels in different parts of the city for their accommodation. Of these, the chief for the Episcopalians is what is commonly called the Cowgate chapel, a plain building, which, though, in a very unfavourable situation, stands apart from other buildings. The dimensions without are 90 feet by 75. It has a good organ made by Snetzeler; some paintings; and is decorated with a steepel of moderate height, provided with a bell said to have formerly belonged to the chapel royal of Holyrood-house. It was founded in the year 1771. Another chapel, dedicated to St George, was built in Queen Street in 1794, after a design in Gothic architecture, by Mr Robert Adam; and Charlotte chapel, a building in which nothing but simplicity seems to have been studied, was still more recently erected in the vicinity of Charlotte Square. There are other three Episcopal chapels; one in Roxburgh Place, another in Blackfriars Wynd, and another in Carrubber's Close.

An elegant Roman Catholic chapel is nearly completed, in place of the one which was burnt in the year 1780. The purest Gothic architecture is studied here; the door enters by a pointed arch supported on columns, and the windows are also pointed above. Pinnacles, according to the antique, rise from the front, which is to the east, and produce a fine effect to those who admire the stile adopted. This chapel we believe is about 100 feet long, by 52 in breadth; it stands a little to the south of York Place, with an end front to the street.

There are three meeting houses belonging to the An- tiburghers, four to the Burghers, three to the Relief, two to the Independents, five to the Baptists, one to the Caramonians, one to the Quakers, one to the Metho- dists, one to the Beneziers, one to the Glassites, one to the Unitarians. There being only four Jews in Edinburgh, they cannot hold a synagogue.

Edinburgh is the seat of a presbytery of the same name; it is also the place where the Synod of Lothian and Tweeddale, and the General Assembly of the Church of Scotland, meet for ecclesiastical business.

After the edifices devoted to sacred purposes, those which next claim attention are the buildings appropriated for some of the judicial establishments abounding in this city. A great irregular pile, partly old and partly new, in the Parliament Square, serves for accommodating the supreme courts of justice. In the year 1692, a building for reception of the Scottish Parliament was commenced, and finished in 1840, which constitutes a large portion of it. This consists of one extensive hall, 122 feet in length by 49 in width, and not less than 40 feet high; the inner roof, of a polygonal figure, of massy oak timbers, ornamented with gilding, and supported by abutments projecting from the wall. There is a very large modern window at one end, besides others at the side for admission of light. It is fitted up with benches for different judges, and accommodation for the public, being now converted to a court room; and in a niche there is a statue of white marble of Duncan Forbes of Culloden, who was long president of the court of session. A stranger would, at first sight, conceive it impossible to conduct business amidst the apparent bustle and confusion which prevail in this large apartment, called the outer-house. Sometimes four barristers are pleading at a time before four different judges; attorneys are forcing their way through a crowd almost impene- trable, in quest of counsel already too late for impatience in dispatching causes; conversations are carrying on,criers vociferating names, and a universal murmur pervading the remotest corner. Yet such is the force of habit, that many may be seen quietly studying their papers, while others are engaged in consultations, or the judge gives deliberate decisions without the slightest inconvenience.

At each side of the outer-house are two chambers, each about 40 feet square, with a gallery, and a lofty roof, called the inner-house, where the remainder of the supreme civil and criminal court sit in judgment. The court of session, the former of these, consists of fifteen judges, who sit in two divisions since the year 1808; previous to which there was such an accumula- tion of business, that the road to justice was totally obstructed. Yet a great portion of the evil, perhaps, arose less from the multiplicity of judges called on to decide in each cause, than from the mode in which the procedure was conducted; for had the regulations of court been rigidly enforced, and some skilful, energetic, and upright person been sought out to preside, the court might possibly have remained entire. But there were examples of judges retaining papers a whole year in their possession without pronouncing a decision; and after judgment was pronounced, it has been known, that it was allowed to be objected to above thirty times successively, for the purpose of delay. Besides the interest of the agent and the client were at direct variance: the advantage of the one consisted in protracting the suit, the safety of the other in bringing it to a close; and from the combination of these and other causes, the supreme court entirely lost the confidence of the public. The late division of the judges in 1808, has been attended with infinite benefit; many excellent regulations have been successively made, and although others seem objectionable from not protecting litigants against causes of delay, the justice is undoubtedly more equably administered. The public confidence is restored, and if care be taken in the selection of liberal and enlightened men to fill the seat of justice, it will not likely be again impaired. By a statute, in 1810, no cause, involving a smaller interest than £25, can be brought originally into the court of session, unless by appeal from an inferior judicature; and every cause is first decided by a single judge in the outer-house, on oral or written pleadings. The party dissatisfied may then carry it before either division of the inner-house within 21 days, where all the proceedings are printed, or if pleadings follow, it is on printed papers. Both parties having stated their case, which is deliberately decided, he who is dissatisfied, may bring the whole matter again under review of the same division within an interval of 21 days. If now unsuccessful, his only remedy lies in an appeal to the House of Peers. Thus, the systematic arrangements practised here, are admirably adapted for the administration of the laws.

The supreme civil court sits only 112 days in the year, infinitely too short a period for discharging the public service; and there is an absolute cessation of
EDINBURGH.

The Justiciary Court.

The Parliament House is a large and imposing structure, composed of chambers, courts, and offices, connected with old buildings and the High Street. The court-room in the eastern wing is an oval room, with a crimson silk roof, and two lobbies below, one of which is to be reserved as an entrance for the advocates to the Parliament House, and a place for attiring themselves in their proper costume. This body has been particularly favoured by government in the part of the new buildings allotted for them. The writers to the signet paid £1,500 for accommodation in the ground floor; and the advocates contributed ground worth only L.2,000 or L.2,500, for a site to the edifice, and the portion they receive, though perhaps not so well adapted for use as a detached structure would have been, is estimated at L.10,000 or L.12,000. Some years ago, the buildings for accommodating the courts of law, certain public officers, and persons in confinement, being found inadequate for their respective purposes, the defect was proposed to be remedied by considerable additions to the Parliament House. Plans and estimates were accordingly prepared, by which it appeared that the whole would amount to L.51,000. However, it was about the same time discovered, that a fund which had long before been appropriated for the salaries of the judges, of later years ceased to be directed into that channel, and then amounted by accumulations to about L.30,000; therefore, above half the expense could at once be defrayed. A bill was precipitately carried through parliament, chiefly founded on the opinions of individuals; and this enormous irregular pile of building has now arisen. But in completing it, the architect has found it necessary to destroy the original front of the Parliament House, to make way for a piazza, forming part of the plan. Perhaps, this is to be regretted, for it was not only ornamental, but intimately connected with the interior, setting aside the expense of that part of the structure from which no material use can be derived.

Immediately adjoining to the Parliament House, and forming part of the new buildings, are several apartments for accommodating the court of exchequer, and a variety of offices under their control, chiefly connected with the revenue. The principal of these is a court-room, approaching a semicircular figure, with a handsome figured stucco roof, commodiously fitted up for exchequer trials. Other apartments are called the treasury chambers, where the barons of exchequer, who are five in number, sit as lords of the treasury, or determine causes without a jury; and various offices fill the whole building, under different denominations. The meetings of this court are held during short terms, four times in the year; but one of the barons is frequently present in the course of the vacations, to oversee and regulate such matters as may be necessary for the public interest. In some of the offices there is a great accumulation of business, and a subdivision into subordinate departments would probably be attended with benefit.

Edinburgh is a royal borough, and the magistracy, collectively called the town council, consists of 33 members, viz. a provost, four bailies, a dean of guild, and treasurer, and the same officers of the preceding year, under the designation of old provost, old bailies, old dean of guild, old treasurer, three merchant councillors, two trades councillors, six ordinary, and eight extraordinary council deacons. All are elected annually; but the provost may be re-elected a second year; the old provost, bailies, dean of guild, and treasurer, are one degree lower in rank than the officiating magistrates of this name, but precede the rest, and are elected as a matter of course, after their own office expiries. There
are fifteen incorporated trades, fourteen of which have an interest in sending a member to the town council, and the council return a representative to parliament. The principal magistrates wear robes on public occasions; also gold chains always while in office, and the provost has a sword and mace borne before him. At present his office is more of a ministerial than a judicial nature; but by strict law, the jurisdiction of the magistrates extends to all crimes, except treason, committed within the city and liberties. In the year 1601, an offender was tried before one of the bailies, at Leith, for stealing a quantity of grain by means of false keys, and sentenced to have his hands tied behind his back, and to be immediately carried out the harbour and drowned. Similar examples are of more recent date, and not long ago, the magistrates were accustomed to banish a culprit without trial by jury, which is a greater exercise of power than belongs to the supreme criminal court of Scotland. Within the city, the provost takes precedence of the officers of state, and all nobility; he is, ex officio, lord lieutenant of the city, and colonel of the town guard. His salary is L. 500 per annum, and L. 300 more to defray the expenses of entertainments.

The bailies preside by rotation during a month, in a court called the bailie court, for trying inconsiderable causes, at which time they are assisted by an assessor, who is a lawyer by profession, and has a small salary annexed to the office. The dean of guild has an extensive jurisdiction. He inspects the weights and measures used in the city; he restrains the citizens from erecting buildings, or making alterations on their property to the detriment of the public, without being deliberately considered; and those that are ruinous, he orders to be examined by a jury of fifteen tradesmen, and pulled down.

The revenues of the city are managed by a chamberlain or factor, whose regular salary amounts to L. 600 per annum.

Part of the Royal Exchange has been lately fitted up to accommodate the various offices and departments necessary for the town council. This building was designed for the resort of merchants, and founded in the year 1753, on the northern bank of the ridge whereon the principal street of the Old Town is situated. From the great declivity, the back wall of the edifice is at least 100 feet high, while the front is only 60. The main body of the building is 111 feet long by 51 in breadth, the south front of a piazza projects, with four Corinthian pilasters, supporting a pediment, with the arms of the city sculptured in stone above. Within there is a spacious staircase, and the entrance is through a porch into a paved court.

There are many inferior judicatories in this city, of which very few are accommodated in public buildings specially appropriated for that purpose; such as the commissary court, a remnant of ecclesiastical jurisdiction, for trial of marriages and divorce, as also actions of scandal or defamation; an admiralty court for trial of cases purely maritime; and a sheriff-court, where almost every question occurring within the county may be brought under discussion. One of the most laudable institutions is the small debt court, wherein the justices of peace preside, and whose jurisdiction is limited to cases not involving a greater amount than L. 5, and the expense is also limited to the nearest trifle, not exceeding a crown. This court sits weekly, legal practitioners are excluded, and the parties state their cause viva voce, unembarrassed by the subtleties of law.

An immediate decision takes place, from which there is no appeal, or at least an appeal is attended with such difficulty, that it is never resorted to. This court has continued fourteen years on its present establishment; during which it has decided 58,510 causes, involving an interest of L. 106,820; 17:8; therefore its decisions are no less than 4179 annually, or about four times the number of those given by the supreme civil court, and the pecuniary interest of the parties is at an average only about L. 1:16:6. The benefit which it affords is therefore very great, especially on considering that it is no charge whatever to the nation; that the services of the magistrates presiding are gratuitous, and the expenses of their clerk and officers defrayed by the litigants.

In 1605, a system of police was devised; but on trial it was found to be in many respects a system of inefficiency and oppression. The obnoxious statute into which it had been embodied was repealed, and, in 1813, a new act, containing a variety of judicious clauses, substituted in its place. The sheriff of the county, and magistrates of the city, are constituted judges of the offences committed within their respective bounds; and they appoint a superintendent of police, who is fiscal or prosecutor on behalf of the public. A number of commissioners are named, under whose charge the streets are cleaned and lighted, and they also take cognizance of other matters connected with the safety and comfort of the citizens. It would be wrong to pass a decided opinion on a system of such short endurance as the present establishment of police; it is undeniable, however, that the statute in general is prudently and temperately framed; though a most important object, economy, seems to have been totally forgotten. The sum levied from the inhabitants the first year, at the rate of 7½ per cent. on the house rents, which is its maximum, was L. 22,000; while the charge of the establishment, including some expenses not subject to renewal, was L. 25,030.

There are two branches connected with the judicial establishments of the country, which may be noticed here, the Register Office, and the prison of Edinburgh. The former is probably the most elegant edifice of which the city can boast; it is appropriated solely for deposition of the records of the kingdom, including writings on which the interests of the individual subject depends, and was erected after a design of the elder Adams. It stands also in the most favourable situation of all others, being north of the North Bridge, and receding forty feet from the street. The building is of an oblong figure, 200 feet long in front, and 120 feet broad; but this is the extreme breadth, as part of a large circular apartment, terminating in a dome above, projects from behind. Here there is a marble statue of King George III. executed by a female artist, the Hon. Mrs Damer. The extremities of the front, and also the middle, project somewhat from the body of the building; where two outer staircases conduct to a landing-place; but these, by a strange inconsistency, are always shut up, and access is gained from behind, by two entrances originally designed as private. There is a small turret at each angle in front; and the royal rooms, executed in a composition, appear in the middle. The interior is divided into two stories, and a sunk storey, and two spacious staircases lead to the chambers above. All these throughout the edifice are arched for security against fire, and paved; they are of various dimensions, but equal in height. The foundation of
this edifice was laid in 1774, and it has cost £40,000, though only half the original plan is completed; nor was that accomplished without very great embarrassment, owing to a deficiency of funds. The total number of chambers was intended to be ninety-seven; but, in fact, the increase of number is attended only with the convenience, that they are longer of being filled. The quantity of writing required for every transaction in Scotland is incredible; more especially if connected with land, or buildings. The acquisition of all property of this description, however inconsiderable in value, requires long and particular deeds, as they are called, of conveyance and investiture; if it is transferred again, the same must be repeated; and if it then goes to a third person, the whole must be renewed. Every paper given in during a law-suit, must be preserved; and every transaction of any importance, from safety or necessity, enters the record. The great accumulation of writings can thence be better figured than described. Nay, it may be remarked, that until lately, the successful litigant was obliged to obtain a copy of every paper in his suit, verbatim, written after a certain form, to enable him to avail himself of his advantage. Within these few years, some arrangements have been made for the better preservation of the records, and publication of the more curious and useful Turions unded.

There are two prisons in Edinburgh, to which may be added the prison of the Abbey, and one, which we believe is no longer used, in the Calton, and Bridewell. The principal prisons are situated in the High Street, and in the Canongate; but they have been devised on principles little consistent with humanity: there is no place for exercise; no circulation of air; no conveniences which health and cleanliness demand; and but few separate rooms for prisoners, who pay certain rents, according to the quality of accommodation. Nevertheless, it is not to be denied, that the unfortunate debtor in Scotland enjoys eminent privileges; nay, in regard to criminals, the liberty of the subject is not to be encroached upon, except in so far as the public security requires. Almost from the day of confinement, the incarcerating creditor may be compelled to provide an aliment for his debtor; and after a month's imprisonment, the debtor may obtain his liberty, by surrendering all his property. Every person accused, can insist on speedy trial, and force it to a conclusion within 100 days. Should the judges require further information, however, he may be remanded to prison. Thus, in the strictest view, there is perhaps less necessity for conveniences, than where pros- trated confinement from unrelenting creditors may ensure; and it is grateful to reflect, that there is a progressive amelioration in the state of prisoners. The prison in the High Street was originally erected for the joint purpose of accommodating the parliament of Scotland, and the supreme courts, and for the restraint of debtors, and malcontents: the last has been its only use since 1641. The better class of debtors are confined in the Canongate jail, which was built in the reign of James VI.; and sometimes, ex speciali gratia, individuals sentenced to confinement by the Court of Jus- ticiary; as in a late instance of a naval officer, who unfortunately killed a seaman. On very recently inspecting the prison in the High Street, we found, notwithstanding all its disadvantages, that much attention was paid to the comforts of the prisoners. Cleanliness was particularly studied; all the ventilation was given which the edifice would admit, and the prisoners were treated with great humanity. Their number amount-ed to forty; but the average throughout the year is about forty-five; of these not above a fourth were debtors, the remainder being confined on accusation of crimes, or as a punishment for committing them. They were divided into two separate and distinct classes, and kept in opposite quarters of the prison; a judicious arrangement, to prevent the contamination of morals. The men and women are also kept in separate apartments, extremely various in size; but among the larger is the condemned hold, whither criminals are con- ducted after sentence of death, and if requisite, chained to a massy iron bar, rivetted to the floor. Here also is a strong iron cage, of small dimensions, which might be employed for the most daring and refractory. An incarcerating creditor pays sixpence per pound on the amount of the debt, for which his debtor is committed; and a Freeman of the city pays two-pence a night of jail fees, which are doubled to all others. A clergyman performs divine service in the lobby or hall of the prison, for which he has a salary of L.80 a year. The principal jailor, who is called Captain of the jail, de- serves much commendation for his exertions to mitigate the hardships of confinement; but the comfort of the prisoners might be greatly promoted, by a very trifling increase in further ventilation and proper soil- age.

The foundation of a new prison was lately laid adjoining to the Parliament House, but, from the apparent want of room, one is to be erected on the Calton Hill for debtors.

Bridewell is a spacious modern building, standing in Bridewell, a very conspicuous situation on the Calton Hill. It was founded in 1791, and opened for the reception of petty offenders in the year 1796. The expense of its erection was defrayed by an assessment on the inhabi- tants of the city and county, so judiciously apportioned as to prove no burden, and an aid of L.5000 from government. In addition to the petty offenders sent here, the commissioners who manage it, are authorised, by a recent statute, to fit up apartments for those unfortunate females labouring under disease, which renders it prudent to separate them from the mass of society. The body of this edifice approaches a semicir- cular figure: it consists of five stories, containing a number of cells; and the governor's house is so placed, that he can see all that goes on within them, and that in concealment from the prisoners. There are thirteen apartments for the purpose of labour in each storey; with a grating in front, and looking into an inner court. The bed-chambers look to the opposite direction, and are lighted by a long narrow window with glass, opening on pivots; each is about eight feet long by seven in breadth, and is provided with an iron bedstead; a straw mat, and a Bible. Wood is excluded in the structure of the edifice, except for doors to the apartments. Prisoners, on being received, are clothed in a costume peculiar to the place; and their own clothes, after being cleaned, are reserved to be restored to them at the time of dismissal. Their food consists of porridge, beer, and broth; and those who are industrious, may procure an enlarged allowance, together with bread. The sole employment of the convicts is spinning by the women, in which many excel, thus proving the indus- trious habits originally implanted in the people of Scotland; and the men pick oakum, or are sometimes em- ployed in digging a garden annexed to the place. Both sexes are allowed payment for their work at a small rate, which is nevertheless still a stimulus to industry; but the expense of their maintenance is deducted. The
whole house is under excellent management; and prisoners, except for the infamy, find it a lighter punishment to be sent there a second time than at first.

Thus, there are excise-offices and a custom-house in this city, not far from each other; both of which were originally built by private gentlemen for their own accommodation. The former is a neat plain edifice, standing in 'St Andrew's Square, receding from the street. The other is inferior in appearance, and stands on lower ground, in London Street. A great deal of business is done in these offices, particularly in the former.

Having described the principal buildings, and their uses, which, in a civil light, are the concern of the community at large, we shall now say a few words on the charitable institutions of this city, and then proceed to consider the literary establishments.

These institutions are either for the relief of the sick and infirm, for the education of unprotected youth, or for the poor and aged. That on the largest and most important scale is the Royal Infirmary, which is a spacious building, near the University, consisting of a main body 210 feet in length, by 36 wide, and two wings, 74 feet long, by 24 in breadth. A statue of George the Second, in a Roman dress, stands in a niche in the front, with an inscription on either side, "I was naked, and ye clothed me;"—"I was sick, and ye visited me." The building is laid out in different wards; and there is a large room at the top, lighted from above, wherein operations are performed; hot and cold baths below; and cells for the restraint of persons insane. A spacious court, where a centinel is always posted, fronts the whole. This institution is now under a system of management, which meets with much approbation: it is attended by two ordinary physicians, and six surgeons, the two senior of whom take charge of the patients and operations. An exact register is kept of the different diseases, their progress, and symptoms; and, as the students at the university have an opportunity of attending the Infirmary, it may be said to constitute a medical school of itself. The different patients are classed according to the diseases with which they are afflicted; and two wards are allotted to the professor of clinical surgery in the University, on the cases of which he delivers lectures. The Infirmary can accommodate 450 patients at a time, or a greater number on urgent occasions; and about 2000 individuals are admitted annually. Of these, between 95 and 110 die; so that the average of deaths scarcely exceeds the proportion of one to twenty; which is extremely small, considering the number of desperate cases which must constantly occur. Patients are admitted on recommendation of respectable persons, who engage, in event of their decease, to become liable for the funeral charges. The funds of this institution are partly certain, partly casual; and the expenditure is dependent on the price of commodities, and the number of patients in particular years; but the charges, at an average, do not exceed L.5 sterling for the relief and maintenance of each, which is a satisfactory proof of the mode in which the funds are administered.

Queensberry House, a large old mansion in the Canongate, has lately been acquired by government, and converted to a military hospital exclusively.

A lying-in hospital, formerly a private dwelling-house, in Park Place, is appropriated for the reception of females in indigent circumstances, who are there attended and maintained until recovery. In the year 1776, a public dispensary was planned by Dr Duncan, senior, professor of the theory of physic, which has been of great utility in affording advice, and supplying medicines to the poor. Numerous patients are relieved, and accounts of the progress of the different diseases are preserved. The Dispensary stands in North Richmond Street.

The principal hospital in Edinburgh for the maintenance and education of youth, owes its origin to the benevolence of George Heriot, jeweller to King James VI., who died the year preceding that monarch. After various interruptions, his intentions were fulfilled, by completion of the edifice since called by his name, in 1650, and at an expense of L.30,000; a very large sum at that period. Instead of being then applied to its original purpose, Oliver Cromwell having taken possession of the city of Edinburgh, converted it into a military hospital; but General Monk, several years after, in 1659, at request of the managers, agreed to withdraw his troops. This is a great quadrangular edifice, of irregular Gothic architecture, with a court within, and a well in the centre. On one side of the court is a statue of the founder, which is carefully decorated with flowers on the anniversary of his birth, when all the objects of his benevolence walk in procession to the Greyfriars' church in the neighbourhood, to hear public service; on which occasion the magistrates of the city are present. Each side of the building is 162 feet long, and the court within 94, both being square. There are 200 windows, almost all of which, to gratify one of the executors of the founder, are ornamented with different devices; and the high angles of the edifice are crowned by turrets. The chapel is rather more than 61 feet by 24, and paved with black and white marble. There are different schools; apartments for the governor and attendants; and a kitchen, which was partly fitted up under the inspection of Comte Rumford, during his residence in this country. The situation of Heriot's Hospital is extremely favourable: it stands in the middle of a small field, with some fine old trees around it: on the north it communicates with the city, though quite detached from all other buildings; and a path from the south leads to the country. The purpose of the endowment is for the maintenance and education of indigent children, the sons of the burgesses and freemen of Edinburgh; and the numbers depend on the state of the funds, conjoined with applications for admission. At first only 39 were received, in the year 1659; in 1753 there were 130; in 1778, 110; but now, in July 1814, there are no less than 175. The average expense of maintaining each, including the necessary expenditure of the institution, is about L.45 yearly. On youth leaving the hospital to follow trades, L.50 is paid as apprentice-fee for them; and those attending a university, with the view of preparing themselves for learned professions, are allowed a bounty of L.120. Thus, there is much liberality practised to promote their welfare. The funds of this hospital are ample; and, as a large proportion consists in land in the immediate vicinity of Edinburgh, they have increased wonderfully of late, and are likely to augment still farther. At present, the annual revenue is reputed to be about L.8500. Recent reforms have greatly improved the whole establishment: the salary of a treasurer newly appointed, is raised to L.500, which is found to be more economical than under former arrangements, permitting him to furnish certain necessary articles for common use.

Not far from this hospital, and still more without Watson's the precincts of the city, is another endowed by George Hospital.

Heriot's Hospital.
Watson, for maintaining and educating the sons and grandsons of poor citizens. It was founded in 1738, and completed in 1741, when twelve boys were admitted. The number has been greatly augmented, and each, on leaving the hospital, receives a bounty for apprentice-fee, and, on attaining the age of 25, a farther bounty, if he produce certificates of good character.

There are two hospitals, on a more limited scale, for the maintenance of young females. The first of these is the Merchants' Maiden Hospital, a plain edifice, where girls, the daughters of decayed merchants, are received. And the other, which is a more regular building, is appropriated for the daughters of tradesmen. In the latter, there are at present 50 girls, who are maintained at an expense of between L.25 and L.30 yearly. Girls pay L.1, 13s. 4d. as entry-money, on admission; and receive a bounty of L.5, 11s. 1d. at leaving the hospital. No entry-money is paid in the other; and the bounties are L.8, 6s. 8d. to some, and L.9, 6s. 8d. to others, on quitting the institution.

The Orphan Hospital was planned by Andrew Gardner, a merchant of Edinburgh, who, being supported by public bodies and individuals, it was erected in the valley east of the North Bridge, in 1784. Its object is more comprehensive than for the children of citizens, as orphans from any part of the kingdom may partake in the benefit of the endowment. None are admitted under seven years of age, and they quit the hospital at the age of fourteen. In the year 1778, nearly 100 children were maintained and educated; at present the number is greater. The building is neat and plain, and ornamented with a spire.

In the year 1461, it has already been observed, that Mary of Gueldres, queen of James II. founded a collegiate church, and an hospital for 13 poor persons, dedicated to the Holy Trinity; but all such institutions, at that period, were more for a religious than for a moral purpose; and, at the Reformation, the hospital was stripped of its revenues. They were restored, however, by a subsequent transaction, and appropriated for the maintenance of decayed burgesses of Edinburgh, their wives, and unmarried daughters; none being admitted under fifty years of age. Each person has a separate apartment, ample provisions, and sufficient clothing; they also receive a trifle annually for the purchase of necessaries, and there is a small library for their amusement. The total number presently on the establishment is 181, at an average expense of L.15, 10s. each. Of these, 56 live in the hospital; the rest are out-pensioners, who have an annuity of L.6. The females are about five times more numerous than the males.

Another hospital, also for the support of aged persons, was endowed by James Gillespie, a snuff merchant in Edinburgh, who died in 1797. None are admitted under 55 years of age; and a preference is given to persons of the founder's surname. The total number at present supported by the institution, amounts to 49, including a housekeeper, chaplain, gardener, and four female servants; and the average expense of maintaining each is about L.27, which testifies prudent and economical management, considering the comforts which are enjoyed. Persons of both sexes are received indiscriminately; and, of 40 now in the hospital, 29 are females. The edifice is a commodious oblong building, situated beyond the south-west verge of the city, amidst a small field, and somewhat withdrawn from the high road. It is ornamented with battlements, and small turrets at the angles, as if the same architecture commensurate with the purposes of a place of defence, should be suitable to one on the verge of the southern district of the city, another in the Canongate, and the third belonging to the West Church parish. All are conducted near the same plan, being appropriated for indigent persons of both sexes, and also children. Those who are able to work, receive a sixth part of the value it produces, besides maintenance and clothing. The first of these is on an extensive scale: it was erected by voluntary contribution in 1743, and is supported chiefly from the same source, and a tax on the citizens. But the numbers relieved are so great, that however liberally the public contribute, the institution is always loaded with debt; which is levied by a new assessment on the inhabitants, and is very considerable at present. The building is large, and so mean in external appearance as sufficiently indicates its purpose. A large committee of managers directs the affairs of the establishment at weekly meetings, and reports of its state are occasionally made public. We are thus enabled to trace the increase of poverty, arising either from the pressure of the times, by which the hands of the benevolent are restrained from the exercise of charity, or from the greater resort of indigent persons to the city. The following numbers were relieved by the aid of the institution, either in the house or out of it.

We find, that, from 1st July 1811 to 1st July 1812, of the 1402 persons relieved, there were 741 maintained in the house; and the children nursed at expense of the institution were 55. The average expense incurred for each individual was L.6, 15s.; and the total expenditure L.6160. In the succeeding year, terminating July 1813, of the 1501 persons supplied, there were 842 maintained in the house, and 49 children paid for at nurse. The average expense for each individual was L.7, 7s., covering all charges, and the total expenditure L.7256. But the debt had increased to L.4554, which the citizens are now called on to discharge. In the former year, the deaths in the house were 77, in the latter 55. Thus the numbers of the poor seem to have doubled in about seven years, and the average expense of relieving each has increased an eleventh part in a single year. Connected with this establishment is an adjoining edifice for reception of insane persons. Another, on a more judicious and enlarged plan, is now erecting at a little distance from the city, under the name of the Lunatic Asylum. An asylum for the industrious blind was instituted, principally under the auspices of Dr Johnstone of North Leith, in 1795, which is supported by voluntary contribution, and the produce of labour. Nothing merits greater commendation than the mode of conducting this establishment. The industrious objects of the institution are taught all kinds of employment adapted to their unfortunate situation; and, from the judicious management, the produce of labour exceeds that of
Edinburgh.

Edinburgh. 339

other institutions of the same kind, where the numbers are great. Here matrasses of hair and wool are made; mats and baskets of all descriptions; and some of the blind have even been occupied in weaving.

The preceding observations lead us to remark, that several expedients have been devised, in different countries, for the suppression and extirpation of mendicity. So long ago as the year 1701, a pamphlet was published in Edinburgh, laying down a system for the suppression of begging, and for aliminating the poor. It was then proposed, that a general contribution should be raised by voluntary subscription, for their reception into hospitals or workhouses; that they should be employed in useful occupations, and that the produce of their labour should be sold for indemnifying those who contributed to carry the system into execution. We know not if this proposal was put in practice; but more than a century later, one not dissimilar has been adopted, and, during its continuance, has been attended with complete success. A society, chiefly through the exertions of Mr Robert Johnstone, one of the magistrates of Edinburgh, was instituted in the beginning of the year 1813, for the suppression of beggars, for the relief of occasional distress, and for the encouragement of industry among the poor. All these different objects have been effected. The city is entirely freed of beggars, a great number of suffering individuals have been relieved, and a considerable quantity of work produced by those who were willing and able to labour. During the first eight months of the institution, 622 persons applied for relief, of whom 456 were females; and it would appear, that the applicants had 481 children dependent on them. Every case is strictly investigated, both to shun the hazard of deception, and to afford the proper means of relief. It is then referred to one of several committees, by which it is suitably disposed of. This institution is entirely supported by voluntary contributions, and the produce of labour.

The author above quoted also suggested, in 1701, a plan for suppressing vice and idleness; and in various places societies have been instituted for the repressing of the vices which are principally prevalent in great cities, or for recalling those to innocent pursuits who are not inured to vicious habits. Youth is easily led astray, and mankind too often fall a sacrifice to the artful contaminations of their fellow creatures. In the city of Edinburgh, there is only one institution, so far as we are aware, for such laudable objects. This is the Magdalene Asylum; an institution, of which the purpose is, to shelter, and occupy in useful labour, those females who may be reclaimed from prostitution, to the paths of virtue. An edifice was built for their reception in 1797, north of the Canongate, and they are not exposed to common view. The work performed there is spinning, sewing, washing, and other occupations; and, unlike most charitable establishments connected with labour, the return nearly equals the expense of subsistence. One-third of the value of the work is allowed to the females for clothing. From the date of the institution, in 1797, until the first of January 1813, there had been received into the asylum 202 females; 32 of whom had claimed protection during the preceding year. Of all that number, only 23 exceeded 24 years of age; which perhaps goes to testify, that vicious habits, when longer rooted, become incurable. Most of the whole had been discharged, and sent to service, or were reconciled to their relations; but some proved irremediable. There then remained 50 in the house. It is singular to remark, that although other vices are eradicated, no instance has yet occurred of reformation from drinking; another proof added to a thousand others, of the pernicious effects attending the use of ardent spirits. The expenditure of the house for the year now referred to, was L.1081; while the receipt was L.1099. Of this, the expense of subsistence amounted to L.732; and the produce of labour to L. 528. The funds arise from annual subscriptions, occasional donations, and the value of the work done in the asylum: But as there is no more than sufficient, even with rigid economy, to support the establishment, cases of a very distressing and urgent nature are sometimes necessarily rejected.

There are other two institutions on a smaller scale: Repository one called the Repository, which is a wareroom where the better class of females may privately send their work to be disposed of; the other called the House of Industry. The latter is for the purpose of affording assistance to aged females wanting employment, and for training the young to industry. It is divided into three branches; spinning, the manufacture of lace, and a school for servants. The spinners have sometimes amounted to 30, and the lace-workers to 24, several under 12 years of age. Each is paid for the work performed, after deduction for materials and the expense of the institution.

The charitable institutions of Edinburgh, which have no permanent funds like those already described, or do not make such a prominent figure, are extremely numerous and useful. There is a Lancastrian School Society, having three large schools under its care, where the children of the poor are well taught, partly gratis, and partly at a very cheap rate. The Kirk Sessions have also a Lancastrian School under their management, and ten Sunday Schools, attended by about 600 poor children, who go regularly to church, and are instructed by competent masters in the principles of religion. A Gratis Sabbath School Society, instituted many years ago, has done much good. The number of their schools at present is 55, and the number of pupils 3170. The annual expenditure is about L.190, or 1s. 3d. for each individual. There are various other charity schools. A school for the deaf and dumb is taught by Mr Kinniburgh with much skill and success. A Destitute Sick Society, and two Female Societies, for the relief of aged and indigent women, have rendered very meritorious services to the lower classes of the community. The Edinburgh Missionary Society, the Auxiliary (to the London) Missionary Society, the Edinburgh Bible Society, with its various subordinate branches, the Religious Tract Society, the Society for Propagating Religious Knowledge in the Highlands and Islands of Scotland, the Society for Promoting Religious Knowledge among the Poor, the Gaelic School Society, the Society for the Erection and Support of Schools in Ireland, the Society for the Sons of the Clergy, the African and Asiatic Society, may all be mentioned as affording favourable views of the religious zeal and benevolent spirit of the metropolis of Scotland.

The commercial establishments of this city, in which the public at large may be said to be concerned, are a mercantile chamber of commerce, (wherein matters connected with the advantage of trade and manufactures are suggested,) merchants, banks, and insurance offices. There are three public banks, ten private banking companies, and about twenty-five agencies for country banks, besides the business done for London. All the public banks issue notes, of from one pound to one hundred in value; and these are also issued by three of the private companies, but
of smaller amount, as we believe none are above L 20. In the year 1604, the Bank of Scotland, commonly called the Old Bank, was constituted by act of parliament; the stock of the proprietors being then only L 100,000. Now it amounts to a million, or more. An elegant and commodious edifice has lately been erected near the south end of the Mound, opposite to the High Street, for conducting the business of the bank. The architecture is greatly admired, from uniting an elegance and simplicity free of needless decoration; but this can only be said with regard to the front and one of the sides, for the remainder of the building bears no distant appearance to a great tower of modern structure. Nothing can be more extraordinary than selecting the spot on which it is founded, the bank being exposed to the principal street of Edinburgh, and rising 100 feet perpendicularly; while the front, being on the top of a declivity, behooved to be restricted to very moderate height. It is ornamental, therefore, only in one point of view; and from Prince's Street, the extreme disproportion is disguised by a kind of curtain, consisting of a wall with a stone balustrade, and an opening of doors. On the front there is a coat armorial, with supporters as large as life, which was executed by an artist with only one hand. The lobby is very spacious; the door-ways supported by pillars; and there is a teller's room, of an octagonal figure, fifty feet in length.

The Royal Bank was constituted in 1727, by royal charter, on L 111,000 of original stock; which was, in 1798, enlarged to L 150,000; and now it is a million, or more. Business is transacted in a mean looking building, down a lane of the High Street, in a confined airless situation.

Some years later, in 1746, a company was established for promoting the linen manufacture, and then constituted into a banking company by royal charter, by the name of the British Linen Company. The advantages soon became conspicuous, by the increase of the linen trade, and other commercial concerns. Its capital at first was small, but very lately it has been considerably enlarged, after a good deal of opposition from the other public banks. That such should have arisen in the earlier years of the nineteenth century, when the spirit of enterprise is so great, as also the usual liberality by which it is met, may appear singular. The terms of dealing in simple accounts by the banks, is their lending money at 5 per cent. and allowing 3 per cent. interest on what is lodged with them for periods less than six months. Some, nevertheless, allow 4 per cent. even on daily transactions. Almost all the banks in Edinburgh enjoy a high share of public confidence; resulting from the acknowledged wealth of the partners, and from it having been remarked, that no bank ever failed in Scotland, which did not pay in full. The transactions of the bankers in Edinburgh are in general characterised by great liberality, not only in countenancing the legitimate objects of speculative traffic, but in relieving individuals from temporary and unexpected pressure.

There are several insurance offices here against losses by fire, of which the oldest is called the Friendly Insurance. In the year 1720, several owners of property agreed to insure each other against losses of this description, whereby the party insured had to pay a premium equivalent to a fifteenth of the property insured. The sum thus paid in by the association was declared a joint stock, and each proprietor had an interest proportional to his share; but this interest was annexed to the property, and passed along with it to every succeeding owner; and as it is still transferred in the same way, property so insured brings a high premium, along with the policy of insurance. In 1727, the association was constituted into a body corporate, and their privileges have since been confirmed by parliament.

More recently three companies, each exclusively of Scotch origin, have since been established, under the name of the Caledonian, Hercules, and North British Insurance Offices. The shares of each are divided among a number of proprietors, some of whom are among the wealthy inhabitants of Scotland, and many insurances which would otherwise be effected in England are now done here. The business of all these offices is chiefly, if not entirely, restricted to insurance from fire; life insurance is little understood in Scotland; but there are several agencies for English offices in Edinburgh, where insurance both on lives and against fire may be easily effected, only, the proposal must always be transmitted to the principal office for refusal or approbation. In general this is a profitable concern for the company; because the usual architecture of the houses in Scotland is an effectual safeguard against the ravages of fire. A fire in Edinburgh is a rare occurrence; a house being totally destroyed is almost unexampled; and we do not know where it is preserved on record that a life was lost.

There are numerous public and private literary institutions in this city; at the head of which is the university. The first proposal for establishing a university in Edinburgh, soon after the reformation in 1560, is said to have been opposed by the universities of St Andrews, Glasgow, and Aberdeen. However, one was founded in the years 1580 and 1581, and a royal grant of certain revenues obtained for its support in 1582. Only one professor, a clergyman of the city, seems to have originally been appointed; but others gradually increased to the number of seven. In 1599, the judges, advocates, writers to the signet, and town council, contributed a joint stock for establishing a professorship of law, and Sir Adrian Damman, a Dane, was the first who held that office. A professorship of Hebrew was instituted in 1610, and Conrad Otto, a learned Jew, appointed by the magistrates to discharge its duties. Successive chairs were established, either under royal patronage, by the magistrates of the city, or by the liberality of private individuals: of the latter description is a modern endowment by the late Sir William Pulamen, for a course of lectures on agriculture; and still more recently, an ample fund has been bequeathed by General Reid, for instituting a professorship of music, to be applied to that purpose on the decease of certain relatives by whom it should be liferented. So lately also as the years 1806 and 1807, the crown created two new professorships, one for military surgery, and another for medical jurisprudence. The total number of chairs now amounts to 27, which are classed as follows:

Faculty of Theology.
Divinity.
Church History.
Oriental Languages.

Faculty of Law.
Civil Law.
Scots Law.
Civil History and Antiquities.

**Faculty of Medicine.**
Anatomy and Surgery.
Practice of Medicine.
Botany.
Materia Medica.
Chemistry.
Theory of Medicine.
Midwifery.
Natural History.
Clinical Surgery.
Military Surgery.
Medical Jurisprudence.

**Faculty of Arts.**
Moral Philosophy.
Rhetoric and Belles Lettres.
Greek.
Latin.
Natural Philosophy.
Mathematics.
Practical Astronomy.
Logic.
Agriculture.

On three of these branches, the law of nature and nations, civil history, and practical astronomy, no lectures have been delivered for several years. The salaries of the professors are for the most part about L. 100 per annum; though some have less and some considerably more; and fees of L. 9, 5s. in some classes, and L. 4, 4s. in others, for the session, are given by each student. The professor of Divinity receives no fees, and those of one class of civil law are L. 5, 5s. The mode of instruction is by lectures; no particular course of academical education is followed, nor do the professors exercise any control over the other pursuits of the students. The professors lecture in gowns, but the students are not distinguished by a particular costume; each attains what lectures he prefers, and he lives where and how he pleases. Particular professions, such as medicine, law, and theology, require a regular attendance at certain classes previous to being qualified for exercising them, certificates of which must be produced before degrees are obtained. The senatus academici forms a liberal and learned body of men, and the reputation of the university bears ample testimony of their capacity. As a medical school, there is perhaps none of greater celebrity in Europe, and students are to be seen attending it from various quarters of the globe. The total number of students at this university during the session, terminating in spring 1814, was 2010.

The buildings appropriated for the professors instructing their respective classes being found mean and inconvenient, an enormous pile was founded, in 1789, the expense of erecting which was attempted to be defrayed by subscription. But although the public displayed unusual liberality, the plan was so gigantic, as might indeed have been anticipated, when compared with the means of putting it in execution, that after a few years of activity the buildings became altogether stationary, and long exhibited the appearance of a stupendous ruin. Some pecuniary aid has lately been obtained, and part of the structure further advanced in consequence. The edifice was planned by the late Mr Robert Adam, and intended to consist of a great qua-
drangle 338 feet by 255, fronting the east, with a spacious court in the interior; and the expense of the fabric was calculated at L. 68,000. Most of the front, and the north and west walls are finished, and part of the internal edifices. The principal gateway enters from a portico, supported by columns of the Doric order, each of single stone, 25 feet high, and, when complete, a lofty dome is to crown the whole. Besides the class rooms adapted for giving lectures on the various branches taught in the university, a very large apartment for a library, and one for a museum of natural history, the college was originally designed to contain accommodation for the chief professors, which we believe is now to be adopted. From the present state of the buildings, it will be many years before they are brought to a close; meantime we cannot but regret, that more recent edifices have been allowed to crowd and encroach on what was meant to surpass all other structures in Scotland.

The High School, devoted to the education of boys, is a compact, plain building, well corresponding to its use, situated in an open area, near the royal Infirmary. It was founded in 1777, and consists of apartments where the different classes are taught, a common hall and library. There are five teachers, one of whom is denominated rector. Each teacher has his class with him during four years; at the end of which time it is put under the tuition of the rector, with whom most of the boys continue for two years longer. A public examination annually takes place in August, when premiums are distributed. Some of the masters of this school have been much distinguished by their literary qualifications; and it has given the elements of liberal education to many who have afterwards made an eminent figure in the world. So high does it stand at present in the public estimation, that it is attended by above 700 boys. Being found too small for their accommodation, it is about to be enlarged.

Besides these, which are the chief public institutions in this city for instruction, the elementary parts of science and literature are taught, either in the way of lectures or otherwise, by private individuals, according to the age and capacity of the pupils.

An association was established in 1810, under the name of the Edinburgh Institute, where scientific persons lecture alternately on certain subjects previously announced; those for the present year, 1814, are natural history, astronomy, magnetism, and Oriental history. Each lecturer receives a guinea for his lecture from a general fund, and the lecture room is open for a small consideration to all who may chuse to attend it. Anatomy and chemistry are successfully taught by private lecturers to numerous audiences; and there are many instructors of the arts and accomplishments, distinguished by their ability. A royal academy for horsemanship was established in 1769, the master or director of which has a salary of L. 200 per annum. There is also an academy for design, under the patronage of the Board of Trustees for encouraging manufactures, the master of which has a salary of the like amount, for the attendance of numerous pupils. Drawing, painting, and music, are besides taught in all their branches, by many different persons.

There are various societies in this city for the cultivation of science and literature, the principal of which is the Royal Philosophical Society. Associations of learned men are numerous on the continent, and some of them have subsisted long. The Royal Academy of France preceded the Royal Society of London; but a much longer interval elapsed before any similar asso-
A Society of Antiquarians was constituted by Royal charter in 1781, for the purpose of investigating antiquities in general, but more particularly those of Scotland. The number of associates is considerable, and they have a small museum; but only one volume of Transactions has been published, and an interval of twenty-four years has not produced another. Although this nation can boast of eminent historians, the genuine study of antiquity is not a popular pursuit at present; indeed it is vain to deny, that works of frivolity, those which engraft an erroneous description of the manners of our forefathers on imaginary events, have vitiating the taste of the public.

A society for the promotion of natural history was instituted about the same period as the former: many valuable compositions were read in it during a series of years, and a small library was collected for its use. But after having declined for some time, it may be said to be entirely supplanted by the Wernonian Society of recent institution, which embraces the same objects. The name, however, is considered as inferring something circumscribed, and is therefore unpopular; for the public justly consider that they ought not to be fettered to any particular tenets in natural history, and least of all to geological theories, yet of such uncertain foundation, and on which the reputation of Werner is principally founded. Some of the most intelligent naturalists have been deterred by these considerations from joining it. Two volumes of Transactions have been published. There are two extensive societies, the Caledonian Gardener Society, chiefly restricted to practical persons, and the Horticultural Society, belonging to this city, both of which award premiums for fruits and flowers at certain seasons. The latter is on a more general scale, in respect to the quality of its members.

A society for promoting astronomical science was lately instituted; and now consists of many respectable individuals. As yet it has produced no Transactions; but by means of its exertions, an observatory, erected some years ago on the Calton-hill, a situation particularly favourable, has been judiciously repaired, provided with several good instruments, and is likely to be preserved in such a condition as to prove useful to the public.

There is another association, on a more comprehensive establishment than any of those we have hitherto mentioned, which may be described as a great patriotic economical society. This association was originally formed for promoting the welfare of the Highlands of Scotland, and is called the Highland Society; but its views are at this day greatly extended, and whatever is connected with the prosperity of the country at large is brought within the sphere of its patronage. Thus it is occupied in advancing the interests of agriculture, manufactures, and the arts, by offering premiums for competition; and all useful inventions and improvements, relative to the same objects, though not originally proposed by the society, are also recomposed. To attain an accurate knowledge of the real state of the country, different districts are periodically selected, and premiums offered for the best report regarding them; the culture of certain vegetables, promising utility, is encouraged; the adoption of implements of agriculture and machines, which have come to the knowledge of the society, is recommended; and when ingenious mechanics, in straitened circumstances, have devised models which apparently might be beneficial, if executed on a sufficient scale, are unable to complete them, sums have been bestowed for that purpose. About £650 is yearly distributed in premiums; a gold medal is occasionally bestowed, and sometimes pieces of plate to those whose merits seem to entitle them to it. The ample funds of this society, the patriotic spirit of its members, and the countenance which it receives from government, all contribute to its general utility and importance. It now consists of above 1200 members, and volumes of Transactions are occasionally published.

The diffusion of knowledge is justly deemed an essential means of civilizing a nation: the government itself is materially influenced by it, and thence the happiness of the people. A literary government is mild, but experience proves that a military one is tyrannical and despotic. Thus in the largest and most populous empire of the world, none but men who have undergone a probation in literature, are admitted to share its administration; and notwithstanding its unwieldy greatness, universal tranquillity prevails: all its measures are mild and paternal. Edinburgh has been called a hot-bed of genius. It is not to be denied that brilliant talents have shone in it; that it has given birth to many celebrated works in history and philosophy; yet in appreciating what ought strictly to be denominated learning, much must be rejected that passes for such in the vulgar eye: little originality is truly seen; the ideas of mankind, always the same, are only reproduced under a different form; every field of ordinary discussion has been exhausted again and again; and unless for scientific inventions, and exposing the phenomena of nature to view, scarcely any thing new is to be found. The diffusion of knowledge is materially promoted by the facility of access to public libraries, and few cities are more favourably situated in that respect than the Scottish metropolis. In the year 1550, Clement Little, an advocate, bequeathed his library for the use of the citizens at large; and immediately on the institution of the university, the books were transferred thither by an order of the magistrates. This considerable collection, of which a catalogue is still extant in the records of the town council, was gradually augmented by the benefactions of Drummond of Hawthornden, and more recent donors, until it now forms a great accumulation, probably exceeding 50,000 volumes. By a statute passed in the reign of Queen Anne, the College Library is entitled to a copy of every book entered in Statieners-hall, in common with the other universities. The whole collection is preserved in three apartments, one of which is a very fine room, though wanting repair, 83 feet in length, hung with many old portraits of foreign literati, and those of Scotland. Among the latter are King James VI, his preceptor George Buchanan, and the first professor in the university. Besides the printed books, there are some historical and classical manuscripts, which have been put in good order, and separated from the others. There is a copy of Fordun's Scotichronicon, written on vellum, and a protest taken against the burning of the early reformers John Huss and Jerome of Prague, by a convention of the Bohemian states, with numerous seals appended. The library likewise possesses a copy of Bellenden's translation of Boethius, printed on vellum, of which only three copies besides are known to
exist, and the *Heures a l'usage de Rome*, also printed on vellum, which is shown as a manuscript. Students have the privilege of borrowing books on depositing their value with the librarian, who is always one of the professors; and each contributes five shillings, which are the sole funds supporting it, on being enrolled in the university register. It is to be regretted, that there is no complete printed catalogue of this collection.

Besides this library for the use of the students in general, there is an excellent one belonging to the divinity hall in particular, furnished with books not only on theological subjects, but on those also of general knowledge.

But the largest and most celebrated library in Scotland is one belonging to the Faculty of Advocates, which was founded by Sir George Mackenzie, in the year 1680. Here the number of printed volumes now exceeds 70,000, and there are about 1000 volumes of manuscripts; the whole are enumerated in a printed catalogue, of above 1700 folio pages, the last part of which was terminated in 1807, except 10 or 12,000 articles contained in the apparatus catalogues. This library possesses many rare, curious, and valuable printed works, and a number of important manuscripts; among the latter are the records of thirteen of the religious houses preserved from the general destruction which took place at the Reformation; the two earliest records of criminal trials in 1494 and 1506; several confessions of faith, written on parchment, with the original subscriptions of those who swore to maintain the established religion; a valuable manuscript of Martial's Epigrams on vellum, nearly 1000 years old; beautiful manuscripts of the Bible; a copy of the gospels in the Malay tongue, written on the leaves of trees, and various treatises on law and history. The printed works embrace every department of science and literature, but more particularly the classics, history, antiquities, and jurisprudence. Among the more curious works, may be named the Mazarine Bible, in two volumes folio, which is probably the earliest printed book with an impression on both pages, and may be dated about the year 1450. It is in the Gothic character, clear and entire as it came from the press; and for the sake of preservation, is never exhibited but by a particular order. This book was purchased in 1805 for 150 guineas. The library also possesses the first and second books printed in Scotland; the one in 1503, containing a collection of maxims and poems of little intrinsic value; the other, dated 1509, is the Breviary of Aberdeen. There are several works printed on vellum, particularly a breviary of the Roman Catholic church, of large size, in black and red, ornamented with beautiful illuminations, from the Venetian press of Jenson, in 1478; a fine copy of the *Heures a l'usage de Rome*, every page of which is bordered with engravings, printed about 1507; a copy of certain Scottish statutes, dated 1541; the *Antiquaria Supplectitis Portucnulæ* of Petavius, in 1610; and three modern works by the same author, printed at Edinburgh in 1809, 1811, 1814. It may easily be conceived, that a library which has subsisted between 150 and 140 years, and belonging to a body always distinguished by learning, must have accumulated an infinity of valuable works. Accordingly, we find, among others, the *Thesaurus of Ecclesiastical Antiquities* by Ugolini; those of the Greek and Roman antiquities by Gravius and Gronovius, with the supplements; the first editions of Homer and Cornelius Nepos; and the modern editions of classics most in repute. There are here the French *Encyclopédie*, as originally published in folio, by D'Alembert and Diderot, and the *Encyclopédie Méthodique*, so far as complete, in about 150 quarto volumes; some other French works of the same description, and all the celebrated Encyclopédias in English. The Transactions of different learned societies belong to this library, as those of the Royal Academy of France, the Memoirs of the National Institute, and the Academy of Inscriptions; the *Memorie della Societa Italiani*; and a valuable collection, called the Scrittori Economici di Milano, in 44 octavo volumes. All the celebrated French scientific journals are here, as the *Journal de Physique, Annales de Chimie, Annales des Arts, Journal des Mines*, and some less important productions, both in French and English, as *L'Esprit des Journaux*, a collection now exceeding 400 volumes; reviews and magazines. There is a set of the *Moniteur* complete, for which the Faculty lately paid above L.250. In typography, the library possesses the works of many eminent printers, such as Fast and Guttenberg, Jenson and Aldus, of the older class, and those of Bodoni, Ibarra, and Degen among moderns; besides the productions of the most esteemed printers of Britain. There is an Egyptian mummy in the original case, belonging to the library; a cabinet of Greek and Roman coins, which are but partly arranged; and a very fine collection of Scottish gold, which is in perfect order. The expense of this establishment is about L.1500 per annum, of which about L.1000 is devoted exclusively to the purchase of books; and the library is besides entitled to a copy of every work entered at Stationers' Hall. With these advantages, greater progress would be made in other hands; but the constant change of management, and the little regard paid by the Faculty to the choice of those of their own body, who oversee the whole, proves a great retardation. Although this is entirely a private collection, ready access is allowed to strangers; and if any reputable literary person has occasion for expensive works, which he himself does not possess, they are purchased by the library for his accommodation; a praise-worthy liberality. Thus, it proves of infinite use to the public; and we should be wanting in gratitude did we neglect to express our sense of the assistance which this work has derived from its ample stores.

There are several smaller libraries in Edinburgh; such as one belonging to the writers to the signet, containing 10,000 or 12,000 volumes, which is under good management, and in excellent order. A library lately instituted for biblical criticism; two private subscription libraries, and some others. There are also six or eight circulating libraries, where works of merit may occasionally be found; but only novels, and that portion consisting of books of mere entertainment, are in common request.

We have yet to speak of the population of the city, population, the division, and pursuits of the people, in so far as not anticipated by the general notices already given. Edinburgh consists of 13 parishes, St Andrew's, Canongate, College Church, St Cuthbert's, St George's, New Grey Friars, Old Grey Friars, High Church, New North Church, Old Church, Tolbooth Church, Tron Church, and Lady Yester's, which are subdivided into 20 wards. The total population amounts to 82,624 individuals, of whom 35,275 are males, and 47,329 females, being an excess of 12,064 of the latter. The total number of families amounts to 18,183; thus each is found to consist of between four and five individuals; or one half the families may be computed at four, and the other
half at five. The number of families engaged in agriculture is 272; in trade, manufactures, and handicraft operations, 7,432; and those employed otherwise amount to 9,579. Thus, the individuals supported by agriculture, trade, and manufactures, does not exceed 31,000, a very small proportion of the whole. It is to be observed, however, that a portion of the most populous parish being in the country, the general amount would be diminished to 77,786, by deducting it; but making a reasonable allowance for omissions, which indubitably took place, the whole population will be found to consist very nearly of 80,000 souls. We are well aware, that many are of opinion that the population exceeded this number twenty years ago, and that it has always been increasing; but we are much inclined to doubt the progressive increase. It can take place only by an influx from the country, or by the greater frequency or greater fertility of marriages. But the expense of subsistence must undoubtedly operate as a partial check on the former, and in no town in the world perhaps are there so few marriages. The excess of females proves the fact in some degree, and it may be owing to a similar cause with the other, namely, the expense of subsistence. The city has extended wonderfully indeed, not so much, however, from new inhabitants seeking an abode, as from those previously residing in it requiring more accommodation. It is indisputable, that there is a gradual and continued migration of the older and less commodious parts of the town to occupy the edifices daily erecting, while their places are left vacant, or are occupied only by similar numbers. But if 61 houses, which we find were building in the year 1811, received as many families from the country, the accession of population would not be great, allowing the due proportion to each; and at that time a number of houses were uninhabited. Thus we are induced to conclude, that although the population may be increasing, the ratio is inferior to the general belief. But to obtain an accurate view of the population of a nation, the whole list, town and country, should be taken up on the same day.

There are few persons of high rank citizens of Edinburgh, or those not engaged in professional pursuits. Almost all are actively and industriously employed, and chiefly in quest of subsistence. The principal professions are the bar, medicine, surgery, that of attorney, and the more liberal mercantile vocations: the ecclesiastical establishment is so confined, that it can scarce find a place in calculation. As families of the highest rank frequently breed their younger sons, or sometimes the eldest, to the bar, the law is usually placed first in order.

The barristers are united in a society, called the Faculty of Advocates, who have the privilege of pleading in all courts, even in the House of Peers, and can claim exemption from prosecution in any but the supreme court to which they belong. The only exception is in regard to a useful judicial institution, of which we have already treated. Candidates for the gown undergo successive examinations in public and private, and they must produce certificates of an academical education. There are at present 276 advocates enrolled on the list, but not above half the number practise at the bar, and scarcely more than 50 gain a livelihood exclusively by their profession.

The first class of attorneys is denominated clerks, or writers to the signet, because they have the privilege of signing certain writings which pass the king's signet. All must serve a long apprenticeship, and undergo trials of their skill in law, before being admitted to practise. The number is at present 367, most of whom follow the profession. As a safeguard to the public, they are permitted to charge their clients only at a certain rate, according to a table of fees submitted to and sanctioned by the Court of Session.

Another branch of the law department consists of solicitors united into a faculty, who practise in the supreme court as attorneys; and some whose profession is of a mixed nature, participating of that of advocate and attorney conjointly, who practise in the inferior courts only. We have been unable to ascertain the numbers engaged in the various branches of the law department, but they probably amount to several thousands.

The medical profession is very celebrated in this city. It consists of two Royal Colleges, the one of physicians, the other of surgeons. Several distinguished foreigners are enrolled among the former; but there are few physicians who practise in Edinburgh. By their charter of incorporation into a college in 1681, and subsequent statute, they were enjoined "to visit all the apothecaries shops within the city and liberties, at least twice a year, and destroy all insufficient and corrupted drugs." The public meetings of the college are held in a beautiful edifice in George Street, called the Physicians' Hall, perhaps unequalled in the city. It is built after the antique, and is in dimensions 83 feet by 63. The entrance is gained by a flight of steps to a portico, supported by four columns of the Corinthian order; and within is a spacious hall, with a gallery supported by ten fluted columns.

A corporation of surgeons was constituted in Edinburgh so early as the year 1505; but, by a strange association, united the barbers of the city, as a thing universal in Europe at the time. This incongruous bond was broken; and, in 1557, the surgeons and apothecaries rejoined in one corporation, more lately formed into a royal college in 1778. The college consists of many skilful, intelligent, and respectable members, whose fame has materially added to the celebrity of the medical school of Edinburgh.

This city cannot be called a place of trade or manufacture; it is chiefly supported by persons in the law and medical departments, especially the former, and by families whose children are attending the high school or university, and other branches of education. But the great bulk of the inhabitants are not engaged in productive industry, compared with many cities of equal extent. There are numerous manufactures, it is true, but almost all are on an inconceivable scale, and conducted without the limits of the city.

There are several distilleries in the suburbs and immediate vicinity of Edinburgh, where great quantities of spirits are made. Independent of what is exported, there are no less than 1048 shops in the city by which they are retailed, and 555 in the county; that is, 1603 places to supply those who require this pernicious beverage. The consumption is too forcibly demonstrated, by the number of dealers finding it advantageous; and but for the attendant expence, it is unquestionable, that the demand would still be greater. For a considerable time extensive breweries have been established for the different kinds of malt liquor, some of which is exported to London. The ale in particular has long been celebrated. Sugars are refined, though not in quantities; and soap and candles of good quality are made.

The preference given to English broad cloths renders the woollen manufacture languid; and from the exten-
five manufactories of Glasgow and Paisley supplying the capital with cotton goods, they cannot be fabricated here equally cheap. But the linen manufacture is flourishing, and that of silks and sarsnets is daily gaining ground. Between 300 and 400 weavers are employed in it; and beautiful shawls are made, of which the prime cost sometimes amounts to twenty-five guineas. Quantities of silk stockings are made, but sent to England for dyeing. There is also a small manufacture of fringe and worsted lace. Such manufactories are greatly encouraged by a board of trustees established in the earlier part of the preceding century. Premiums are there offered for the best commodities, at a certain price, as the best dozen of shawls at five guineas each, or the best linen, of an appointed texture, at so much a yard; and after due consideration awarded. But the manufacturer competing, must part with his goods, if any member of the board, or another, is willing to take them at the value, which prevents articles of greater worth than they ought to be from being put in competition for the premium. The tanning of hides is a large branch of manufacture, and formerly great quantities of shoes were made for exportation. Buttons were also made in quantities, and a small steam engine employed in the different operations of the work; but we believe it is not carried on at present to any great extent.

Household furniture is made in quantities, both for home use and export; and the fabrication of travelling carriages occupies a number of hands. Perhaps, however, while their quality is improving, the demand is decreasing. There are several manufactories of cart and carriage wheels, of agricultural implements, and machinery for mills.

Of late, a considerable trade has been carried on by lapidaries, not so much in the greater operations of marble cutting, which is also practised, as in the polishing of the beautiful pebbles so common in Scotland. The avidity with which these are required, as personal ornaments, by strangers visiting the metropolis, has proved a great encouragement to dealers; but the Edinburgh lapidaries do not understand the art of working in the precious stones, though some are expert in cutting facettes on those of inferior hardness.

Seal engraving is well executed; and engraving in relief, after the stile of the antique cameos, has sometimes been attempted. There are many copperplate engravers, who are often employed for the London market. Excellent specimens of their skill may be seen in the Plates of this Work. A few busts are executed in marble; casts in plaster of Paris are rarely done; and there are artists who work beautifully in enamel.

The fabrication of musical instruments has much increased within these ten or fifteen years. And during a sudden and ill-advised spirit of speculation in trade to Buenos Ayres, in the year 1806, piano forte were to be a considerable article of export. But there is a strong prejudice in favour of London made instruments, therefore many of home manufacture are merely lent out on hire; and there is probably no city in Europe where they are so invariably seen an article of domestic furniture. A single shop has been known to have above 100 out on hire at a time.

There are several iron foundries here, where extensive orders are executed; and also brass foundries, where the smaller work required by breweries, distilleries, and steam engines, is finished. Bells of moderate size are likewise founded, but, we believe, that no cast of any magnitude has been recently produced in this city, nor is such almost ever required, unless we except one of nearly a ton weight, which Mr Armstrong has founded for St George’s Church. Besides, the vicinity of Carron, a foundry celebrated over the world, renders it a powerful and depreciating rival. Though the art is well understood, and sound and beautiful metal produced, difficulty seems to attend any cast in brass exceeding the weight of 40 pounds.

There is an extensive manufacture of cotton cards near Edinburgh, which we have understood carries on a regular traffic with the city of Morocco. A glass-house has lately been established in the city, where excellent glass is blown; a seasonal substitute for what was formerly manufactured at Leith.

A great quantity of paper is made in the neighbourhood, and much is also imported from London, for English writing papers are in general preferred. But the quantity of paper, on the whole, is not equal to what it was in some of the former years. However, the consumpt in printing law proceedings, and the books published in this capital, must always be considerable. Bookselling and printing are among the principal trades carried on in Edinburgh. The number of booksellers has nearly quadrupled within twenty years; and, in 1806, it was calculated, that 120 printing presses were at work in the city. It has been said, that 100,000 Bibles are annually thrown off by the king’s printer, who enjoys this as an exclusive privilege. Works of literature and science, which would formerly have been printed and published in London, are now printed and published in Edinburgh. A considerable deal of work is likewise done by the Edinburgh printers on commission, for London booksellers. Music sellers have increased nearly in the same proportion, but almost all merely deal in retail, nor does it seem so profitable a traffic as the former. It is rare to find a variety of music with them, except for the piano forte.

Nothing but the ordinary trades, found in towns of lesser population, are carried on here, and none in particular to great extent. The traders supply both the city and the country; and 232 carriers are weekly employed in transporting goods. But a large proportion of these is in transitu to Leith harbour for export. However, the whole quantity conveyed in this way is probably about 500 tons weekly. The principal articles of trade are silver and plated articles, jewellery, and cutlery, almost all brought from England; Leather, cloths, silks, linens, and stockings; groceries; books and paper; wines and spirits; Such articles are for home consumption in general, and few for export.

Various improvements in the city and its suburbs are Projected in contemplation. The most important of these is the improvement access to Edinburgh from the cast over the Calton hill. We have not room for any minute description of it. But when we think of the continuation of Prince’s Street through Shakespeare Square—the magnificent bridge that is to connect it with the hill,—the elegant and spacious public buildings that are to be erected there—the new town which is to be built on the eastern declivity—and the rich, magnificent, and extensive prospects which are to be seen from the eminence in every direction, and to which there will now be the greatest facility of access—we figure to ourselves one of the most tasteful improvements that have yet taken place about Edinburgh, and one of the grandest and most enchanting scenes that can be seen in any part of the world. It is but justice to record, that though the plan which embraces so much advantage, and so much beauty, was suggested a long while ago, we believe by more than one individual, we are indebted for the efficient pro-
The public amusements are the theatre, concerts, and assemblies. The theatre is small, plain without, but neatly fitted up within; when very full it produces about L.180; when over flowing, about L.200. On the whole, it is but poorly attended—solomon or never crowded, indeed, except when an actor of first rate talents happens to perform. Card assemblies can scarcely obtain a company, and dancing assemblies are full but seldom throughout the winter. The rooms are admirably adapted for this amusement, one being 94 feet long by 42 in width, and 40 high; besides others sufficiently spacious. A concert on an excellent principle subsisted near a century, but it was given up about the year 1797, from want of attendance. Another was established in 1819, under the name of the Amateur Concert, where it was intended the performance should chiefly be by gentlemen. After subsisting two seasons, it also was abandoned, from the city producing too few amateurs to preserve the performance in the style that was desirable. Public places are now very much superseded by private parties, which are preferred, for reasons that we have not leisure to investigate, nor limits to detail.

The manners of the inhabitants of Edinburgh are characterised by sobriety and decorum. We meet with elegance among the higher ranks; respectability and good sense among the middle classes; honesty and industry among the common people; and such a degree of intelligence among all, as the literary metropolis of a well-educated kingdom might have taught us to expect. (c)

**EDUCATION.**

*Education, in the most extensive acceptation of the term, comprehends every thing, whether systematic or accidental, which has any influence in developing, or biasing, the powers of the mind, and the tendencies of the heart. The object of systematic education is to cultivate the intellectual and moral powers, with a view to some specific result: and education is good or bad, proper or improper, complete or deficient, as the end which it proposes is laudable or reprehensible, as the course of discipline is more or less conducive to that end, and as the means employed are adequate or inadequate to its accomplishment.*

To promote the happiness and the excellence of the individual, to render him a valuable member of society, and to accustom him to aspire, by the regular discharge of all his religious and social duties, to the happiness which awaits the good in a future world, are the great ends which should be kept in view in the education of all, whatever place in society they may be destined to occupy, from the son of the meanest cottage, to the heir apparent to the throne. But the indefinite variety of relations in which men stand to each other, require a corresponding variety of accomplishments, to enable them to fill their respective stations with respectability and satisfaction to themselves, and with advantage to the community to which they may belong. Education, therefore, is either general or particular: general, while it regards us assentient, moral, and intellectual beings, susceptible of happiness, and capable of improvement; particular, when it is designed to qualify us for some particular station, or occupation in life.

In whatever light we view education, it cannot fail to appear the most important subject that can engage the attention of mankind. When we contrast the ignorance, the rudeness, and the helplessness of the savage, with the knowledge, the refinement, and the resources of civilized man, the difference between them appears so wide, that they can hardly be regarded as of the same species. Yet compare the infant of the savage with that of the most enlightened philosopher, and you will find them in all respects the same. The same "high-capacious powers" of mind, "folded up" in both; and in both, the organs of sensation adapted to these mental powers are exactly similar. All the difference, which is afterwards to distinguish them, depends upon their education. While the mind of the savage, left entirely neglected, will scarcely raise him above the level of the animals around him, insensible to all the wonders of creation, and shut out from all the treasures of nature, the more fortunate member of enlightened society, whose capacities shall be evolved by a proper education, will comprehend within the ample range of his intelligence the universe of God; all the beauties of creation will lie unveiled before him; nature will unlock to him her sacred stores, and reveal her secret laws; the powers of other creatures will become subject to his control; and the faculties and the attainments of men will be made subservient to his advantage or his delight. Such is the importance of education to the intellectual improvement, and consequently to the happiness of man. But it is not by his intellectual improvement alone that it enlarges the sphere of his enjoyment. It opens to him sources of still more exquisite pleasure, in the moral and religious
tendencies of his nature. The untutored barbarian, like the beasts which he hunts for subsistence, or from which he dreads destruction, acts merely under the guidance of instinct, or from the impulse of appetite, passion, or feeling. A stranger to control, he acknowledges no law but his own will. Not disciplined to subordination, or trained to reflect on the relations of society, and the duties which arise out of these relations, he submits to no superior, but the leader whom he chooses to conduct him to the gratification of his private or national animosities; and his wildest desires are indulged without the slightest regard to any future consequence, or to any feelings or interests but his own. His enjoyments, therefore, are entirely selfish; and gloomy as they are contracted, they spring merely from the gratification of the most ferocious passions, or the most grovelling appetites. Even his religion tends only to debase his nature, and to increase his wretchedness. His devotion is a feeling of terror; and the whole system of his superstition is a fabric reared by his vices, which it serves, of course, to fortify and confirm. Ascribing to his gods his own passions and partialities, he hears in the thunder and the hurricane only the voice of their wrath, which he is led to appease by some dreadful expiation, or by some deed of sanguinary vengeance against their enemies and his own. He may hope for immortality; for who ever left the precincts of this world, without casting forward an anxious look to another? But the scenes which he pictures to himself beyond the limits of time, derive all their colouring from his own dark imaginat ion; and the expectation of a heaven, not of tranquil benediction, but of insulting triumph over vanquished foes, infuses to greater violence the malignant passions which rankle in his breast. Can a nature thus selfish, thus fiend-like, thus wretched, be transformed by any culture into the likeness of man, as we contemplate him in the more enlightened and happier regions of the world? Do the men whom we see united in regular communities, directed by the same government, submitting to the same laws, and, even in the pursuit of their private interest, co-operating towards the general good, bear any affinity to the lawless and untractable nature of the wilderness? Are the benevolent schemes, which embrace in their object the happiness of millions, conceived by minds akin to those, whose ingenuity was never exercised but in plans of murder and devastation? Is the heart which knows no aim superior to the gratification of the lowest appetites, and the most odious passions,—which invests in its own grossness even the powers of heaven, whom it fancies the abettors of its lust and malignity,—of a common descent, and of a kindred nature, with his, who, spurning each low and sordid object, "exalts his generous aim to all diviner deeds,"—who, glowing with the inspiration of celestial love, beholds in all creatures the objects of the Creator's paternal regard, and rejoices in co-operating with the divine beneficence? Can the earth-bound soul, which scarcely darts a glance beyond the tomb, or which, through the mist of sensuality, seems to descry a country, where the unhallowed desires by which it is now agitated, shall riot in full enjoyment,—claim alliance with the heaven-born, heaven-aspiring spirit, whose thoughts, wandering through eternity, rejoice in the anticipation of its escape from the encumbrance of mortality, and of its perpetual progress in excellence and felicity? 

Yes! these natures, opposite as they appear, are formed originally after the same image. It is to education alone, that the civilized and enlightened man owes all his superiority. It is education, which, raising him above the degenerating dominion of sense, teaches him to respect the voice of reason, and to follow her as the guide of his conduct. It is education which reminds him of the necessity of subordination in regular communities; and which, convincing him how much the happiness of the individual is promoted and secured by submission to government and laws, expends even his selfish feelings into loyalty and patriotism. It is education which, leading him to reflect on the ties that unite him with friends, with kindred, and with the great family of mankind, makes his bosom glow with social tenderness, confirms the emotions of sympathy into habitual benevolence, imparts to him the elevating delight of rejoicing with those who rejoice, and if his means are not always adequate to the suggestions of his charity, soothes him, at least, with the melancholy pleasure of weeping with those, who weep: in a word, which renders even his self-love only a modification of generosity, and enables him to gather his purest bliss, from seeing others blest.

It is education, which, elevating his thoughts habitually to his Creator, gives constancy to his virtues amidst all the trials of life, and serenity to his mind amidst all its evils; which leads him to repose on the wisdom, the goodness, and the omnipotence of the Lord of the universe; and carries forward his views to the regions of immortality, where the apparent confusion and intricacy of the ways of Providence shall be unravelled into the most perfect order; and the toils, and struggles, and sufferings of persevering goodness, shall be rewarded with an eternity of unalloyed enjoyment.

Is this, then, a general and a faithful representation of the civilized and enlightened portion of our race? And do these happy effects invariably flow from a well-conducted education? Vices may prevail in the most refined and enlightened communities; but their vices are not the consequence of their knowledge and refinement. The most judicious system of education may be counteracted by unfavourable circumstances; but the failure is not chargeable on education. The excellence which we have described as the result of good education, has been attained by many; few are incapable of attaining it; and it is this capability which renders education an object of such inestimable importance, and such deep responsibility to all who have the charge of forming the human mind.

So great and so obvious is the influence of education in the development and direction of our moral and intellectual faculties, that many ingenious authors have ascribed to this cause alone all the varieties of human character. The great variety observable, however, in the external organization of infants, and the innumerable diversity of temper and capacities, which they display almost as soon as they are susceptible of any impressions, are objections to this theory in our opinion insuperable. The intimate connection between our physical and mental powers, and their mutual dependence, will make it impossible, we suspect, for the most attentive culture, to render human beings exactly alike, while nature continues to vary the structure and the sensibilities of their corporeal system. But though the influence of nature in diversifying the characters of men be great, the influence of education is still more remarkable. By the hand of nature, our organs of sensation may be formed lively or dull: to give efficacy to our actual sensations, is the part of education. Nature must bestow the sensibilities of our frame: by education, they may be excited or repressed. The powers of the mind are the
We know not what apology those parents can frame to their own minds, who can resign a charge so sacred, to the ignorance or indifferency of a hireling. Yet, whenever luxury has made any progress, it has been common for mothers, in affluent circumstances, to disregard so far the claims of affection, as to forego the pleasure of nursing their own children, or even of watching over them in the helpless years of infancy. To those who place all the happiness of life in the dissipation of perpetual amusements, and who persuade themselves that they were sent into this world merely to pass through it in the most easy and unthinking manner, it is in vain to represent the immorality of so unnatural an indifference. Yet, if every spark of feeling be not extinguished within them, they might, we should suppose, be led to ask their own hearts, whether they consult their happiness in thus resigning all the endearments of so tender a connection — whether all the varieties of that "tolling pleasure which sickens into pain," might not be well exchanged for the delight of cherishing so engaging a dependant; of seeing its cherub countenance brightening with the smile of reciprocal affection, receiving the caresses of its kindness and gratitude, and winding around its gentle heart the cords of indissoluble love? We might hope, that even a regard to their own future comfort would make them unwilling to allow their child to transfer those affections, which cannot easily be recalled, to the person whom they have engaged to perform to it the duties of a mother. But if none of these considerations can reclaim them from the selfishness of luxurious indulgence, and the unfeeling dissipation of fashion, let them at least do their child the justice to select for it a nurse, whose sound and healthy constitution may impart vigour to her charge; whose calm and patient temper may bear with all its wants and its cries, and save it from the fretfulness of perpetual irritation; whose conscientious integrity may be a substitute for maternal tenderness; and from whose language or manners it cannot contract no improper habits.

We all know, from experience, how much the vigour of our mental powers depends upon the state of our corporeal frame, and how much our thoughts and feelings may be influenced, how materially even our moral and intellectual character may be affected, by the external organs of the mind, and by the firmness or delicacy of our muscular and nervous system. The culture of our corporeal powers, therefore, considered as the instruments of our mental faculties, is entitled to the anxious attention of all who have the charge of a human being; and it is in the period of infancy that such attention will be most efficacious.

It is not our design to give such detailed and explicit directions for the management of children, as some writers have collected under the title of Physical Education; this would carry us far beyond the bounds which we have prescribed to ourselves for this article; and would, besides, be encroaching upon the province of medicine. Yet we may be allowed to suggest, in general, with the eloquent, though whimsical Rousseau, that, in the treatment of infants, it should be our endeavour to second and call forth nature, not to oppose her intentions and operations. Let not the infant, the moment he opens his eyes on the light, be wrapped in swathing bands, which restrain the freedom of motion essential to the growth and vigour of his limbs, and render even the internal parts of his frame incapable of their proper functions. Let him be frequently bathed in cold water, if he can bear it; but if he has been at first accustomed to the warm bath, let it gradually be made colder, till at length he be able to endure it perfectly cold. When the constitution, however, is weakly, or exhibits any phthisical tendencies, the cold bath cannot be employed with safety. Let the food of children be nourishing, but plain: their appetite, if neither pampered nor laid under unnatural restraint, will be the best guide as to the quantity that should be given them. When the weather permits, let infants be carried frequently abroad. The open air is peculiarly favourable to health; and the freshness, the beauty, the variety of the scenes of nature, impart, even in infancy, a serenity to the temper, and enliven and invigorate the powers of the mind. Healthy children, especially after they have learned to walk, will exercise themselves sufficiently if they are permitted; nor should they ever be restrained, during that period when their bodily vigour is the first concern. We are apt to adopt too many expedients to assist children, when beginning to walk: it is enough if we guard them from any dangers to which they might be exposed by their first efforts to move about. Neither should we be too anxious to preserve them from those slight hurts which they may incur, from their disposition to activity, before they have acquired sufficient caution or strength. Our excessive attention teaches them to confide in it, and to become careless of themselves; and while we seem to regard as a dreadful calamity every trifling accident that may befall them, we are forming habits of timidity and effeminacy, of which they may find it difficult or impossible to divest themselves in future life.
Let it never be forgotten, that, even in the earliest period of infancy, children are acquiring those habits which are to determine their future character, and to influence their future happiness. It becomes, therefore, of the last importance, so to regulate their associations, that their desires and partialities may be directed only towards what is useful or good; and that aversions and dislikes towards what is bad or pernicious. The effect of example is here omnipotent. Children are the creatures of imitation, and adopt implicitly the manners and the sentiments of those under whose protection and influence providence has placed them. This imposes on every parent a sacred obligation to weigh well the motives which actuate his own conduct, and anxiously to examine the temper and dispositions of his own mind. A child necessarily connects the idea of good with that object towards which he sees the desires of his parents, or his elders, invariably pointed; and with the objects of their aversion, he as necessarily associates the idea of evil. By the silent instruction of example, therefore, even before they have learned to articulate our language, we may be forming them to virtuous conduct, and inspiring them with benevolent affections. It is a fatal mistake to suppose that children are at any time too young to be contaminated by the contagion of evil example. Long before they can question us with regard to our motives, they are accurate observers of our actions, which, whether good or bad, they are ever prone to imitate. Let us always act before them, therefore, with that reverence, which, as the poet reminds us, is due to a child; and exhibit, in their presence, the qualities which we wish them to acquire, in such a manner as to tempt their imitation. Even their intellectual improvement may be promoted in no small degree by the aid of this useful principle. Through their proneness to imitation, excited and cherished by their anxiety to please those who have gained their affection, much useful information may be conveyed to them, without the formality of direct instruction, and without repressing that sprightly gaiety which distinguishes this innocent and unclouded period of life. From this principle, likewise, parental authority derives much support. The habit of implicit submission is of the utmost consequence to the improvement of a child; and it is but fair that they should be convinced, that we require of them nothing which we are ourselves unwilling to perform. To the command of a parent, thus seconded by his example, they will submit with the same implicit resignation as to the laws of nature. How far the restraint of parental authority should be imposed, it is not easy to prescribe: but it may be laid down as an invariable maxim, that it should never be allowed to yield to any resistance or remonstrance on the part of the child. At a very early age they are capable of reasoning and of moral distinctions, and are therefore proper subjects of authority; while at the same time they are so feeble, so inexperienced, so ignorant of the powers and qualities of surrounding objects, and of the language, the manners, and the arts of men, and of course so incapable of supporting or conducting themselves without direction and assistance, that the habit of ready and full obedience is essentially necessary to their safety and their welfare. It may not be always proper to explain the reasons for which their obedience is required; for, while the range of their ideas is less extensive than ours—while they are yet unacquainted with our language, and cannot understand our reasoning—we may be unable to make them comprehend the causes of our restraining them, or to convince them of their propriety. With one conviction, however, we should endeavour at all times to impress them,—the conviction that we impose no restraint but from affection to themselves, and to promote their advantage. For the direction of parents and guardians in the management of children during infancy, we beg leave to refer them to the excellent treatises of Miss Hamilton, Miss Hannah More, and Miss Edgeworth, on the subject of education; and shall in the mean time content ourselves with observing, that the grand objects of attention during this important period, should be, to subdue the malevolent, and to foster the benevolent affections; to counteract all unreasonable aversions and antipathies; to correct extravagant partialities; and to regulate all the active principles of their nature, so as to prepare them for engaging, with vigour and success, in the studies and occupations of the succeeding stages of life.

At what age it may be proper to fix the attention of children to regular tasks, and to begin to teach them to read, it is not easy to determine. So much must depend on the health, the articulation, and the apprehension of children, that the discretion of the judicious parent or guardian will be, in this respect, the best guide. Perhaps it might be proper to make them familiar with their alphabet as soon as they can articulate distinctly. But learning must approach them at first in the most alluring form. Let them not be confined to their task till it become tiresome and disgusting; nor be subjected to any harshness, severity, or restraint. When they have been accustomed, for some time, to this gentle exercise of attention, we may venture to require of them a more regular and steady application during a stated portion of time. The quickness of apprehension, and tenacity of memory, which children display at a very early period, enable them to acquire, without much difficulty, the art of reading. When the pupil has learned to read with considerable facility, he may with propriety be taught the first principles of grammar. To name and define the different parts of speech, will at first be all that can well be expected of him; but when, by practice in parsing, he has acquired a sufficient knowledge of these, he may then be initiated in the syntax of the language, and taught the principles on which the construction of sentences depends. This will be an admirable exercise for his understanding and his ingenuity; and will prepare him for entering, with peculiar advantage, on the study of any other languages, to which his attention may afterwards be directed. We have sometimes been highly gratified by seeing children, under the tuition of an able English teacher, parsing and constructing any passage that was presented to them, with all the readiness and precision which we had been accustomed to expect only from classical scholars. Important as this acquisition is in itself, the habits of steady attention, quick apprehension, and accurate discrimination, which it necessarily imparts, are still more valuable.

This is the proper time, likewise, for storing the pupil's memory with such passages from the most approved writers, particularly the poets, as may at once captivate his fancy, enlarge his comprehension, and improve his morals. Though he should not be able to perceive at first all the beauties which these passages contain, they will still afford him instruction, if not pleasure; they will recur spontaneously to his recollection in his hours of solitary recreation; and he will be led, as his judgment matures, to appreciate their
E D U C A T I O N.

This, too, is the period, when he should be made acquainted with the relation in which he stands to his Maker and to mankind; with the obligations of morality and the duties of religion. In communicating this branch of instruction, we are aware that much caution and judgment are necessary. It is so difficult for children to form any proper notions of the uncreated Sovereign of the Universe, that we should perhaps allow their faculties to have advanced far towards maturity, before we attempt to explain to them the nature of God, or the sublime tenets of the Christian faith. Yet their hearts are, at a very early period, susceptible of religious impressions; and though it may not be proper to speak to them of the incomprehensible attributes of God, we see no harm, but we think many advantages which might result from teaching them, even from the dawn of reason, to regard him as the Creator, not of themselves alone, but of the whole human race; to refer to him all their comforts; to look up to him as the inspector of all their actions; and to cherish the sentiments of love, and gratitude, and submission, which these considerations are fitted to inspire. In the mean time, these religious impressions must be aided and confirmed by the uniform tenour of our own example. Let us shew them our reverence for piety and virtue; let them often listen to us, while we discourse, though not directly to themselves, of the existence of a Being, who is the creator, preserver, and governor of the world; let us speak of the constant dependence of all creatures on the gracious care of their Creator; let us descant, with ardour, on the gratitude and obedience which we owe to him, as our Great Parent and unwearied Benefactor. From such discourses, well-timed and properly conducted, they will catch insensibly the glow of piety, and will be prepared for a fuller explanation of the great doc trines of religion.

There is one caution which we would most earnestly enjoin with regard to the religious education of children. Let religion be associated in their untainted minds, only with what is lovely, cheerful, and inviting. Let her never assume the frown of austerity, or be armed with the terrors of vengeance. Let her never be ushered in as an unwelcome intruder upon their innocent joys; nor, even in the moment of transgression, let their hearts be appalled by the dread of her unrelenting severity. Let her speak to them only in the accents of gentleness, and captivate them with the smile of benignity. Let them be taught to regard her as their best friend; rejoicing in their happiness; interested in their welfare; and watching with tender affection over their progress in wisdom and virtue. Let them learn to regard the duties which she enjoins, not as irksome restraints, from which they would be glad to escape, but as directions which have no end in view but their own advantage, and with which it should be their delight, as it is their privilege, to comply. Let her sometimes be admitted to their parties of pleasure; but let it only be to give zest to their enjoyments, and to heighten, while she refines, the native gaiety of their hearts.

Whoever has considered the influence of early associations, will at once admit the propriety of connecting religion in the youthful mind with the most pleasing ideas, and the most grateful recollections. Who has not experienced the power of association in biasing the affections, and determining the conduct, even in opposition to the plainest dictates of reason, and the decided conviction of the understanding? Who has not felt his heart revolt against persons and objects, which his sober reason represented as in all respects estimable, merely because they had at first been connected in his imagination with something unpleasant or unlovely? Who has not seen their adoption of the most pious and exemplary parents, when they came to be the masters of their own conduct, exulting in their emancipation from the restraints of religion, triumphing in the sophistry of scepticism, and plunging with eagerness into the depths of vice and profanity? What could there be in that religion, which speaks peace and goodwill to the children of men, which breathes a spirit of universal benevolence, which unites earth with heaven in the bond of mutual love, which opens every avenue to happiness in the human heart, and fortifies it against every evil,—what could there be in such a religion, to excite their aversion, and make the escape from its influence appear so happy a deliverance? Alas! it was not the religion of Jesus which they were taught: it was a religion obscured by prejudices, and clouded by fears, which the Saviour of the world would disclaim! a religion, in which the malignity of human passions mingled with divine goodness, and the voice of mercy was lost in the voice of accusation and of vengeance. Their obedience to this religion was founded on the most degrading principle in their nature, the principle of fear; and all the duties which it enjoined were regarded as so many restraints, which inclination must resist, and which reason did not sanction, but which, as the unquestionable mandates of divine authority, a regard to their own safety rendered it necessary to comply. Is it wonderful, then, that they should be impatient of a religion connected in their minds only with the most painful associations; that they should eagerly embrace the first opportunity of recovering their native freedom of action; and, instead of raising their minds in habitual devotion to their Heavenly Father, should endeavour to escape from the recollection of a Being, whom they had been accustomed to regard as a relentless and avenging tyrant, the enemy of every social joy?

But is religion, it may be asked, a system of unlimited indulgence? Does it impose no restraints on our evil passions? Does it denounce no punishments against transgressors? Does it not speak of the justice as well as of the clemency of God; and does it not deter us from sin by the dread of his wrath, as well as allure us to virtue by the hope of his favour? Unquestionably. To creatures imperfect as we are, a system which recommends unsullied purity in thought, word, and deed, must certainly be a system of restraint. Punishments, dreadful in magnitude and duration, are denounced against the obstinate offender; and the same voice that proclaimed from heaven the tender mercies and long-suffering of God, proclaimed likewise that justice which can by no means clear the guilty. But is there any tinge in all this inconsistent with that character in which the Almighty delights to be represented,—the character of a gracious sovereign, an affectionate parent, an unceasing benefactor? Parental authority, even in its mildest form, must certainly be a species of restraint, while the propensities and passions of children require to be controlled or subdued. It is not restraint, but the mode of imposing it, from which the human heart revolt. Once convince a child of the unbounded kindness of a parent, and of his solicitude, even while he forbids or...
thwarts, to promote his dearest interests, and to multiply his enjoyments, and there is no species of self-de\n\nduct which he will not account happiness, compared with the evil of incurring his displeasure.

On the same principles of respect, affection, and gra\ntitude, must religious obedience be founded. "Thou shalt love the Lord thy God," said our Saviour, "with all thy heart, with all thy soul, and with all thy strength. This is the first and great commandment."

Let it be our endeavour to prepare the hearts of our children for this ardent love, by accentuating their tendency to please, by cheerful obedience, so affectionate a guardian, protector, and friend! How dreadful an evil will it appear to incur his displeasure? How unpar\ndonable a crime to requite his goodness with ingrati\ntude and disobedience! When the youthful breast is thus occupied with love to God, it will not be difficult to make it ex\npand in benevolence to all the human race, the family of the same Heavenly Father. "The love of God," says the excellent Miss Hamilton, to whose work on education we have already referred, "is the purest, the most sublime emotion of which the heart is capable, must, from the very nature of the human soul, result in purify its affections, preparing it for the exercise of those generous sympathies that flow from unbounded benevolence. When the first conceptions of the Deity have tended to expand the heart with grati\ntude and love, every additional step in the knowledge of his attributes, every new light thrown on 'the mys\ntery that was hid for ages,' but now displayed in the Gospel of Jesus Christ, will add force to these sen\ments, and inspire a deeper humility, and a more pro\found veneration. With such feelings, no selfish or vindictive passions can possibly mingle. By true piety, no such passions can possibly be produced. From whatever has a tendency to inspire these passions, un\nder whatever imposing form it may appear, I would endeavour to preserve the infant mind; and therefore, instead of warming the infant heart with zeal for any dogma that may be the object of veneration to myself or my party, I would present it as a sacrifice to Him, who fills heaven and earth with the majesty of his glo\ry, and, by the idea of one common Father, connect it in affection with the wide circle of the human race."

We cannot quit this interesting subject without ob\erving, that all our endeavours to impress our children with proper sentiments of religion will be unavailing, unless we shew, in all our conduct, a consistent regard for whatever is sacred; a reverence for pious and good men; in whatever station they may be placed; and a marked disapprobation of vice and irreligion, however imposing the form in which they may appear. While we enjoin on our young pupils a respect for the ordi\nances of religion, let us beware of countering the in\junction by a marked contempt, or habitual neglect of them. While we exhort them to aspire to piety and virtue, as the only estimable possessions, let them not be tempted to question our sincerity, by seeing us fixing our esteem and affections on possessions of a very different kind. While we express our abhorrence of vice and profanity, let us not taint their moral atmos\sphere by the contagion of our impurity. While we endeavour to direct their natural love of praise to its legitimate gratification; while we teach them to hope for distinction only by superior worth, and to prize, above all other fame, the approbation of the wise and the good,—let us never be seen bestowing our own admiration on the trifling distinctions of wealth, or rank, or even talents unaliued to virtue; let us be seen uniformly respecting excellence, however obscured by poverty; and disclaiming all intercourse with bad men, however they may bask in prosperity, or be encircled in the dazzling glare of dignity and fashion.

We find that we have been carried away by the import\nance of our subject, far beyond the bounds which we had prescribed to ourselves in entering upon it. Yet we must still crave the indulgence of our readers, while we express our opinion of the usual modes of imparting reli\gious instruction to children. These modes, we fear, are but ill adapted to the great end which they have in view. It is not by loading the memory of a child with tedious catechisms, comprehending a whole system of divinity, that you will either enlighten his mind with any proper ideas of his Creator, or raise his heart to\wards him in the glow of spontaneous devotion. As formal instruction, however, may be necessary, it might be extremely useful to have a short and simple cate\chism, which might be easily committed to memory, and which should contain only those leading truths of religion, to which the attention of a child may with prop\erty be directed. One great advantage of such a catechism would be, that, to parents, whose time or oppor\tunities do not allow them to frame a plan for themselves, it would serve as a valuable guide in this important department of education.

But it is to the scriptures that we must teach them chiefly to look for direction in moral and religious duty. Reading the scriptures, impressing them with deep reverence for the sacred writings, as the revelation of their heavenly Father's will, let us teach them to regard it as their greatest privilege, and their indispensable duty, to peruse a cer\tain portion of them daily, and with becoming atten\tion. At first, it will be proper to confine them to the simple but interesting narratives of the Old Testa\ment; to the life, the miracles, and the precepts of Je\sus, recorded in the Gospels; and to the delightful and animating effusions of devotion in the book of Psalms.

To insure regularity in their study of the scriptures, we would be disposed to recommend, that a stated portion of each day should be devoted to this employment. One evil, however, to be dreaded in this case, would be, that they might regard an employment recurring so reg\ularly as an irksome task; and we think it would be a most important point gained, to accustom them to look forward to the reading of the scriptures as the re-
ward of good conduct, rather than to associate with it any idea of compulsion. We are quite convinced, that the aversion which many persons, who have been piously educated, have afterwards shewn to the sacred volume, has been occasioned more frequently by the injudicious manner in which the task of reading it has been imposed upon them in their early years, than by any other cause. Surely it is possible to excite and to preserve in youth, such a relish for the inspired writings, that they shall read them with as much pleasure as any productions of human genius. One effectual way of guarding them against any dislike at least, to the scriptures, is to train them, even in the most ordinary, and apparently trivial, parts of education, to those dispositions and habits which the scriptures require. If we have never taught them to subdue their passions, and to restrain their desires, we cannot wonder if they should revolt from those lessons of sobriety which the gospel delivers, and that spirit of self-denial which it demands. If they have not been trained to ready obedience to their parents and superiors, they will be but ill prepared for that unreserved submission to their Heavenly Sovereign which revelation enjoins. If they have been encouraged in the idea of their own importance, and taught to expect, that every thing must bend to their pleasure, they will scorn the humility, meekness, and patience, in short, all the graces and virtues which are required as the distinguishing marks of the follower of Jesus. They will, of course, never open, but with reluctance, the sacred code, in which they can read only their own condemnation; which requires a spirit which they have never cultivated, and prescribes duties for which their hearts are not prepared. If, therefore, we would have our children religious, let us begin with cherishing within them, from their earliest infancy, those affections and tendencies which religion requires, and training them to those virtues which religion prescribes. Thus, when they come to study the record of the divine will, they will be delighted to find how much it harmonizes with their own feelings, and how easy their advances in the "way of God's commandments" are rendered, by the progress which they have already made. Against persons thus gradually prepared for the reception of the doctrines and precepts of religion, all the arts of the infidel will be practised in vain. Even the allurements of temptation will not unseat the principles of those, whose feelings are all engaged on the side of religion; and amidst all the storms and agitations of life, that hope, which is the anchor of the soul, will secure them from making shipwreck of their faith.

When children have learned to read with fluency, the curiosity natural to their age, and the equally natural pleasure of exercising their newly acquired powers, will probably induce them to read with avidity any books with which they may be furnished, that are not beyond the reach of their comprehension. To supply them with the most proper books for engaging their attention, and improving their minds, becomes, therefore, an object of the greatest importance. Amidst the infinite variety of books which have recently been published for the use of the rising generation, the principal difficulty is to select those which may at once afford them present amusement, invigorate their mental powers, and confirm, while they direct, their taste for reading. Many writers, wishing to accommodate themselves to the capacity of the youngest children, have published more childish nonsense than the merest infant was ever known to utter: others, by way of conveying to them very useful information, have penned for their instruction a number of those obvious facts, which every baby knows before it has learned to articulate; such as, "that is the fire—the first you see, is red, and it is hot; for if you touch it, it will burn you," &c. Such contemptible productions are calculated, not to improve, scarcely even to please children; but only to perpetuate their infancy, and to give their minds a frivolous turn, which may unhappily characterize them through life. The books which will most captivate their fancy, and at the same time impart the most useful instruction of which they are yet capable, will be those which describe the more common actions and characters of men, the scenes of external nature, the properties of material objects, the forms and tempers of animals, and whatever either at present exercises their active powers, or can open up to them a new sphere of employment. We ought particularly to endeavour so to regulate their reading, as to point their curiosity to those objects which are soon to occupy their more serious attention, and to prepare them for engaging with eagerness and with advantage in their future studies. Were we to recommend any books for children, where there is such variety of choice, we know none which we would prefer to the "Children's Friend," and "Evenings at Home,"—productions so generally known, that to have mentioned them is sufficient.

When our pupil has acquired a due facility in reading his own language, and a competent knowledge of its grammar, it will be proper, if we are to allow him the advantages of a classical education, to engage him in the study of Latin. The acquisition of classical literature is a very important part of a liberal education. We believe we may safely hazard the assertion, that those who have denied the advantages of an acquaintance with the languages of ancient Greece and Rome, have, with the single exception, perhaps, of Mr Locke, been men whose classical education had either been entirely neglected, or at least had not been prosecuted so far as to enable them to estimate, from their own experience, the value of the acquisition. Nor does even Mr Locke forbid that a certain share of attention should be given, in the education of a gentleman, to the study of Latin; while he admits the necessity of an intimate acquaintance with both Latin and Greek to those who are to follow any of the learned professions. Classical knowledge, if pursued as an ultimate object, is, we own, of very inferior importance to those sciences which explain the properties of matter and of mind, which multiply the resources of man, and invest him with new powers; and, perhaps, Mr Locke might have seen men who knew the classics, and knew nothing more; who would dwell with enthusiasm on the sublimities of Homer, and the subtleties of Aristotle, while they were incapable of appreciating the still higher sublimity of the discoveries of Newton, or the profound speculations and acute reasoning displayed in the Essay on the Human Understanding. Such instances might have led him, with a partiality of judgment unworthy such a philosopher, to ascribe to the study evils which resulted only from the absurd mistake of making that study a principal or exclusive object;—while he rather ungratefully forgot the benefit which he himself, with a long series of great and learned men, whose names adorn the annals of our country, had derived from a regular classical education.

We do not know that any objections have been urged against the study of the polished languages of anti-
The question, which have not arisen out of the same mistake that induced Mr Locke—not to reprove that study, but to undervalue it. If it be said that the time spent in acquiring these languages might be more profitably employed; we admit the validity of the objection, if the scholar's attention is to be confined merely to words, or if to construe the sentences of a Greek or Roman author, is to be the amount of his attainments. But while he is engaged in the study of the classics, he is, if properly taught, acquiring a more perfect knowledge of the principles of grammar, than he could have attained in any other way; while he analyses compound words, traces back an expression through all the steps of its progress, from its simple and contracted, to its figurative and more extended meaning, and explores in the history or institutions of antiquity, the origin of particular phrases and idioms; he is forming habits of accurate discrimination, gaining insensibly a knowledge of some of the most interesting operations of the human mind, and storing his memory with many important facts in the natural and moral history of man.

If it be said, that a knowledge of the ancient authors is apt to engender pedantry, the same objection may be made to any study which is calculated to give us the least appearance of superiority, particularly if pursued with any degree of enthusiasm; and we fancy we can discover at least as much pedantry in those who quote Rousseau or Madame de Stahl, or who quote modern sentimental poetry, as in the classical student, who edifies his company with a precious sentence from Plato or Cicero; or with the rich and melodious strains of Horace and Pindar. Of the latter species of pedantry, however, there is but little danger. Classical learning furnishes few topics for common conversation; and scholars have in general too much sense to exhibit their treasures where they cannot be appreciated. The pedantry with which we are most frequently annoyed, is the pedantry of those, who, having by some unlucky chance picked up a few of the facts or allusions contained in the writers of antiquity, are producing them on all occasions, to show the extent of their classical lore.

A more formidable objection has been urged against a classical education, as tending to corrupt the minds of the young, and to lower the tone of their moral feelings, by rendering them familiar with the gross vanities of the Heathens, and the licentious effusions of their poets; and by directing their admiration towards heroes and sages, whose conduct and whose principles were, in many respects, at variance with the pure and gentle spirit of Christianity. "However," it has been said, "the study of the classics may have opened the understanding, enlarged the views, and elevated the sentiments of men, it is to be feared that many prejudices have flowed from the same source, which are inconsistent with the spirit of the religion which we profess; prejudices that are inimical to that spirit, at variance with the whole tenor of our Saviour's precepts, and the cause of a perpetual and manifest inconsistency between the practice and profession of Christians. These prejudices have thrown a shade of ignominy over the mild glories of humility, meekness, and mercy; and exalted pride and revenge into the rank of virtues. They have substituted the love of glory for the love of truth; emblazoned the crimes of ambition with the lustre of renown, and taught men to prefer the applause of a giddy multitude to the approbation of God. By introducing false associations of regard and preference, with adventitious circumstances altogether foreign to the moral character, as learning, strength, valour, power, &c. they have destroyed the just criterion of human worth, and given to situation, which marks the nature of the duty to be performed, that respect which is morally due to the just performance of duty. They have gratified the pride of man at the expense of his virtue." Were these the necessary or the probable effects of the study of ancient literature, we can conceive no advantages by which they could possibly be compensated. But the charge, if not altogether groundless, is certainly much broader than facts will support. We shall admit, that there are many very exceptionable passages in the captivating poems of antiquity; that the ancient heroes possessed many qualities worthy of reprobation; and that the ancient philosophers held opinions, and enjoined practices, altogether repugnant to the spirit and doctrines of revealed religion. But are our own poets, or, indeed, the poets of any nation, more distinguished for their purity? Do our own histories record deeds more elevating, or delineate characters more perfect? Nay, are the works even of our philosophers less chargeable with error, or less exceptionable in morality? The indiscriminate perusal of the classics would certainly be pernicious:—would not the indiscriminate perusal of English authors be equally hurtful? Would you deny your pupil the privilege of reading his own language, because there are English books of an immoral tendency? Would you lock up from him the history of his own country, because, with the virtues which will command his admiration, are connected qualities, which it would be improper to imitate? Would you debar him from the regions of philosophy, because, while pursuing the road to truth, he may occasionally be tempted into the paths of error? or because, amidst the fruits and flowers by which, every step he advances, he is charmed and invigorated, there may be some that bloom but to deceive, that allure but to destroy? The teacher of the classics, as well as the teacher of English, has the power of selection; and where, except in the sacred volume, can be found finer precepts of morality, recommended by more captivating elegance, than in the writings of the poets and philosophers of ancient Greece and Rome? where can be found deeds of nobler generosity, of more magnanimous heroism, of sublimer virtue, than the ancient historians record? Let every teacher impress on the minds of his pupils a deep respect for revelation, and acustom them to refer, on all occasions, to the Divine law as the standard of morality. Thus directed, they may expati ate with safety over classic ground; nor can there be a more delightful, or more improving exercise, than to trace the various systems of the ancient sages, and while we mark the approaches of human wisdom and virtue towards the perfect system of the gospel, to gather new materials for gratitude to the Divine goodness, which has revealed, even to the most simple, those important relations and duties which the wisest men, in the most enlightened nations, were unable to discover. Even Mr Locke recommends that, in the education of a gentleman, Cicero's Tressise De Officiis should be studied along with the Bible, as his best guide in the science of ethics.

But supposing no particular evil to accrue from the study of the classics, what advantages does it promise of a classical education? To some of these advantages we have already adverted; to enumerate them all would require more time, and fuller detail, than we can at present afford. Every classical scholar knows, how essentially a know-
Edward Channing

In ancient times, before the revival of literature, the languages of modern Europe were rude and barbarous; and when the study of the perfect models of antiquity introduced a taste for elegant composition, men of genius, renouncing their own uncouth and untractable languages, adopted the Latin, by general consent, as the medium of all their communications. Their example soon diffused an universal predilection for a language, which was thus made the vehicle of all valuable information. Latin became the language, not of literature alone, but of business; and to persons of both sexes, and of every rank, the knowledge of it became nearly as necessary as that of their vernacular tongue. One happy effect of their intimate acquaintance with this elegant language was, that it improved and enriched their own. They learned from it to express ideas, for which they had formerly no adequate signs; they transferred from it, of course, many words into their native dialect, where they soon became naturalized. Thus more than one half of the English language is of Latin origin; and who ever wishes to study it with precision, will find a knowledge of Latin indispensably necessary to enable him to ascertain the full force of many of the most familiar words, by tracing them back to the root from which they spring.

For the same reason, it is evident, that a knowledge of the classics is the best key to all the modern languages. The facility with which a person who has had a classical education acquires any modern language, is to those who have not enjoyed that advantage, almost inconceivable. Thoroughly versed in all the principles of grammar, he soon becomes master of those peculiarities by which the grammar of any particular language is distinguished; and in studying any of the modern tongues, he finds that his knowledge of Latin has already put him in possession of half its vocabulary.

But it was not only by the addition of new words that the classical languages of antiquity contributed to the improvement of those of modern Europe. They whose ears had been accustomed to the melodious terminations of Greek and Roman words, and to the harmonious construction of which they are susceptible, could not endure the harshness and dissonance of their native jargon. Yet the intercourse of life would often require that they should speak in the language of their country, and the patriotic desire of benefiting even the lowest of their countrymen by useful instruction, would induce them sometimes to employ it in their compositions. Thus obliged to retain their vernacular tongue, they found it necessary, for their own convenience, to smooth its asperities, and to correct its irregularities, till acquiring a partiality for what they were daily contributing to improve, they conceived the lamentable imitation of raising it from barbarism, to vie in elegance, precision, and vigour, with the noble languages of antiquity. Whoever will look back a few centuries, to contrast the language of his ancestors, fit only for the intercourse of savages, with the language in which Johnson has written, in which Burke has spoken, and Pope has sung, will have some idea of the extent of our obligation to the admirable productions of ancient Greece and Rome. From them were drawn the treasures by which our own language has been enriched; in them were contemplated the models according to which it has been improved; with them we must have an extensive acquaintance, before we acquire the full command of our vocabulary, or understand the philosophy of our own grammar; and the study of these classical works will be our best security against the corruption of the language, which they have so wonderfully improved.

The principal value of all education, however, arises from the exercise which it gives to the faculties of the mind, and from the habits which it has a tendency to form. In this respect we think classical education particularly, we would almost say peculiarly, valuable. No department of education gives such exercise to the memory, the judgment, the imagination, and all the mental powers, as the study of the ancient languages. Even the first elements of these languages cannot be acquired without such a patient exertion of memory, as must contribute essentially to improve it in readiness and retention; and the frequent repetitions that are required throughout the whole course of classical discipline, form the habit of industrious application, while they store the mind with the most valuable treasures. For imparting precision of thought and accuracy of discrimination, no employment which we know can be more useful, than to mark the distinction between words apparently the same in signification; nor can any means, perhaps, be more effectual for enlarging the understanding and quickening ingenuity, than to trace back expressions to the substances and qualities in nature which they are used to represent, or the peculiarities of thought in which they have originated, to compare the idioms of different languages, and explore the general laws of their analogy and construction.

The utility of classical literature, in cultivating the imagination and refining the taste, has never been denied. Whatever partiality men may have entertained for the writings of their own country or age, all have been willing to acknowledge the advantage of studying those splendid monuments of genius, which the ancients have bequeathed to posterity, and which, through many centuries, have been contemplated with unabated admiration. The only dispute on this point has been, whether the moderns have not already so far improved by these models, as to have attained nearly equal excellence; and whether the fine specimens which our own language affords of every kind of composition, may not be sufficient to form the taste of the present and of future generations, without leading them back to their prototypes, through the perplexed and toilsome paths of languages long discarded. High as our admiration of antiquity is, we are far from wishing to deny the merit of the classical productions of our own times, or to assert that no excellence in composition may be attained, without being conversant with the philosophers, the historians, and the poets of Greece and Rome. Works of much genius, and of considerable elegance, have, we know, been produced by some who had not the advantage of a classical education; but let it not be forgotten, that the beauties which they could not contemplate in the original, they still admired and admired, though perhaps with diminished charms, in the writings of those whose genius they had elevated, and whose taste they had refined; and if, even in the pages of Franklin and of Burns, we can occasionally discover some approaches to rudeness, we may perhaps, without rashness, conclude, that, in composition as in the other fine arts, perfection of style can only be attained by studying the genuine productions of the great masters of antiquity. This, at least, is certain, that, among modern authors, there will not be found one entitled to the rank of a classic, whose mind was not deeply imbued with ancient literature, and whose genius was not elevated and chastened by the habitual
contemplation of those pure and exalted standards which were produced in the flourishing days of Greece and Rome. It is thus that we recognise in the "Paradise Lost," the fire and sublimity of the Maenad bard; that the "Pleasures of the Imagination" recall to us the sonorous harmony of Lucretius, the lofty conceptions, and the magnificent eloquence of Plato; that the "Seasons" delight us with the same beauty of description, the same rural elegance, the same discursive fancy, which we admire in the Mantuan swain; that in the enchanting verses of Pope and of Campbell, we see removed that extreme felicity of expression, that magic melody of numbers, that delicacy of sentiment, and graceful ease of manner, for which the poems of Horace have been so justly admired; that the pages of Addison reflect the sweet but simple grace of the "Memorabilia"; and that our three great historians have restored to narration, the beauty, the dignity, and the animation, which impart such interest to the histories of Herodotus, Thucydides, Xenophon, Livy, Tacitus, and Sallust. It were of itself a sufficient recommendation of classical learning, that our admirable countryman, Dr. Robertson, when visiting, as Principal, one of the literary classes of the University of Edinburgh, declared, for the encouragement of the young men in the prosecution of their studies, that if he had acquired any fame as a historian, he owed it entirely to his acquaintance with the historians of antiquity. "To all such then," we borrow the words of Dr. Blair, "as wish to form their taste, and nourish their genius, let us warmly recommend the assiduous study of the ancient classics, both Greek and Roman:"

Nocturna versus manu, versus diurna.

Without a considerable acquaintance with them, no man can be reckoned a polite scholar, and he will want many assistances for writing and speaking well, which the knowledge of such authors would afford him. Any one has great reason to suspect his own taste, who receives little or no pleasure from the perusal of writings, which so many ages and nations have consented in holding up as objects of admiration. And it will be found, that in proportion as the ancients are generally studied and admired, or are unknown and disregarded in any country, good taste and good composition will flourish or decline."

Great, however, as, in our estimation, the advantages of classical acquirements are, we are far from wishing that, in any stage of education, they should be the sole object of attention. The enthusiasm of pedants, who maintain that every thing valuable in knowledge is contained in the treasures of ancient literature, and the absurd custom which that enthusiasm has established in many of our public seminaries, of making the ancient languages, for seven or eight years, the exclusive study of youth, have done more, perhaps, than any other cause, to retard the progress of science, and to bring classical learning into discredit. Even where the partiality to the Greek and Roman languages is less extravagant, we are afraid that a very undue proportion of time and attention is devoted to them. Aware as we are of the difficulty of acquiring these languages, we maintain, and we are supported by experience in maintaining, that at least one half of the time usually spent in studying them, might, without retarding the progress of the pupil, be saved for the acquisition of other branches of knowledge. The attention, when exercised long upon one subject, becomes fatigued and languid; and it is not the least important, or the least difficult duty of those to whom the education of youth is entrusted, so to regulate their studies, that in the hours of labour, their minds may be kept on the stretch, without being overstrained, and that every moment employed in business may be employed to advantage. With two hours a-day of assiduous preparation, and an equal portion of time spent under the direction of an able teacher, a boy of ordinary capacity would, we are confident, advance more rapidly in knowledge, than if he were doomed to drudge eight or ten hours daily at the same study. This would leave a great proportion of his time vacant for other studies; and would thus remove one of the strongest objections which have been urged against a classical education.

But though it would be wrong to confine the pupil's attention exclusively to the classics, to distract it with too great a variety of objects would be still more improper. A change of subject is always a relief to the mind; but if the subject be too often changed, the attention will become unsteady, and the memory will be bewildered. Neither ought the different subjects of study to be entirely homogeneous. A person who is engaged with two or three subjects of a similar nature, will be more apt to be confused, than one whose attention is occupied with a greater number of objects perfectly distinct. Thus, whoever has attempted to learn several languages at the same time, must have found, that while his memory was perpetually confounding them, each was an incumbrance to retard his progress in the other.

In varying the studies of our pupils, we should endeavour to adapt them, as much as possible, to the different powers of the mind, that they may all be invigorated by their proper exercise. With the study of language, which improves the memory, let arithmetic be joined, which affords more exercise to the reasoning powers, than any branch of learning to which the attention of a child can be directed. An early and accurate acquaintance with arithmetical notation and numeration, is peculiarly calculated to impart habits of precision, arrangement, and classification. Notation, originating in the operation of necessity or the powers of the human mind, is an object worthy of the attention of the philosopher; while, at the same time, from its distinctness and simplicity, it serves as a most important exercise to the juvenile understanding. Arithmetic, according to the usual modes of teaching it, is little more, indeed, than an exercise of memory; but, if taught judiciously, with a constant reference to the principles on which its rules are founded, it will contribute more than any other department of early education, to the vigour and acuteness of the powers of the understanding, and will give a tendency to order and method, which will be of the most essential importance in every mental operation. To the teacher who wishes to make the rules of arithmetic conducive to the improvement of the reasoning powers, there cannot be a more valuable assistant than a little posthumous work of Condorcet, entitled, Moyen d'apprendre a Comptar Soinamment et avec Facileite. The first thing, as the French author justly remarks, in the elements of arithmetic, is, that they are, at the same time, the elements of the art of reasoning. By a clear explanation of the principles on which every rule is founded, the learner is prepared for that which is to succeed it; and, when he has attained to the utmost height of the science, he sees, by one retrospective glance, the successive steps by which he has been conducted. Thus, while he acquires a precision in his operations, which
no other method could impart, his judgment is cultivated; he learns to form distinct ideas; and commences those intellectual habits which are subservient to the highest attainments of knowledge, and to the best conduct of life. This valuable work, which was long unknown, or strangely overlooked in this country, has been lately translated into English by Mr Elias Johnston, teacher of writing and mathematics in Edinburgh. See Connoctet.

When our pupil has acquired a competent knowledge of the principles of arithmetic, he may proceed to the study of algebra, which possesses nearly the same advantages, and, along with them, others conducive to a still higher degree of mental culture. The study of algebra counts the powers, invention, and combination; it accustoms the mind to general reasoning, while at the same time it leaves it at liberty to check and correct that reasoning at every step.

Geography. About this time, or even along with the study of arithmetic, geography may with propriety be made an object of attention. Were it only as an exercise of memory, and as subsidiary to the knowledge of history, the study of geography would be highly valuable. It is valuable, too, as it forms the habit of arrangement, and of associating names with the objects of which they are the signs. But it is chiefly valuable, because it is the proper vehicle for many important topics of information; and, by leading the mind beyond the narrow sphere of its own observation, it enlarges its comprehension, and weakens its prejudices, and forms an interesting link between mere sensation and abstract speculation. The plan which Rousseau proposes for imparting a knowledge of the relative motions of the sun and the planets, is extremely judicious. "The earth," says he, "which we inhabit, and the sun, by whose beams we are enlightened, are the first objects which claim our attention. We will therefore direct the attention of our pupil to the phenomena of nature. We will lead him out, on some beautiful evening, to behold the setting sun. Here we take particular notice of such objects as mark the place of his going down. Next morning, we visit the spot, to contemplate the rising of the glorious luminary. After contemplating for some time the successive appearances which the scene before us assumes, and making Emilius observe the hills and the other surrounding objects, I stand silent a few moments, affecting to be occupied in deep meditation. At last I address him thus: I am thinking, that when the sun set last night, he went down yonder; whereas, this morning, you see he is risen on the opposite side of the plain here before us. What can be the meaning of this?" I say nothing more at this time, but rather endeavor to direct his attention to other objects. This is our first lesson on cosmography. Our last observation was made about Midsummer; we will next view the rising sun, on some fine morning in the middle of winter. This second observation shall be made on the very same spot which we chose for the former. When Emilius and I perceive the sun now emerging above the horizon, we are struck at the change of the place of his rising. By such lessons as these may the pupil be taught a real, not a seeming acquaintance with the relative motions of the sun and the planets, and with geography." 

Natural history is another branch of knowledge by no means to be neglected in a liberal education. Of all the studies in which the youthful mind can be engaged, this is at once the most entertaining and the most instructive. Conversant about the objects in which we feel the earliest concern, it is peculiarly calculated to gratify the eager curiosity of children; while, by engaging this strongest principle in the juvenile breast, it trains them to the habit of observing accurately, of attaching distinct conceptions to words, and of classifying and arranging the subjects of knowledge: it gives a new interest to every thing around them, and, by extending their acquaintance with the Works of nature, it enlarges their ideas of their Great Author, towards whom it of course inspires them with warmer devotion, and with deeper reverence. "I would recommend botany," says an eminent naturalist, "for its own sake. I have often alluded to its benefits as a mental exercise; nor can any exceed it in raising curiosity, gratifying a taste for beauty and ingenuity of contrivance, or sharpening the powers of discrimination. What then can be better adapted for young persons? In Sweden, natural history is the study of the schools, by which men rise to preferment; and there are no people with more acute, or better regulated minds, than the Swedes." The next study in which we would engage our pupil, is the study of the mathematics, which, from the days of Thales to our own, has ever been regarded as of the most essential importance in the culture of the mind. We are told by almost every writer on the mental powers, or the means of improving them, that if we would enjoy the use of those powers in all their perfection, we must devote ourselves to the study of mathematical science. This alone, we are assured, or, at least, this more than any other study, will correct the wild flights of imagination, and will give to judgment its due superiority; will teach us, by perpetual examples, to conceive with clearness, to connect our ideas in a train of dependance, to reason with strength and demonstration, and to distinguish between truth and falsehood. Something of these sciences, they add, should be studied by everyone; not so much, as Mr Locke expresses it, to make us mathematicians, as to make us rational creatures. Now, while we admit the utility of the study of the mathematics in improving the powers of reasoning, it is not to be disguised, that, in one respect, their operation on these powers is often unfavourable. On subjects susceptible of strict demonstration, those who have been disciplined to the clear and consecutive arrangement which characterizes mathematical science, will probably reason most successfully. But there are many subjects on which, though not susceptible of demonstration, we may attain a certainty nearly as absolute. In the investigation of such subjects, mathematical reasoning will not apply; and we have not unfrequently seen mathematicians, who, refusing to believe what they could not demonstrate, were incapable of estimating the evidence of testimony and of circumstances, and were left in all the darkness of uncertainty on points which, to less confined understandings, were clear as the light of day. A less questionable advantage of mathematical knowledge is, its subserviency to most of the other sciences. To natural philosophy, in all its branches, it is indispensably necessary. Mathematics may be called the language which that science speaks, without which scarce a principle it unfolds, or a fact it communicates, can be properly understood. When our pupil, therefore, has acquired a competent knowledge of mathematics, let his attention be directed to natural philosophy, which will open to him a wide field of entertainment and instruction, and tend wonderfully to expand the powers of his mind. What employment
can be more interesting, or more worthy of a rational being, than to investigate the laws by which the universe is regulated, to describe the phenomena which result from these laws, and to trace them back through the long chain of causes, which may have contributed to produce them? Such an exercise will necessarily form the mind to habits of accurate and persevering observation; of patient enquiry, of abstract speculation, and of correct reasoning. While it restrains the thoughts within the limits of reality, it at the same time affords abundant scope for the most sublime conceptions, and the most excursive flights of imagination. Carrying us beyond the boundaries of sense, it weakens each selfish feeling, by interesting us in every thing around us. It is the best preparation for the study of mind; for the rigour with which its researches are conducted, and its cautious mode of reasoning by induction from ascertained phenomena, check that extravagant rage for theory, which is the bane of all science. To religion it is a most powerful auxiliary; extending our knowledge of the works of creation, and leading us "through nature, up to nature's God."

From the study of the material universe, let our pupil be conducted to the higher and more important study of the human mind. In some of our systems of education, mental philosophy is very preposterously made one of the earliest objects of the student's attention. In our Scotch universities, it is not uncommon to see lads, who should not yet have escaped the discipline of a grammar school, occupying the benches of a metaphysical class, and listening to grave lectures on the powers and operations of the human mind:—powers, which their minds have scarcely begun to exercise; operations, of which they are almost unconscious. How can boys, whose faculties are only beginning to open, be supposed capable of that reflective attention to their own ideas and emotions, often too fleeting to be arrested, too complicated to be unravelled, too faint to be perceived, which is the basis of all mental philosophy? Or, what benefit can they be supposed to derive from disquisitions on abstract subjects, of which they cannot form an idea, and which can be presented to them in no palatable shape? The inevitable, and almost the only consequence, of engaging them at so early an age in the study of what they cannot understand, is to excite their disgust, and thus to leave them in hopeless ignorance of science, which, if once by previous discipline they were prepared for comprehending it, they would have found the most delightful study, as it is the most important, in which man can be engaged. To the successful pursuit of mental science, an accurate and discriminating judgment, a clear and penetrating understanding, and a habit of correct and cautious reasoning, are indispensably necessary: the study of the mathematics and of natural philosophy is peculiarly useful in cultivating these valuable qualities, and ought, therefore, always to precede the more abstract and difficult study of mind.

One peculiar advantage of this study is, that, while it gives exercise to the highest of our faculties, it suggests at the same time the best means for improving them. By rendering us acquainted with human nature in all its parts; with its various faculties, powers, and sources of enjoyment; and the effects which are produced on these principles, by particular circumstances and situations, it aids us essentially in the proper and liberal culture of the mind, enables us to judge of our own acquisitions, and to employ the most effectual means for supplying our defects, and removing our improper habits. A philosophical analysis of the principles of the mind, is the only foundation on which can be raised a proper system of education; and as scarcely any of the existing systems are founded on such an analysis, almost every person of reflection, when he arrives at maturity, finds it necessary to begin a new course of education for himself. Now, to render that course as complete as possible, to enable him to estimate properly his attainments, and to know how to supply his defects, it is necessary that he should have an accurate and comprehensive view of his intellectual and moral powers; and such a view it is the professed object of mental philosophy to give. All the different branches of our knowledge bear a common relation to the philosophy of the human mind; and to that philosophy, of course, must be referred all our inquiries concerning the divisions and the classifications of the objects of human knowledge, and all the various rules for the investigation and the communication of truth. "As a philosophical system of logic," says Mr. Stewart, "would assist us in our particular scientific investigations, by keeping steadily in our view the attainable objects of human curiosity; so, by exhibiting to us the relation in which they all stand to each other, and the relation which they all bear to what ought to be their common aim, the advancement of human happiness, it would have a tendency to confine industry and genius to inquiries, which are of real practical utility; and would communicate a dignity to the most subordinate pursuits, which are in any respect subservient to so important a purpose. When our views are limited to one particular science, to which we have been led to devote ourselves by taste or by accident, the course of our studies resembles the progress of a traveller through an unexplored country, whose wanderings from place to place are determined merely by the impulse of occasional curiosity, and whose opportunities of information must necessarily be limited to the objects which accidentally present themselves to his notice. It is the philosophy of the mind alone, which, by furnishing us with a general map of the field of human knowledge, can enable us to proceed with steadiness, and in a useful direction; and while it gratifies our curiosity, and animates our exertions, by exhibiting to us all the various bearings of our journey, can conduct us to those eminent facts from whence the eye may wander over the vast and unexplored regions of science to which it has ascended.

While the study of mind is thus useful in teaching us how to exercise our own intellectual faculties, it is found of peculiar advantage in those arts which operate on the minds of others. The success of the poet, the painter, and the orator, depends on the skill with which they adapt the efforts of their genius to the powers and sensibilities of mankind; and a philosophical analysis of the mind is the only solid foundation for the improvement of all the fine arts. The human mind, too, is the subject on which the moralist and the statesman have to operate; and while the former endeavours to allure men to their truest happiness, by the cultivation of their noblest powers and their finest qualities, and the latter proposes to second the benevolent intentions of Providence, by diffusing as widely and as equally as possible the advantages of the social union; to each of them an extensive and accurate knowledge of human nature is equally necessary. To the moral improvement and happiness of the individual, the study of mental philosophy is still more eminently conducive. Enabling us to trace back through all their intricacy, our propensities and habits to their origin, it suggests
the best means of confirming those which are laudable, and correcting those which are faulty. Teaching us duly to appreciate the real excellencies of the mind, it guides us in our efforts for their attainment. And showing us how our happiness is affected by different modes of conduct, and by what means our excellence is promoted or obstructed, it enables us to form the most judicious plans for the regulation of our future life.

After being initiated in the philosophy of the human mind, our pupil will enter with peculiar advantages on the study of history, which will introduce to his observation, the passions, propensities, and faculties of mankind, acting on the ample theatre of the world. To a person who has made himself acquainted with the general properties of human nature, the study of history is peculiarly edifying. While it exhibits man in all possible circumstances, it enables him to refer to their true cause all the diversities of human character; and, amidst the almost boundless variety which obtains in the sentiments and modes of action that prevail in different communities, he learns to discriminate those which originate in the native and universal feelings of mankind, from those which are the result of local or national contingencies. He reaps the advantage of the accumulated experience of all nations and ages; and in the progress of states and their decline, can trace, with unerring precision, the causes of their prosperity and of their ruin. He sees the operations of Providence displayed here on the most magnificent scale; and while he compares the end with the beginning of the important transactions which history records, he obtains the most exalted and comprehensive view of those grand principles, which regulate the moral government of the Great Ruler among the nations. His ideas of society are enlarged, and he escapes from those illiberal prejudices, which the love of country, amiable as it is in itself, is too apt to excite against those who live under different governments, and in other climes. "There is scarce any folly or vice," says Lord Bolingbroke, "more epidemiical among the sons of men, than that ridiculous and hateful vanity, by which the people of each country are apt to prefer themselves to those of any other, and to make their own customs, and manners, and opinions, the standard of right and wrong, of true and false." This vanity is effectually removed by the enlightened study of history. He who is accustomed to contemplate the transactions of other nations, to view them in their mutual dependencies and connections, and to take a warm concern in all their interests, learns to consider the community to which he belongs as only a part of a still greater community; and without necessarily becoming indifferent to its prosperity and its fame, is enabled to discern the value of opinions and practices of foreign growth. To every student, however, the history of his own country is by far the most interesting. To trace the origin of those laws and institutions, to which, in common with his fellow citizens, he is subject, and of those customs and establishments by which the character of the nation is at once indicated and determined, is an employment no less pleasing to curiosity, than it is improving in its tendency. To the native of Britain, the study of the history of his own country is, in this respect, particularly important and gratifying. In no country have all the great virtues been more eminently displayed; no where has the struggle for civil privileges been carried on with more perseverance and success; liberty has here advanced through many vicissitudes and successive revolutions, to the most perfect triumph she ever obtained; protected by every security which wisdom can devise; and accompanied with all the blessings which usually follow in her train,—arts, science, commerce, pure religion, and enlightened toleration.

With the reading of history should be combined the study of political economy, and of the peculiar laws of our country, in so far as to enable us to understand exactly the extent of our respective rights and privileges, and the tenure by which they are held.

While the student is engaged in the acquisition of these accomplishments, let him be carefully trained to the practice of composition. The beneficial effects of this practice are too many to be here enumerated, and more extensive than we can easily calculate. The perfect command which it will give him of his own language, and the facility of communicating to others his sentiments and ideas, are perhaps among the least of its advantages. In whatever study he may be engaged, his progress will be more accelerated by the practice of composition, than by any other means. This will accustom him to think on every subject for himself; to ascertain exactly the extent of his attainments; and thus to advance with a steady progress towards proficiency. To write one page from his own reflections, will give him a more perfect knowledge of his subject than to read a volume. The habit of correct composition almost necessarily produces precision in our ideas, and perspicuity in our reasonings; and by obliging us to think closely, prevents us from resting satisfied with vague and superficial notions. The improvement of our taste is another effect of the practice of composition, scarcely less valuable than those which we have enumerated. He who has, learned to relish the beauties of nature and of art, has access to the most inexhaustible sources of enjoyment. It is of the last importance, therefore, to the future happiness of our pupils, to imbue their minds with an early relish for the pleasures of taste. Nor is it more essential to their happiness, than it is conducive to their excellence. A taste for what is great and beautiful is favourable to the growth of many virtues, and sanguine hopes may be entertained, that they whose minds have this elegant and liberal turn, will become conspicuous for the discharge of all the higher and more important duties of human life. There are, indeed, few good dispositions of any kind with which the improvement of taste is not in some degree connected. It increases by frequent exercise, the sensibility of all our tender and benevolent feelings; while, on the other hand, by impressing us with a deep sense of propriety, it tends to weaken all the fierce and violent emotions. To be devoid of taste, is justly regarded as an unpromising symptom in youth, indicating their propensity to low gratifications, and their incapacity for any thing but what is vulgar and illiberal.

Such are the attainments which constitute a liberal education; and such is the order, according to which, in our opinion, they ought to be acquired. But small is the proportion of mankind, whose circumstances enable them to cultivate their faculties by so extensive an education. A numerous class of men, destined for particular professions and employments, receive only such an education as seems necessary to qualify them for the situations which they are to occupy in society; and a still more numerous class, doomed to toil, almost from infancy, for a scanty subsistence, receive little or no education at all. Fortunately, men may become good and respectable members of society, without any very
extensive acquaintance with science and literature; but in whatever station or circumstances an individual may be placed, it is indispensably necessary to his respectability and his happiness, that he receive such an education as may enable him to exert the powers of his mind, and prepare him for all the duties of life. Among all classes of society, a proper education is the only permanent source of good conduct; and it is now pretty generally understood, that national prosperity and happiness depend, more than on any other cause, on the diffusion of instruction among all orders of the people. Ignorance is the parent of depravity; and most of the vices which degrade the character, particularly of the lowest class of the community, may be traced to the want of knowledge.

We are proud in having to appeal to our own country for a proof of the influence of general instruction in raising the national character. Since the establishment of parochial schools in Scotland, the people have been distinguished for their honesty, sobriety, and decency; and there is perhaps no country in Europe, as Dr Currie very justly observes, in which, in proportion to its population, so small a number of crimes fall under the chastisement of the criminal law as in Scotland. Every benevolent heart must rejoice in the prospect which the Lancastrian system affords, of the extension of the same advantages to our sister kingdom, and throughout the wide range of his Majesty's dominions. We do not mean at present to enter into an investigation of all the merits of that system, or its defects. One distinguished merit it does unquestionably possess, sufficient to recommend it to the warmest patronage of every lover of his country and of mankind,—the merit of placing within the reach of the lowest of the people the blessings of instruction, by enabling them to acquire a knowledge of reading, writing, and accounts, at an expense which the poorest can afford, and in a time so short as scarcely to deprive the most necessitous of any advantage which they might derive from the industry of their children.

EDWARDS, George, a celebrated naturalist, was born at Stratford, a village in Essex, in the year 1693; and, after receiving an ordinary school education, was put apprentice to a tradesman in Fenchurch-street, London; but before the term of his engagement was half expired, his attention was diverted, by an accidental occurrence, into a course of study altogether foreign from commercial pursuits. The library of a deceased physician, a relation of his master, having been removed into the apartment of the young apprentice, he embraced, with avidity, this unexpected opportunity of acquiring knowledge; and spent all his leisure through the day, and frequently a considerable part of the night, in perusing treatises on natural history, astronomy, antiquities, &c. Losing all relish for business, he adopted the resolution, at the expiration of his servitude, to improve his mind and enlarge his knowledge by travelling in foreign countries. In 1716, he visited the principal towns of the United Provinces; and, about two years afterwards, spent a considerable time in examining the natural productions of Norway. In the year 1719, he went to Paris, with a view to enlarge his acquaintance with natural history; but, finding the menagerie almost totally neglected, he applied his attention to the works of sculpture and painting; and made several journeys on foot to different parts of France, with no other object of being acquainted with the scenes on the Mississippi. Upon his return to England, he employed himself in drawing and colouring animals, particularly birds; and, by his assiduity and skill in this pursuit, he at once acquired a decent subsistence, and a number of valuable friends. By the recommendation of Sir Hans Sloane, he was in 1733 appointed Librarian to the College of Physicians, an office which afforded him the best opportunities of pursuing his favourite
EDWARDS.

1743, 1747, 1750, and 1751, he published his "History of Birds," in four volumes, with coloured plates and descriptions, in French and English. The last of these volumes he dedicated to the Supreme Being; an act in which his piety may be acknowledged, but of which the example is not to be imitated. Resuming his labours, he published in 1758, 1760, and 1763, three additional volumes, under the title of "Gleanings of Natural History," consisting of coloured plates of birds, fishes, insects, and plants; and thus completed a work containing engravings and descriptions of more than 600 subjects in natural history. As an artist, he was remarkable for his scrupulous exactness in copying nature. He communicated occasional papers to the Royal Society, of which he was chosen a member; and, in 1770, he published, in one volume octavo, several essays, which had been prefixed to his larger volumes, containing instructions in drawing and painting in water colours, etching on copperplate, &c. He was admitted a member of several academies in different parts of Europe; and, besides the friendship and correspondence of the great Linnaeus, enjoyed the patronage of the principal promoters of the arts and sciences in his native country. In 1769, he retired from all public employments to a small house at Plaistow, and devoted the evening of his life to the conversation of a few select friends, and the perusal of a few favourite books. During his latter years, he was greatly affected by the stone, and by a cancer in one of his eyes; but remarkably patient. Emancipated with age and sickness, he died in 1773, and was interred in his native parish of West-Ham, where a stone is erected over his grave, with a plain inscription, to perpetuate his skill as a zoologist.

He was a man of middle stature, inclining to corpulence, of a benevolent disposition and cheerful temper; an entertaining and communicative companion to persons of congenial taste with himself; but, from his diffidence and humility, little calculated to shine in general conversation. See Biog. Brit.; Memoirs of the Life of Geo. Edwards; Anecdotes of Bunyan; and New Biog. Dict. (q)

EDWARDS, Thomas, a critic and a poet, was born in London or its vicinity, in the year 1699, and received his grammatical education at Eton school. He entered upon the study of the law at Lincoln's Inn, with the view of practising at the bar; but was discouraged by a remarkable hesitation in his speech, from engaging much in the duties of that profession. He applied himself indeed from his youth rather to the cultivation of polite literature, than to the perusal of the statutes; and was, in particular, an ardent admirer of the works of Shakespeare. He first appeared as an author in 1744, by publishing a letter to the author of a late epistolary dedication, addressed to Mr Warburton, in which he attacked the critical tenets of that celebrated writer. Warburton had hinted in the preface to his edition of Shakespeare, that he had once intended to have given his readers a body of canons for literary criticism; but now referred them to what he had occasionally said upon the subject in the course of his annotations. This idea was humorously taken up by Mr Edwards, who framed a set of canons ridiculously absurd, which he illustrated by examples from Warburton's notes. This performance appeared in 1747, as "A Supplement to Mr Warburton's edition of Shakespeare," and afterwards under the title of "Canons of Criticism." It was remarkably well received by the public; and besides effectually exposing the singular aberrations of the ingenious critic in question, holds up to deserved contempt, the rash and fanciful style of critical exposition and emendation which then began to prevail. Warburton, in return, introduced Edwards into the Dunciad, in a scurrilous note upon line 567, &c. of book fourth; a retort which the latter, from the irascible character of his antagonist, might have been prepared to expect, and which scarcely deserved the indignant reply which he prefixed to a future impression of his "Canons." He produced another small piece, entitled, "An Account of the trial of the letter y alias Y," which regards the orthography of the English language; and in which he chiefly recommends attention to uniformity in spelling, and to the marks of etymology. He was more eminent as a classical scholar, and an elegant critic in the English language, than as a writer of poetry. All his pieces in this last mentioned capacity, excepting one ode, were in the form of sonnets, in the style of Spenser, thirteen of which are printed in Dodson's collection, eight in Pearch's, four in Nicoll's; and the whole of these, with twenty-seven additional, are to be found in the last edition of his "Canons," in 1765. A small tract on predestination, was published after his death. From the year 1789, till his decease, he resided at his estate at Tur- rick. He died in January 1757; and, in an inscription upon his monument in the church-yard of Ellesborough, is described as a sincere Christian, a friend to the cause of liberty, and an enemy to licentiousness and faction. See New Biog. Dict. and Biog. Brit. (q)

EDWARDS, Jonathan, an eminent American divine, was born at Windsor in Connecticut in October 1703; and entered Yale College in 1716, where he received the degree of bachelor of arts, before he was fully seventeen years of age. He gave very early indications of his genius for abstract enquiries; and in his thirteenth year, used to take the utmost delight in studying Locke's Essay on the Human Understanding. He made a rapid progress in scientific pursuits, especially in the study of natural philosophy; but was particularly attached to moral philosophy and theology, as connected with his future occupation. Having continued at college two years after he took his first degree, he was licensed as a preacher of the gospel; and, in the year 1722, he preached during eight months with much acceptance, to the English Presbyterians in New York; but, as he did not consider the circumstances of that society such as to justify him in settling as their minister, he returned to his father's house in the following spring, where he spent the summer in close application to study. In September 1723, he was admitted master of arts; and, in the following year, was chosen tutor of the college in which he had been educated, where he continued in that office above two years. In 1726, he resigned his tutorship, and was ordained pastor of a congregation at Northampton, and colleague to his grandfather, the Rev. Solomon Stoddard. In this situation he continued to labour with the greatest success and approbation till the year 1744, when his endeavours to check the dissemination of licentious publications among the young persons of his congregation, and to exercise greater strictness in admitting communicants to the Lord's supper, excited such violent disputes and dislikes, as, in a great measure, terminated his comfort and usefulness at Northampton. In the midst of the most violent and uncandid opposition, he
EDWARDS. 361

remained nearly six years longer, but was at length formally dismissed by a vote of his congregation, in which only 20 persons appeared in his favour, and more than 200 against him. During the whole of this afflictive struggle, he preserved the greatest calmness and meekness under the most injurious treatment, and, within a few years after his removal, was amply vindicated by the public acknowledgment of one of the most virulent of his accusers. He was, in short, the last minister in New England, of whom such an event could have been anticipated; and the whole transaction presents one of the strongest objections, from actual experience, to those forms of church government which empower the people to dictate to their religious instructors. In 1751, Mr Edwards was appointed Indian missionary, at the town of Stockbridge, in Massachusetts, where he was honourably supported by the Society in London for Propagating the Gospel in Foreign Parts; and where, for the space of six years, he discharged the duties of his office to the entire satisfaction of all concerned. During his residence in this retired situation, he produced the most valuable of his writings. In the year 1757, without any solicitation, and even with much reluctance on his part, he was elected to the presidency of the college of New Jersey, and removed to Princetown in the beginning of the following year. Searcely had he entered upon the duties of his office, and given testimony of his eminent qualifications, when he proposed, with the advice of the physicians, and the consent of the corporation, to be inoculated with the small-pox, which was then spreading its ravages in his neighbourhood. He had the disease in a favourable manner, and all danger was considered as past, but a secondary fever put an end to his valuable life, on the 9th of March 1758, in the 55th year of his age. He uttered very few words during his sickness, but evinced, in every stage of his disease, the most patient submission to the Divine will; and died at last with the utmost composure, as one falling asleep. Mr Edwards had a very infirm constitution of body; and, on that account, as well as from religious principle, was remarkably abstemious in his diet. He was nevertheless capable of great mental application, constantly rising about four or five o'clock in the morning, and commonly spending thirteen hours every day in his study. His usual recreation in summer was riding on his buck, or walking; and in winter he was accustomed, by way of exercise, to spend half an hour or more every day, in chopping wood with an axe. He possessed an uncommon thirst for knowledge, and read all the books, especially in divinity, that were within his reach. His own principles were strictly Calvinistic; but he drew them for himself from a thorough investigation of the sacred scriptures, and was least of all men led by the mere authority of others. He always studied with his pen in his hand, and, in this way, committed to paper many observations on almost every subject in divinity. The number of these miscellaneous reflections amounted to more than 1400, and a selection of them was published, in one volume, after his death. He was particularly careful in the composition of his sermons, which, for the first twenty years of his ministry, he generally wrote out at full length, and carrying them with him to the pulpit, usually read the greater part of what he had written. This, however, he considered as one of his deficiencies as a preacher. His mode of delivery was easy and natural, deficient in gesture, but full of solemnity. His voice was not strong, but distinct; and his words, without much noise or external emotion, were so full of meaning and expressive of inward fervour, that few speakers were more successful in commanding the attention of an audience. He was seldom tedious either in prayer or preaching, and generally employed the greater part of his discourses in the application or improvement of the subject. Unless when he was called by the sick, or heard that any of his people were under some particular affliction, he did not visit them in their own houses; because he was aware that his talent consisted in preaching and writing, rather than in teaching by conversation; but he encouraged all who desired his advice, to repair to his study, and regularly catechized the young persons and children, both in public and in his own house. He kept himself remarkably free from worldly cares, and committed the direction of his domestic concerns so entirely to Mrs Edwards, that he seldom knew even whence his table was supplied, or how many cattle he possessed. He was, however, most anxiously attentive to the education of his children; and his parental authority, exercised with uniform calmness, was productive of the most cheerful obedience. He spoke little in general society; avoided disputes in mixed companies; and was rather reserved among strangers; but, with his intimate friends, whom he selected with the greatest caution, he was peculiarly affable, communicative, and instructive in conversation,—patient of contradiction, and ready to hear every objection that could be made to his sentiments. He was distinguished by inviolable integrity in his dealings, and a sacred regard to truth in his words; uniformly impressed by a profound sentiment of piety, and characterized by an unaffected gravity of demeanour; exemplifying in practising, as he was most urgent in recommending, charity to the poor; but always inclined to conceal the amount of his alms deeds, and the exercises of his private devotions. His principal writings, besides single sermons and smaller tracts, were, "A Treatise on Religious Affections," published in the year 1746; "An Account of the Life of the Rev. David Brainerd, Missionary to the Indians, in 1749;" "An Inquiry into the modern Notion of that Freedom of the Will which is supposed to be essential to Moral Agency," in 1758; "A Defence of the Christian Doctrine of Original Sin," which was in the press at the time of his death; "A History of the Work of Redemption;" "Miscellaneous Observations;" and "Eighteen select Sermons," with an account of his life and character, which were published from his manuscripts. His writings, though expressed often in a clumsy and disjointed style, and capable of being greatly improved by judicious abridgment, have been highly valued, and extensively useful in the Christian world. He was certainly one of the greatest divines, and ablest metaphysicians, of the age in which he lived; and, whatever may be the theological sentiments of his readers, they must, if at all capable of appreciating his talents, allow him the praise of having possessed extensive knowledge of his subject; of having exercised sound judgment in his argument; and of having produced the ablest defence of the doctrines which he espoused. See General Biography, and The Life and Character of Mr Jonathan Edwards, prefixed to eighteen of his select sermons. (g)

EGYPT.

PART I. HISTORY.

Among all the ancient nations which have been distinguished in history, there is none more worthy of our notice than the kingdom of Egypt. If not the birth-place, it was the early protector of the sciences; and cherished every species of knowledge, which was known or cultivated in remote times. It was the principal source from which the Grecians derived their information; and after all its windings and enlargements, we may still trace the stream of our knowledge to the banks of the Nile. Every ancient nation lays claim to a higher origin than legitimate history can sanction; and Egypt extends its claims to a fabulous period.

Antiquity of Egypt.

To extend the existence of Egypt as a nation to more than a hundred thousand years, is evidently fictitious; and the period 478,000 at Babylon, or 1,907,000, with more extravagant calculations still, which are found in the Indian chronology, are sufficient to convince us, that the pretensions are excessive, and the calculations untrue. There is a degree of vanity which every nation feels over its origin and its honour; and to this may in some degree be ascribed the extravagant claims of ancient nations. But this tendency is not sufficient to account for the inconceivable pretensions of Egypt, Chaldea, and Hindostan; nor are we certain that we shall be able to point out precisely the source of such claims. As Egypt was anciently divided into different kingdoms, the reign of cotemporary princes might be stated in traditionary history, as the reign of successive kings; but even this is quite inadequate to account for the incredible length of years, to which their pretensions extend. We have heard of a poetical and solar method of calculation in the East, in which a thousand years of the former are only equal to one of the latter. The Caliyoug of the Indian astronomers is clearly an imaginary period, as well as many other times and calculations so often alluded to in the ancient annals of the East.

It is impossible to ascertain correctly the circumstances which gave rise to these modes of reckoning, or the occurrences which from time to time enlarged or changed them; but we may easily believe, that, having once departed from the plain path of rigid calculation, they would branch out into many bye-ways, according to the ignorance, the fashion, or the fancy of the times. It appears that the earliest mode of reckoning was by the appearance and departure of the sun, when the evening or the morning marked the conclusion of a day. The changes of the moon, too, were periods of calculation. The revolution of the moon, and that of other planets whose courses were of short duration, appear to have been denominated years; as were also the terms of three and of four months. We speak not of the distinctions between the lunar and the solar year; for that was a mode of reckoning comparatively of recent date, and not once to be named among the circumstances, which have contributed to occasion the extravagance and uncertainty of remote calculations. But whether we have ascertained the true sources of those incredible pretensions, or even approximated their genuine causes, yet there cannot remain a doubt that their history is fabulous, and cannot be explained by the present modes or measures of reckoning. The want, or very imperfect method, of recording ancient facts, leaves us without the means of entering completely into their history; and we must content ourselves with partial inductions, or even with probable conjectures.

Menes is the first king of Egypt who is presented to our notice; but the circumstances of his reign distinctly imply, that the age in which he lived was an advanced period of the Egyptian history. The arrangements which he made did not belong to rude times; the wealth and the luxury of his court, were far removed from the savage state, and the magnificence which he introduced into the services of religion, manifest an improvement in the arts, and a progress in the splendour of society. Sir Isaac Newton ascribes to him the building of Memphis, which was not founded, or at least not famous, in the time of Homer; for it was Thebes and not Memphis which he celebrated as the glory of Egypt. Norden supposes that the latter was adorned from the ruins of the former; but even if this be true, it would not imply that Memphis was un-built till Thebes was in ruins. It will only shew, that, as the ancient capital was deserted, the new city was adorned with some works of art, which had been admired in the city of Thebes.

The imperfect state of the Egyptian history, in the period under review, is further apparent, from the deficiency of its annals immediately after the time which we have supposed to have been filled up by the reign of Menes. A list has been presented of 330 kings, many of whom were probably cotemporaries, and not a few of them perhaps imaginary. For if the reign of Menes was in some degree described, and did exhibit features of eminence and improvement, it is not likely that a period in immediate succession would be so void of information, and bear so many marks of romance and fiction. From the 1400 years which is fancifully ascribed to this interval, there is scarcely a circumstance which could claim attention, by any promise of entertainment or knowledge. For the story of the Shepherd kings, which seems to be connected with this place, is too obscure and undefined to excite much interest, or merit much notice. It cannot, however, be altogether passed over, as it is evidently entwined with the history of Egypt.

Various conjectures have been formed concerning that race of obscure kings; and some have supposed that it is the history of the Israelites in Egypt, misrepresented by fable, magnified and deformed by the uncertain traditions of ancient times. But the history of that people in Egypt has no resemblance to a reign of kings. In the time of Joseph, they must have had influence at the court of Pharaoh; but their subsequent condition in Egypt was a state of degradation, and affords a tale of misery and oppression. The Shepherd kings must have been cruel and severe, for their memory was detested; and their reign must have been previous to the abode of the Israelites in the kingdom of Pharaoh; for when Jacob and his sons went down into that country, a shepherd was an "abomination to the Egyptians."
Osyman-
dias.

It would be fruitless to fatigue ourselves with con-
jectures about the name or race of that people who invaded
and over-ran Egypt, and whose governors are denomi-
nated Shepherd kings. They must have been an un-
polished race of men; a wandering and unsettled tribe of
warriors, whose habits of life had not risen above the pas-
torial state. Being intruders, they must have been unwel-
come in the land of Egypt. Different in their manners,
rude and unformed in their habits, their conduct and prac-
tice must have been abhorrent from the milder manners of
a more polished people. Severe in their habits, and cruel
toward a conquered nation, their yoke must have been gal-
ling to a subdued and an oppressed people. Their de-
li
erance from so afflicting a thraldom must have been de-
lightful, and the memory of their sufferings would be
depth and lasting. The vast number of years during
which they are said to have held Egypt in bondage, was
a period which could not be reviewed but with distressful
remembrances, and the names of their oppressors must
long have been detested.

Osymandias is the next Egyptian king whose history
has assumed any probable shape; and yet the narrative
of his reign is doubtful and imperfect. While he was
upon the throne, the city of Thebes was still in its glory,
and some of its most remarkable ornaments are attribu-
ted to this prince. His palace was an edifice of exquisite
workmanship; and in the manner of those times, it was
of vast extent. In front there was a court of an immense
size; adjoining this space there was a portico of 400 feet
long, the roof of which was supported by animal figures
of fifteen cubits high. This portico led into another court
similar to the first, but much superer. Here, among other
ornaments, were three statues of vast size, which is alone
sufficient to shew the antiquity of Osyman-dias' reign.

In the infancy of science, every thing is vast; and
to command admiration among the uncultivated, immensity
is better calculated than beauty, deep design, or elegance
of workmanship. These statues are said to have repre-
ented Osyman-dias and some of his family; but this is
of little importance to the history of those times, which
leads us to approximate the period of society in which
Osyman-dias lived, by the state of literature and science
which belong to the period of his reign. Sculpture and
the art of building had evidently arrived at considerable
improvements. For the style of architecture, as well
as the art of the statuary, which the ruins of Thebes have
disclosed, have justly commanded the admiration of the
curious and discerning. There were other courts, and
other porticos, together with piazzas, halls, and galleries,
which excelled in workmanship as well as in extent.
There the chisel had sculptured, with wonderful art, the
triumphs of the king, the sacrifices which he offered, the
administration of justice in the courts of law, and many
other emblems of his transactions and reign. But his
tomb has been celebrated above all other buildings at
Thebes; and it has been chiefly remarkable for the em-
blems of astronomy which it bore. It was encompassed
with a golden circle of 365 cubits in circumference, to
represent the number of days which were then included
in the year, and shews that the solar year was not then
distinctly understood. Here the rising and the setting
of the stars were represented to view; various parts of
the ceiling in the public buildings of Osyman-dias were
painted blue and bespangled with stars, to exhibit an idea
of the firmament; and a hall was stored with the most
valuable writings of those times, and was significantly
denominated the dispensary of the mind. From the
whole it appears, that the reign of Osyman-dias, though
remote and not accurately defined, was in a period of
considerable improvement.

His lineal descendants are said to have reigned in Egypt
during the course of eight generations; but their trans-
actions, and even their names, are not distinctly known.
Uchoreus was the last of that race; and in his time the
city of Memphis appears to have become the successful
rival of the ancient and venerable city Thebes. It is in-
deed added, that he transferred the abode of the Egyp-
tian kings from Thebes to Memphis.

Passing by other sovereigns, who are rather alluded to Meri-
than specified in the conjectural parts of this history, we
shall take notice of Meris, who would probably have
been left in the same obscurity as many other ancient
kings of Egypt have been, had not the lake which bears
his name preserved his memory. That work of stupen-
dous labour will be adverted to in a subsequent part of
this article; and it may be considered as a remnant of
those mighty works which Meris did to aggrandiz his
kingdom. He adorned the temple of Vulcan at Mem-
phis, and must be supposed to have been the author of
many important improvements, which have been lost in
the lapse of time, and forgotten among the changes of
early and obscure events. He was the 330th king from
Menis; and the immediate predecessor of Sesostris,
whose history is now to claim our attention.

Sesostris is known by various other names, according
to the variety which different languages and other cir-
cumstances are calculated to produce, such as Sesonchis,
Sesoasis, and Sesothis. He has also been supposed to
be the Sesac or Shishak who took Jerusalem in the reign
of Rehoboam; while others have supposed that he was
the Pharaoh who reigned in Egypt, and who was drow-
red in the Red Sea, when pursuing the Israelites to bring
them back; but these are conjectures, and not historical
facts—they may amuse, but they cannot instruct. Under
the pretext of a dream, his father adopted measures
which, in his view, were calculated to furnish his son
with certain means of conquest and power. Exercising
the influence which he seems to have possessed, he col-
clected a number of youths of the same age with his son,
and trained them up together at his own expense, that
they might be attached to the person of Sesostris; and
that, by being trained up in a hardy and active manner,
they might be able to brave dangers, and be the means
of honour and aggrandisement to his son.

Having made successful inroads into Arabia, and be-
ing led to put confidence in his own resources and skill,
Sesostris returned into Egypt, and devised measures for
such campaigns and conquests as have perpetuated his
fame. Being resolved to take the field in person, and
having the prospect of being a long time absent from his
kingdom, he adopted prudential means for preserving
tranquility while he was abroad. By promises and sal-
atory arrangements, he attached the army to his inter-
rest; and he provided carefully for the internal peace
of the state. He divided the empire into 36 provinces,
and having appointed a governor to each, he constituted
his brother regent of the kingdom, with supreme power
till he himself should return. He fitted out two fleets,
one in the Mediterranean, and the other in the Red Sea.
With the former he conquered the islands of Cyprus, to-
gether with several islands of the Cyclades, and the whole
coast of Phoenicia; and with the latter he secured the
Red Sea, and entered the Indian ocean.

His army was in great force. It consisted of 600,000
EGYPT.

EGYPT.

Sesostris II, or Phœnus as he is sometimes called, scarcely deserves to have his name mentioned in history; for his life was inactive, and his reign inglorious. Like the former Sesostris, he was seized with blindness; but by patience and proper remedies his sight was restored. We give no heed to the fabulous manner in which his cure has been represented; blindness appears to have been of old, as it is now, a common disease in Egypt. Now a period fruitful of no authentic information occurs again in the history of Egypt; for here and there are only some casual and ill ascertained spots of verdure transiently appearing amidst a vast succession of ait wastes. About this time, though we cannot speak with precision, we may venture to suppose, that the Israelites departed from the land of Egypt. For in the reign of Actæanes, the Ethiopian adventurer, who drove the detested Amasis from the throne, there is an obscure, and seemingly disguised account, of a foreign people being driven from Egypt toward the land of Palestine.

After a long interval we meet with Cetes, who, in the Protes or language of Greece, was denominated Proteus. He was celebrated in ancient fable, and on account of his wisdom, and perhaps his dexterity in the art of deception and enchantments, was said to have the power of changing his form. Dwelling upon the sea-shore, or perhaps encouraging commercial affairs, he was said to be a sea god. Into one of his ports Paris was driven when he was carrying off Helen from her husband Menelaus. Finding that Paris had violated the rights of hospitality, and fled with the wife of his friend, he dismissed him from his presence; but retained the fair, though faithless lady, to be sent back to her injured lord. In the mean time a war was undertaken against Troy; for the Greeks would not be persuaded that Helen was not concealed in that devoted city.

The reality of this memorable siege has been called in question by Mr Bryant; and in many respects his opinions are singular; but similar sentiments seem to be entertained by some modern travellers; or at least, they have not been able to discover the scene of those splendid actions, which have adorned the classic page, and delighted the heart of the youthful student. We believe that the fall of Troy was a real and momentous transaction, though disfigured by tradition, and short comedies embellished by the poets. It is not wonderful, that the site of Troy should not be known. Ancient cities in the East consisted chiefly of mud or very perishable cottages, except the temples and a few public buildings, which were easily overthrown in a deserted city, and even their fragments sunk or carried away.

To Proteus succeeded Rhampaulius or Remphis, who would scarcely deserve our notice, if he had not been the son of the last king, and raised to the throne in due order of succession. He is represented as having been excessively attached to riches; and as having erected an expensive building for the reception of his treasure. In times like those in which he reigned, it is natural to believe that means would be employed to spoil him of his wealth; but the story of Herodotus concerning the device of the architect for giving himself a private mode of access to the king's treasure, and other circumstances attending the abstracting of his money, are unworthy of record. Snares might be laid to detect the offender who had plundered the King, but that one brother should cut off another's head when he was held fast, and could not escape from the trap, which was laid to discover the
offender, and that he should carry off the head to prevent a discovery, is rather fabulous than probable. Far less can we conceive, that a father, though wicked, would induce his daughter to enter into criminal intrigues to obtain from her admirers the secret of the theft. He is said to have enlarged and adorned the temple of Vulcan.

Here, again, there is a gap in the history of Egypt; and the first king, who claims our notice, is Cheops, who was also distinguished by a variety of other appellations, and is said to have erected the largest of the Egyptian pyramids. He began his reign with shutting up the temples of the gods; and forbidding every species of religious worship. He was as tyrannical as he was impious; and he oppressed the people for the space of fifty years.

His successor Cephen, or Chabryis, trode in the steps of the former king. He, too, built a pyramid with excessive labour and expense to the people, whom he had enslaved; and so much was he detested during the course of a long reign, that the place of his burial was kept secret, lest the populace had treated his remains with dishonour and indignation.

Myrcinus. Myrcinus, or Cherinus, the son of Cheops, detesting the injustice and impiety of his father, pursued a different and an amiable course. He honoured the gods, threw open the temples, and encouraged sacrifices to be offered. He delivered the people from every species of tyranny, and restored to them a life of tranquillity and freedom. He tempered the severities of the law, and was in truth a benevolent father to his people. But while he was diffusing happiness around him, and all classes of society were enjoying the fruits of his benevolence, a heavy and domestic calamity befell himself. The death of a favourite daughter threw a gloom over every object of nature, and appears to have affected the strength and steadiness of his mind. Her sepulchre seems to have been adorned with much splendour, and her memory to have been preserved, by the frequently occurring observance of solemn and impressive rites.

The honours, which were ordained in remembrance of his daughter, appear to have been connected with some sacrifices or offerings of respect to the god Apis; and upon these circumstances, a fabulous story seems to have been invented, about the manner of the princess's death, and the whole scene was represented before her tomb. The king himself appears to have been affected in the exercise of his intellectual powers; for he abandoned his former quiet and virtuous mode of life, and gave himself up to every species of riot and intemperance. It is said also, that he too built a pyramid, and inscribed his name upon its northern front.

The first king who is mentioned in the Egyptian history, after the preceding sovereign, is Gnephactus, who is of no celebrity in the annals of his country. His manners were simple, and his abstinen ce proverbial. The luxury of his time appears to have been excessive; and its tendency was the more alarming to his mind, when he brought it in contrast with his own moderation. The beginning of those luxuries, of which, we presume, he justly complained, was ascribed to the reign of Menes, who introduced many valuable improvements of civil life; and who, along with these, gave a currency perhaps to many indulgencies which had risen to excess. It is said, that with the approbation of the priests and courtiers, a curse was pronounced upon the memory of Menes, and the curse inscribed upon a pillar.

What effect the proceedings of Gnephactus had upon the dissolute manners and habits of the Egyptians, we are not informed; but his son and successor, Bocchoris, was a prudent prince, and appears to have adopted such measures, as were best calculated to correct the excesses of which his father complained. He introduced the best regulations into every branch of police; and administered the public revenues with judgment and moderation. He was accounted one of those princes, who properly deserved the name of legislators in Egypt; for he improved its domestic economy, and enlarged its foreign relations. Like the Chinese, the ancient Egyptians resisted an intercourse with other nations; but this hurtful prejudice had gradually given way under the administration of different kings; and Bocchoris gave his aid towards the removal of so pernicious a restraint. He encouraged commerce, and promoted the general happiness of his kingdom. But in the midst of these valuable improvements, he was attacked by Sabacco, a prince of Ethiopia, by whom he was overthrown in battle, and having been made a prisoner, was inhumanly put to death.

Though Sabacco ascended the throne of Egypt by a striking act of cruelty; yet when he had attained the sovereign power, he was remarkable for clemency and conciliating manners. But he never appears to have reigned in the affections, or with the consent of the nation. In particular, the priests were hostile to his government; and we are told in the legends of those times, that he was warned in a dream to destroy the priesthood, if he wished to remain king of Egypt. But we are rather to believe that he found the nation unfriendly to his authority; and as the priests were then the nobles and most powerful persons of the kingdom, and inimical to his reign, he had probably conceived a plan of putting those enemies to death, by a sudden and unexpected attack, and thereby overawing the people to submission; but either from principle or fear, abandoning so desperate an undertaking, he abdicated the throne, and retired into Ethiopia. He is supposed to have been the So of the scriptures, who entered into a league with Hosea the king of Samaria, to oppose and keep in restraint Shalmaneser the king of Assyria.

Sethon is the next king of Egypt, who lays claim to our consideration. He was a person of the sacerdotal order, and belonged to the temple of Vulcan. He had no warlike dispositions, nor was he at all habituated to the use of arms. Till now the soldiery had been cherished, and were a conspicuous body of men in Egypt; and therefore being neglected by Sethon, they were dispersed, and hostile to his interests. The kings of Assyria being at this time bold and successful warriors, and finding Egypt in a feeble and unprotected state, they entered that country in a hostile manner, and filled the nation with alarm. The soldiers being scattered and disgusted, Sethon's army consisted only of raw and undisciplined troops, who were unable to meet a host of victorious invaders. Semnacherib king of Assyria, with a numerous army, entered Egypt, and committed great devastations.

In this threatening and dangerous situation, when ruin was apparently ready to burst upon the head of the Egyptian king, a host of rats in one night gnawed the bow-strings and shield-strings of the Assyrian army; and being thus deprived of their weapons of warfare, they fled before the Egyptians with great slaughter. A story somewhat alike to this Egyptian representation, is handed,
ed down to us in the history of Palestine, where 185,000 men of Sennacherib's army were found dead by some sudden disaster. The better authenticated Jewish history would lead us to suppose, that the story is the same, but misapprehended and disguised in the obscurer annals of Egypt. The Babylonish Talmud supposes, that this sudden destruction was brought upon the Assyrians by the effect of lightning; while others are of opinion, that the disaster was occasioned by the sudden or hot wind of the desert, which is known to be so destructive and so sudden in its effects; and this idea seems to correspond with the language of our sacred books. " Behold I will send a blast upon" Sennacherib, and he "shall return to his own land."

But to whatever cause we ascribe the destruction of Sennacherib's army, it was equally the work of God; for all the parts and elements of nature minister to his will.

For some time past there had been a feebleness in the government of Egypt. At one time the country had been over-run and taken possession of by an Ethiopian adventurer, Tirhakah, a prince and warrior from Upper Egypt, fought against Sennacherib, and appears to have been a principal agent in driving him from the country; Setbon seized upon the kingdom when there was no powerful claimant to oppose his pretensions; and in short there seems, about this time, to have been a period of misrule, when no legitimate sovereign was invested with full authority.

Upon the death of Setbon, the kingdom of Egypt was divided into twelve governments; and each of them was entrusted to a separate head. Nothing can be a more decisive proof than this, that there was no lineal prince to demand the throne; or that for some malversations in government, the reigning family had been dismissed from the sovereign power. The twelve princes, to whom the government was now entrusted, appear to have entered upon their high office, with every resolution of concord and public spirit; but, like all common alliances, the harmonious union was soon dissolved.

Psammeticus, one of the twelve, was soon raised to the sovereign power, and his colleagues were overthrown. The story runs, of an oracle having asserted, that if any of the twelve governors should offer a sacred libation in a brazen helmet, that person should ascend to the sovereign power. The story adds, that upon a festival of Vulcan, when all the twelve governors were to offer libations to the god, eleven vessels through mistake were only provided, upon which Psammeticus presented his libation with his own helmet of brass. The prediction of the oracle was remembered; and Psammeticus claimed the sovereign power.

This elevation of Psammeticus to the throne of Egypt, we presume to be contingent rather in appearance than in reality; for it was more probably a scheme, that was concerted for restoring him to the kingdom of his fathers. He was the son of Nechus, whom Sabaco, an Egyptian invader, first dethroned, and then put to death; and his pretensions to the throne appear to have been neglected during the troublesome and unsettled period, which has just been described. The claim of the ancient royal family in the person of Psammeticus would naturally be supported by the priests, who were the nobles and hereditary counsellors of state. If the story of the helmet be not a fiction, it was probably contrived beforehand by the friends of Psammeticus, to be a signal for a powerful rising and declaration in his favour, as the destined sovereign of Egypt.

But he seems to have required the aid of foreign power to place or establish him upon his throne; and his reign was distinguished by an intercourse and friendship with Greece. The soldiers of Egypt, who are said to have retired in disgust into Ethiopia, were probably the adherents of the eleven governors whom Psammeticus had deprived of their power, and the remaining supporters of the surreptitious kings, who had reigned between them and his father Nechus. The restoration of the legitimate family appears to have been the means of removing the factions and discontented from the bounds of the kingdom. Psammeticus, in order to be more secure from the dangers of intestine commotions, returned to a residence near Bubastis, on the Pelusian branch of the Nile; and, by cultivating commerce, he enriched the nation. He was not a warlike prince, for the siege of Azotus employed all his force for the space of twenty-nine years; and it is not certain, that he ever obtained it. Fearing the warlike Scythians, he entered into an alliance with that nation, and was rather desirous of peace than war. He was the first prince who introduced wine into Egypt, and he attempted to discover the source of the Nile. If, as it has been reported, he brought up two children from their infancy, till they could distinctly articulate without having heard a human voice, in order that he might discover the language which is natural to man, if this be not a fiction, it was an evidence of a vain imagination rather than a sound judgment; for whatever was the first language of the human race, it could not be the effect of any natural organic tendency to speak one language rather than another. Psammeticus commenced his reign 679 years before the Christian era.

His son Nechus succeeded him on the throne, who was called in scripture Pharaoh Necho. He prosecuted with vigour the system of navigation, which some of his predecessors had begun; and, by the assistance of Phoenician sailors, he not only investigated the coasts of the Mediterranean; but fitting out a fleet in the Red Sea, passed through the Straits of Babelmandel, doubled the Cape of Good Hope, and returned to Egypt through the Straits of Gibraltar. Owing to inexperience in naval affairs, this voyage, which could now be performed in three months, cost the Egyptians as many years. Notwithstanding what has been said to the contrary, there is no reason to doubt the authority of Herodotus, who mentions this navigation; for in those early times the Phoenicians sailed to Britain for obtaining tin. Hanno established colonies on the western coast of Africa; Sylax came from the Indus to the Red Sea; Nechus passed from the Indus to the Euphrates; and the fleets of Solomon made long voyages, in search of gold and precious merchandise.

His expectations by land were no less enterprising and grand. He made war upon the Medes and Babylonians, who, according to Josephus, had jointly overthrown the Assyrian throne; but we are rather authorised to assert, that he carried his arms against the Assyrian king himself. Josiah, who was then king of Judah, and in friendship with Assyria, refused to let Nechus pass through his kingdom; wherefore a battle was fought, in the valley of Megiddo, between him and the king of Egypt, when Josiah was wounded, so that he died. Pharaoh Necho, marching on to the banks of the Euphrates, took the great city of Carchemish; and having occupied it with a garrison, and made various important arrangements, he returned toward Egypt. Jehoshaz had assumed the royal dignity at Jerusalem upon the death of
Josiah; the king of Egypt commanded him to appear before him at the Riblah, cast him into chains, and sent him into Egypt. His brother Eliakim had his name changed into Jehoiakim, and was left tributary king of Jerusalem. But the Assyrians having been added to the Babylonian empire, Nebuchadnezzar retook Carchemish, and, seizing upon Nebuchadnezzar's other conquests, pursued him and his army to the city of Pelusium.

Besides his enterprise by sea and land, Nechus attended to the improvement of his kingdom; and, among other undertakings, he attempted to join the Red Sea and the Nile, by means of a broad and deep canal. The enterprise failed; and owing, we may presume, to experience, much money was uselessly expended, and 12,000 men were lost. After having reigned for sixteen years, this active prince terminated his career about 600 years before the birth of Christ; and was succeeded by Psammis, who only reigned six years, and left nothing of consequence for the historian to record.

Psammis, B. C. 594.

Psammis, the son of the former king, now got possession of his father's throne; but though active, he was unwise and unfortunate. The king of Judah, bearing ill the tributary condition of his country, manifested signs of disobedience, and Judea was invaded by the armies of Babylon. To oppose those mighty forces, Zedekiah king of Judah entered into treaty with the king of Egypt; but Jerusalem was overthrown, and the king, as well as the other inhabitants, treated without mercy; while one of their former kings, and many of their countrymen, were prisoners at Babylon.

The Jews were warned to put no trust in a confederacy with Egypt; and any alliance with the kings thereof was evidently precarious; because the country had been long torn by intestine divisions, and during that period, every successive monarch had found more difficulty than enough to maintain his own power and prerogatives. The prince now upon the throne does not appear to have possessed the favour of his subjects; and therefore it was rather the unsettled condition, than the deceitful intentions of those Egyptian kings, which made them unworthy of alliance or trust. This observation is clearly illustrated by the fate of Apries.

When the Lyrians were invaded by the people of Cyrene, the king of Egypt sent his assistance in support of the former; but he and his allies being overcome, his discontented subjects at home broke out into rebellion. To quell those disturbances, and reduce the people to obedience, he sent Amasis on an embassy into Egypt; but the ambassador proved faithless, and being proclaimed king by the tumultuous multitude, he assumed the royal authority. Patarbemis being sent to bring the people of Egypt back to their duty, found it impossible to accomplish his mission; but upon his return to Apries, he was dealt with as a traitor; and these severities increased the hatred of the Egyptians. Apries collected a considerable body of adherents, mingled with foreign troops, and fought a battle with the army of Amasis; but being overthrown, he was kept a while in confinement, and finally put to death. During these intestine commotions, the king of Babylon made inroads into Egypt; but plunder being his chief object, he retired from the country without further molestation.

Amasis, who had been called unexpectedly, and without any pretensions, to the throne, began his reign by attempting to improve the moral condition of the country. He appears to have lived freely, as well as sometimes riotously, while he filled an inferior station; and he was sometimes devoted to excess, even after he had ascended the throne; but he was nevertheless aware how important it is for good order, that the habits of society should be sober. To attain this end, he required every inhabitant of Egypt once a year to inform the government, by what means he obtained his living. But while he was endeavouring to establish order at home, preparations were made abroad to invade Egypt, and overthrow its government. The Persian king was making vast movements, in order to enter that country and get possession of its dominions.

We cannot ascertain the reasons of this projected invasion in the court of Persia; for while no well authenticated records remain, we cannot speak with certainty from traditional tales. It might be ambition, and it might be revenge, or a mixture of passions and motives, which incidents and unknown events might bring into action. The story runs, that instead of permitting his daughter to be numbered amongst the women of the king of Persia, he had sent Nitetis, the daughter of Apries, the former king. This affront and double dealing being discovered at the Persian court, Cambyses made war upon Egypt. Several circumstances occurred to render the invasion of Cambyses successful; and of these occurrences Amasis himself appears to have had a share. Phanes, a Grecian general of considerable note, who was engaged in the service of the Egyptian king, fled to the court of Persia, and assisted Cambyses to conduct his operations against the interest and power of his former master. Polycrates, the successful sovereign of Samos, was formerly the ally of Amasis; but the king of Egypt seems imprudently to have forfeited his favour, and he also joined with the Persian king. While these preparations and adverse circumstances were going on, the king of Egypt died, and escaped from the disasters which fell immediately upon his devoted country. In the year 523 before the birth of Christ, Psammithus, the son of Amasis, succeeded to the kingdom; and he was severely invested with the powers of royalty, when Cambyses approached the frontiers of Egypt. The new king prepared for defence, and the king of Persia laid siege to Pelusium. Taking advantage of the Egyptian superstition, the invaders placed in the front of their army a variety of dogs, cats, and other animals, which were held sacred by the besieged; and the Egyptians not daring to injure the sacred animals, the Persians entered Pelusium without resistance.

Scarcely had Cambyses taken possession of the city, when the army of Psammithus drew nigh; and the Greeks, who were in the service of the Egyptian king, to revenge the deflection of Phanes, their countryman and former general, brought forth his children into the camp, and put them to death before the eyes of their father. Then, in conformity to the Grecian manner, they tasted of the blood mixed with wine, in token of exclamation.

It was thus also that Catiline prepared his adherents for the bloody deeds, which he intended them to do. Enraged at this scene of horror, the Persians put the Egyptian soldiers to flight, and chased them with great slaughter to the very gates of Memphis. Having sent a vessel up the Nile toward Memphis, with a demand to surrender the city, the messenger and the crew were assaulted and torn to pieces. Memphis was soon after taken; the adjoining countries to the west of Egypt readily submitted to the conqueror; and now Cambyses,
in his turn, did more than fill up the measure of retaliation upon the king of Egypt and his devoted subjects. Placed in a particular situation in the suburbs of Memphis, Psammeutus was forced to behold the misery, the degradation, and even the death of some of his family, and many of his nobles. The grief was too great to permit the feelings of the king to be otherwise expressed than by expressive silence, till last of all, an intimate companion, old and infirm, was presented before him, begging his bread; and then the afflicted monarch burst into tears.

We are told that Cambyses himself was moved with compassion; but making every allowance for the rudeness and severity of the times, the conduct of Cambyses was marked with cruelty. He inhumanly scourged the priests of Apis, and increased the madness and hatred of the people, by saying that god himself. Indeed the whole government of Persia in Egypt was unfortunate and severe. The conquerors were not only disliked as foreigners; but they were hated as sacrilegious persons, and detested as cruel and unjust. Though Psammeutus was preserved at this time; yet he survived but a little while the loss of his kingdom; for either he attempted to recover the throne, and excited an alarm, or Cambyses was determined to free himself of a rival; and in a very short time he was put to death.

The ancient race of kings had now ceased in Egypt. For several successive generations, the claims to the throne had been wavering, the country unsettled, and the kingdom feeble; but Egypt was now a province of Persia, and was destined to bear a foreign yoke. This species of government, at all times unpleasant, was rendered grievous, by the cruelty and madness of Cambyses. He trampled upon the laws of their country, and violated all their prejudices and prepossessions. He insulted the dead bodies of their ancestors, which are dear to every nation, but peculiarly sacred to the Egyptians. In order to affright that people the more, he violated the remains of their patriotic king Amasis; and by every enormity insulted their feelings.

In his madness for conquest, he dispatched an army of 50,000 men from Thebes in Upper Egypt, to seize upon the temple of Jupiter Ammon in the deserts of Africa; but after suffering every hardship, and losing nearly the one half of his army, he wreaked the vengeance which should have been directed towards his own folly, upon the afflicted and despairing Egyptians. He reached Memphis at the time of a high festival, and, with that jealous violence which belongs to tyranny, he was transported with rage, and would not be convinced, that the public rejoicings were not occasioned by his disappointment and defeat. Under this persuasion, he scourged the priests, put the magistrates to death, and, with his own hand, slew the god Apis, whose festival the Egyptians were observing. But a period was soon put to his cruelty and his life; for having returned to Persia to quell an insurrection in his own kingdom, he appears to have been assassinated; or, as the incident is generally related, he was mortally wounded by his own sword, from which the scabbard had dropped, as he was eagerly mounting his horse. Thus died Cambyses, an object of hatred to his subjects, and a detested tyrant to the Egyptians.

Aryandes, to whom the government of Egypt was committed when Cambyses returned into Persia, endeavored to compose the agitated feelings of the Egyptians, and render himself in some degree acceptable; and his exertions were not unsuccessful. He was mild and gentle as a patriot governor; by consulting the sages and priests, he complied with the institutions of the country, and honoured the religious worship of their fathers. Favored with the support of the Egyptian people, he assumed the ensigns of royalty; and appears to have become formidable to the Persian power. When Darius was meditating revenge upon Greece, for the defeat which he had sustained at the battle of Marathon, he found it necessary to direct his army towards Egypt, to overthrow the influence and kingly authority which Aryandes had acquired. In the mean while, Darius died; and his son Xerxes undertook the enterprise, which his father had intended to perform; and having overthrown Aryandes, his brother Achimenes was constituted governor of Egypt.

No sooner was this arrangement made, than 300,000 men were dispatched to Greece to place that country under the power of Persia; and the whole of this mighty army was to derive its provisions from Egypt. Achimenes furnished 200 vessels of war properly manned; and a considerable body of Egyptian troops joined the Persian army. But the brave Greeks, though comparatively few in number, opposed and overthrew the mighty invaders. Upon this defeat, Xerxes returned to Persia, and having given himself up wholly to dissipation, the affairs of his government ran into confusion, and he fell a sacrifice to a powerful conspiracy. Artaxerxes, one of his sons, ascended the throne; but under his reign the Egyptians were equally oppressed, and many of them fled into different countries for safety and protection. Inarius was at that time king of Lybia; and a multitude of Egyptians invited him to their aid. They also solicited and obtained help from the Athenians; but after various results and partial successes, they were compelled to yield to superior power, and sunk again under the Persian government.

For some time after this, the affairs of Egypt remain unnoticed; but at length we find that Amyrteus, who had found protection among the sons of the Delta, had become formidable to the Persian king. During this period, Artaxerxes died, after a reign of forty-eight years, and his son Xerxes succeeded to the throne; but his reign continued only a few weeks, when he was assassinated by his brother Sogdianus; and the assassin himself was soon put to death by his brother Ochus, who assumed the name of Darius, and is distinguished in history by the appellation of Nothus, which is descriptive of his illegitimate birth. During these commotions in Persia, Amyrteus, in connection with the Athenians, marched against Persia; but at last died, or was slain in battle, when he had reigned about six years. The reign of his successor, Pausiris, was short but tranquil; and the patriots of Egypt acquired considerable strength. Artaxerxes, who was now king of Persia, saw the increasing power of Egypt, and was determined to suppress it. Achorius, who had acquired the government of Egypt, made formidable preparations to oppose the invasion, but he died in the midst of his exertions, and was succeeded by Psammuthis, whose reign was unimportant. The same may be said of Nephrenitis, who held the government but a few months; and then Nectanebus obtained the sovereign power.

Nectanebus made active preparations to repel the Persians;
When unfazed for national but literary, skilful, but Persian, but a warrior, render.

This Bugos, chos in influence being difficulty with purpose. Pherendates, a Persian, was now intrusted with the government of Egypt; and his conduct was marked by rapacity and oppression. Hitherto the severities of Persia had been warded off or mollified, by the intervening influence of a national governor; but now the people were exposed to the prejudices and cruelty of an unrelenting foreigner, though in the mean time the government of Persia was on the eve of destruction. The unfeeling conduct of Ochus towards Egypt was avenged by Bagoas, an Egyptian, who held a place of trust under the Persian king. Upon the death of Ochus, Codomanes was raised to the throne, with the surname of Darius. This feeble king was unable to maintain his power, and both he and Bagoas were soon humbled in the dust.

It was in this enfeebled condition of Persia, that it was attacked and overthrown by Alexander the Great. Persia, from being an obscure but warlike state, rose to great eminence in the scale of nations. In the days of its vigour and glory, it had frequently been the terror of Greece; and when its power declined, the Grecian states in their turn were desirous of invading Persia. Philip of Macedon had not only strengthened his country by the military knowledge and science of Greece, but he became generalissimo of the Grecian armies, and was ready to invade Persia, when he fell by the pious hand of an assassin. His eldest son Alexander was but twenty years of age; yet having distinguished himself by extraordinary talents as a warrior, and having been trained up under the care of the celebrated Aristotle, he succeeded his father in commanding the confederated army of Greece. He marched into the Persian dominions, and was no less successful in gaining the affections of every country which he entered, than he was in conquering the armies whom he engaged in battle.

In returning from Persia, he passed as a conqueror through Syria, took Sydon, and compelled Tyre to surrender. Continuing his march, he was received in Egypt rather as a friend than a conqueror; but his vanity led him to the temple of Jupiter Ammon, where he was declared to be the son of that deity. When he returned into Egypt, he founded the city of Alexandria, as a good commercial station, and connected it by canals with the river Nile. On the eve of his departure, he invested Dolopes, a native Egyptian, with the sovereign power, and he carried along with him the affections and the regret of the Egyptian people.

Returning into Persia, he became master of Babylon, Susa, and Persepolis, while Darius was treacherously murdered; and after a few struggles, the great and celebrated empire of Persia was dissolved. But the termination of his own life drew nigh; for returning to Babylon, he expired in that city, amid the revels of feasting and wine. It has been suggested, that he died by poison, which had secretly been administered amid his draughts of pleasure and excess; but whatever might be the cause of his death, he was prematurely cut off in the 32d year of his age. An event so unexpected, and such extensive conquests left without a head, naturally occasioned consternation, mingled with ambition, among the principal chiefs of Alexander.

After a pause of several days, Aristides, the brother of the late king, was raised to the throne; and if Roxana should be delivered of a son, it was appointed that he should reign along with him, to the exclusion of his brother Hercules, who was born to Alexander by the daughter of Darius; but these arrangements were of short duration; for Perdiccas, who had been a favourite of Alexander, assumed the regency, trusting to his address and influence for the establishment of his power. But this step raised violent commotions among the generals of Alexander; and after a battle which was fought in Phrygia, the empire of Alexander was divided into separate portions. Ptolemy Lagus, who was afterwards denominated Soter, was entrusted with the government of Egypt.

It was in the year 368 that Ptolemy took upon him the sovereign authority in Egypt; and though he was not till afterwards honoured with the name of king, yet he was under no control, and he exercised his power for the good of the state. Having added Palestine, Syria, and Phoenicia to his new dominions, he proceeded to acquire Cyprus, which abounded with wood, for the building of ships; but he was interrupted in these proceedings by the invasion of Antigonus, whose capital was Babylon, and whose possessions were immense. He made a successful inroad into the dominions of Ptolemy; and Gaza, Joppa, and Tyre, were subdued. After various struggles, and interchanging successes between Antigonus and Ptolemy, the former was slain in battle, and his son Demetrius, after various reverses, was taken a prisoner of war, and retained a captive till he died. Ptolemy Soter was of a literary character, as well as a skilful and intrepid general. He wrote the life of Alexander the Great, which was lost amid the ravages of time; but from comments and observations which remain, it appears to have been elegant and much esteemed.

His taste for literature, and his love of science, appeared in the exertions which he made to promote knowledge and enquiry. He founded a college or museum, which became the asylum of learned men, and he formed a library, to assist the cultivation of science. Among the men of learning who flocked to Alexandria upon the invitation of Ptolemy, was Demetrius Phalaris the Athenian. He was a wise and a favourite governor in that city; but upon Athens being taken by Antigonus, the people received the conqueror with extravagant demonstrations of
joy, and they banished Demetrius with threatenings of death. In this situation he fled to the court of Ptolemy, deeply afflicted with the changeable temper, the ungrateful and hasty proceedings of the populace, when the government is invested in their hands. The accomplished Demetrius took charge of Ptolemy's library, and assisted his royal master in literary arrangements.

The munificence of Ptolemy was manifest in the splendid buildings of the museum, as well as in the magnificent temple which he reared for Serapis in Alexandria, and in the watch-tower of Pharos, which he constructed for the commercial interests of the country. In the mean time, Ptolemy Soter was far advanced in years; and, by the influence of his favourite wife Berenice, his son Philadelphus was nominated his successor, to the prejudice of Ceraunus his eldest son.

Ptolemy Philadelphus obtained full possession of the throne, upon the demise of his father; and his accession was celebrated with uncommon splendour. At this time the empire of Asia was engaged in war, by Seleucus and Lysimachus, the only surviving generals of Alexander the Great. Ceraunus, the elder and disappointed brother of Ptolemy Philadelphus, had left Egypt, either from choice or necessity; and he took an active part in the wars which were subsisting between Seleucus and Lysimachus. By his artifice, the ruin of Lysimachus was accomplished; and then he put Seleucus to death with his own hand. Having perpetrated these deeds, and being supported by a multitude of adherents, he obtained the throne of Macedonia; but just retribution soon overtook him, for he was slain in battle, and his dead body was treated with indignity.

During the reign of Philadelphus, the Romans attracted the public notice, in their disputes with the city of Tarantum; and the king of Egypt solicited their friendship. Hence a close alliance was formed between the courts of Rome and Alexandria. Ptolemy Philadelphus attempted to assist the Greeks, when they were invaded by the Macedonians; but the assistance he granted was unsuccessful, and his affairs at home assumed a gloomy aspect. His brother Magas, who was governor of Lybia and Syria, took advantage of his perplexing condition, and, by the assistance of his father-in-law Antiochus Soter, king of Upper Syria, he attempted to wrest the kingdom of Egypt from the hands of Ptolemy Philadelphus. During these preparations, and while the king of Egypt was employed abroad, there was a revolt in the bosom of his kingdom, by 4000 Gauls whom he had employed in his service; but overcoming all these difficulties, he finally established his throne. From fear, or a sense of duty, his brother Magas was desirous of being at peace with Ptolemy; and, as a bond of union, proposed that his daughter Berenice should be united in marriage to Ptolemy the son of Philadelphus, that the possessions of both brothers should at length centre in one family. This proposal was carried into effect; but in the mean time Magas died, and did not see the marriage solemnized. This settlement was opposed by Apamin, the mother of the young princess; and she stirred up Antiochus Soter to declare war upon Egypt. But the threatening storm passed away, and Ptolemy Philadelphus was left at peace.

This sovereign of Egypt built many cities, and erected various temples. He had even a share in constructing the celebrated Pharos of Alexandria; for that watch-tower was built in the latter end of the former reign, when he was united with his father in the kingdom. He finished the canal from Suez to the Nile, and watered the deserts of Lybia by reservoirs and ductile streams. The court of Philadelphus might be called the seat of learning and politeness; for strangers and the unfortunate were received with courtesy, learning flourished, and books were increased. But where is the perfect character? and we find a considerable stain upon the conduct of Ptolemy the Second. Demetrius Phalaris, the friend and confidant of his father, had counselled the old king not to retire from the government, and to nominate his eldest son Ceraunus to the succession. A different destination was obtained, as we have seen, by the influence of Ptolemy the Second's mother; and the young prince, not forgiving the counsel of that venerable man, cast him into prison after the death of Ptolemy Soter, and suffered him to die by the bite of a scorpion. Philadelphus at length being far advanced in years, and much afflicted by the death of his Queen Arsinoe, sunk under the infirmities of his constitution, and only survived her a few months.

Ptolemy III, and eldest son of the late king, was invested with the powers of government; but his reign was opened with a severe though prosperous war. No sooner had Antiochus the king of Syria heard that Ptolemy Philadelphus was dead, than he divorced the Egyptian Princess Berenice, and dismissed her with her infant son. Having recalled his former Queen Laodice, she shewed herself unworthy of the favour, for she conspired against the life of her indulgent husband; and upon his death raised her eldest son Seleucus Callinicus to the throne of Syria. No sooner were these proceedings known at the court of Egypt, than Ptolemy marched with an army to avenge his sister's wrongs; but he was too late to save Berenice's life. The conduct of Laodice, however, had rendered her odious to the Syrians, and Ptolemy inflicted upon her the reward of her crimes. Seleucus was banished from the kingdom, and the dominions over which he reigned submitted to the power of the Egyptian king.

In process of time, Seleucus recovered some of his revolted possessions; but in attempting to regain the whole, he was defeated by Ptolemy, and forced to retire to Antioch without an attendant. To deliver himself from this situation, he applied to his brother Antiochus, who had then the command of an army, which he had attached to his interests; but having made peace with Ptolemy, his brother was dissatisfied, and opposed the interest of Seleucus. But his brother Antiochus was reduced by a series of calamities; and Seleucus having acquired additional power, endeavoured to overthrow the rising influence of Arsaces. This man being governor of Parthia, took advantage of the disasters which were prevalent in the kingdom; and he attached to his interest many of the soldiers, as well as of the people. It was in vain that Seleucus attempted to counteract his influence; and he laid the foundation of the famous Parthian empire, which continued in the family of Arsaces for many generations.

Ptolemy III was a successful as well as a warlike prince, and, as appears from a monumental inscription, he not only subdued the provinces which lie on this side of the Euphrates, but crossed that river, and conquered Mesopotamia and various small kingdoms, which extended as far as Bactria. As he was returning from this expedition, he visited Jerusalem, which was then tributary to Egypt; and, amidst many expressions of affection for the people of Judea, he offered up sacrifices to the God of Israel. Onias, the high priest, had neglected for many years to pay the tribute, and soon after his return
to Egypt, Ptolemy sent a messenger to demand the ar-
rears. But indeed the tribute of Phcenicia and the neigh-
bouring provinces had also been neglected, and a sum-
mons was everywhere issued requiring payment of the
debt. Deputies arrived from various places to obtain an
accommodation; but Joseph, the nephew of the Jewish
high priest, discovered so much integrity and unaffected
plainness of dealing on his mission, that he not only ob-
tained the most favourable terms for his country; but
was also entrusted with the power of levying the tribute
from all the adjoining provinces.

Ptolemy had raised the kingdom of Egypt to a very
commanding height of power; for, besides his immense
influence by land, he was powerful at sea, and had ex-
tended his conquests to the straits of Babelmandel. His
assistance was requested by the members of the Achaean
league; but Aratus having formed a connection with
Antigonus of Macedon, Ptolemy was offended, and lent
his aid to Cleomenes king of Sparta. But his new ally
being defeated and overthrown in the battle of Sellasia,
flled into Egypt, and received protection. Amid the spoils
which Ptolemy acquired in his Eastern conquests, be-
sides immense sums of gold and silver; he recovered a
prodigious number of statues; gold and silver shrines
and images, which Cambyses had carried away from the
temples and palaces of Egypt. These valuable and re-
vered relics Ptolemy returned to their proper places;
and hence he was stiled Euergetes, or the Benefactor.

While Ptolemy Euergetes was absent on these expe-
ditions, his affectionate Queen Berenice was alarmed for
his safety; and vowed, if he should be restored to her
wishes, she would consecrate her hair in the temple of
Zephyrium. Ptolemy returned, and the sacrifice was
made; but by some accident, the consecrated hair was
lost. The king was offended, and the priests were in
danger; for the female hair was the chief ornament of
the Egyptian as well as the Eastern ladies; and the sa-
crifice had acquired an additional value, because it was
consecrated as a monument of Berenice's affection for her
lord. But the superstition of the times, and the address
of Conon, the celebrated mathematician of Samos, de-
dered the priesthood from their fear. In those days,
heroes were deified, and sometimes had a place assigned
them in the starry heavens; but Conon's fancy took a
wilder flight, and affirmed, that the consecrated hair of
Berenice had been translated to the firmament, and com-
pared the seven stars in the tail of Leo.

Ptolemy Philopater, whose father Euergetes died in the
27th year of his reign, ascended the throne of Egypt in
due order of succession. Toward the commencement of
his reign, Antiochus, the King of Syria, attempted to wrest
from the hand of Ptolemy, the eastern provinces, which
had so long been objects of contention. In this, however,
he was disappointed; and if the new king of Egypt had
possessed the vigour and genius of his father, he would
have driven Antiochus entirely out of Syria. But he
was deeply immersed in pleasures, and, by excesses of
dissipation, lost his dignity, and paved the way for re-
bellion at home. His queen, Arsinoe, was distinguished
for military ardour; and having accompanied her lord
to the field of war, she frequently shewed her spirit, by
riding along the ranks, and animating the men to battle.
And though the armies of Ptolemy obtained several vic-
tories, and the kingdom of Egypt suffered no diminution of
extent; yet it became feebie at home, and the present
reign terminated in the midst of disorders.

When Ptolemy was at Jerusalem, he attempted by
force to enter into the most holy place of the Jewish
temple; into which none but the high priest, and that
only once a year, was permitted to enter. Being for-
cibly prevented from accomplishing a wish, which was
sacriliege in the eyes of the Jews; he became frantic with
rage, and returned to Egypt, determined to wreak his
vengeance on the Jewish people, who had hitherto en-
joyed many indulgences in the kingdom of the Ptolemyes.
He instantly published a decree, putting every Jew with-
out the protection of the law, who should refuse to com-
ply with the rituals and substance of the Egyptian wor-
sip, and at the same time he offered protection and ho-
ners to those who should worship the gods of Egypt.
Few of them were indifferent or profane enough to for-
sake the religion of their country; and his wrath rising
to a greater height, he resolved to extirpate the whole
Jewish people.

For this cruel purpose, he commanded those of Alex-
andria to assemble in the Hippodrome or place of public
diversion; and he collected 500 elephants for the de-
struction of that devoted people; but these enraged ani-
mals rushed upon the crowd of spectators instead of the
Jews; and many who had assembled from curiosity were
put to death. In short, the reign of Ptolemy was alto-
gether feeble; and the latter part of it unjust and cruel.
The affairs of Greece were now placed in that situation,
that Cleomenes, the king of Sparta, conceived it to be a
proper time for him to return and retrieve his affairs.
He had continued in Egypt from the reign of the for-
mear king, with many professions of affection, and pro-
mises of aid; but his request was now absolutely refused,
and he was treated with severity by the Egyptian go-

gernment. Frantic with disappointment, and mad with
despair, he attempted to instigate a rebellion in the ca-

cital of Egypt. Having acquired some adherents, he

sallied forth into the streets of Alexandria; but being

drowned by the guards and soldiers, many of them

were slain; and those who survived, put one another to
death, in order to avoid public disgrace.

Besides his unfeeling conduct in refusing assistance to
Cleomenes, his reign is tarnished by many cruel acts.
Soon after his accession to the throne, his brother Ma-
gas and Berenice his mother were basely put to death.
His wife Arsinoe was so completely disgusted with the
conduct of the king and the court, that, after having tried
every scheme to rectify the public and private abuses,
she prayed that an end might be put to her existence.
The wicked Sosibes, who was the king's favourite, de-
vised means for complying with her demand; but it is
not to be supposed, that he durst have ventured upon
such a step, if he had not been well assured, that her
death would be acceptable to the king his master. Pto-
lemy Philopater sunk at last under a ruined constitution,
and died in the 87th year of his age.

Ptolemy Epiphanes, the only son of the late king,
was but five years old when his father died; and it re-
quired some skill, as well as bold efforts, to protect him
from dangerous designs, and fit him for the important
station which he was destined to fill. Agathocles at-
tempts, upon the death of the king, to have the ma-
agement of the young prince, and the direction of pub-
ic affairs. For this purpose, she called to her aid her
brother Agathocles, and engaged their creatures and mi-
nions in the service; but the indignation of the people
was roused by so base an attempt. Agathocles was the
favourite of the late king, and was not considered as
innocent of the despair and death of the queen. There- 
fore she and her unworthy associates fell victims to
the popular fury, and the young prince was proclaimed
king.
In the former reign, the Romans had renewed their
friendship at the Egyptian court; and the adherents
of young Ptolemy on this occasion applied to Rome for
assistance and direction. This was the more necessary,
because the infancy of Ptolemy required protection;
and because Antiochus and Philip of Macedon had
determined, in the feebile state of the Egyptian
government, to dismember that empire, and divide it amongst
themselves. The aid of the Roman government was
given with readiness and effect. An ambassador was sent
from Rome to each of the confederated hostile kings, and
M. Aemilius Lepidus hastened to Alexandria to manage
the affairs of the Egyptian court. Having placed them
in a state of proper direction, he returned to Rome,
and set the prudent Aristomenes at the head of
the Egyptian government. Finding the Egyptian army
disorganized, as well as the court dissolved in dissipa-
tion, he resolved to inspire a new spirit into the soldiery;
and for this purpose, he engaged in the service of
Egypt 6000 Grecian troops, under the command of
Scopas, a general of Ætolia.
The Macedonian king having been invaded and kept
in check by the Roman armies, had neither the means
nor the opportunity of annoying Egypt; but Antiochus,
the king of Syria, seized upon Palestine, together with
the adjoining provinces, which had been conquered
by Ptolemy; and though he was driven back by the troops
of Scopas, yet he recovered his former conquests. With
the apparent view of a permanent friendship with
Egypt, he proposed to bestow his daughter, Cleopatra,
upon the young king, and to give, as her portion,
those provinces, which had been so long objects of con-
tention and war between him and the Egyptian king.
But nothing could be more remote from his intentions
than the serious fulfilment of this proposal; for his nu-
merous successes had fed his ambition, and he seemed
to aim at universal monarchy.
Upon a report prevailing that Ptolemy Epiphanes was
dead, Antiochus sailed with a fleet to invade the country;
but the news was unfounded, and he directed his course
to Cyprus. Here he was repulsed, and escaped with
but a small remnant of his fleet. The Romans obser-
ving the views of Antiochus, and being desirous of ex-
tending their own dominion, attacked this sovereign
with consummate skill, and forced him to surrender
not only his conquests in Europe, but to abandon all
that part of Asia Minor, which lay to the west of
Mount Taurus. After the Egyptian king had taken
the reins of government into his own hand, he received
the daughter of Antiochus in marriage; for the Syrian
king wished to strengthen his hands against the en-
croaching power of Rome in the East. But Ptolemy
was feeble at home, and inefficient abroad. He renewed
an alliance with the Achaean league; but his whole
reign was a series of disasters. The king was corrupt,
and the people were disaffected; the court was treacher-
ous, and his generals were insinuere. Under Scopas
the Eolian, one conspiracy was formed, and though it
was detected, another more formidable was contrived;
and though it too was discovered and overcome, yet the
seeds of discontentment and revenge were so cherished
by the perfidy and violence of the king, that his ene-
mies increased, both in numbers and resolution, till he
was cut off by poison in the 29th year of his age.

Upon the death of Ptolemy Epiphanes, Queen Cleo-
patra assumed the regency; for her son, the heir to the
throne, was but six years of age. Her firm and judi-
cious conduct rendered the administration of public
affairs quiet and successful. The disputes between
Syria and Egypt, were either temperate or wholly sus-
pended; for Seleucus, who had succeeded his father,
was the brother of Cleopatra, who managed the affairs
of Egypt. But Seleucus died, and was succeeded by
his brother Antiochus, who assumed the surname of
Epiphanes; but his character was base and illus-
trious, as the name would intimate. In the mean time
the queen regent of Egypt died, and the young king
was called to the throne as he entered upon the 15th
year of his age. In this situation of public affairs, the
uncle of the young king marched an army into Egypt,
and got possession of the frontier towns.
The winter was spent in mutual preparations; but
Antiochus invaded Egypt in the spring, and became
master of the whole country, excepting the city of
Alexandria. Ptolemy himself was taken prisoner; and,
after a variety of changes, was nominally declared to
be the sovereign of Egypt. Finding that Egypt was
really under sujeetion to Antiochus, and that the young
king was only a prisoner of state; the city of Alexan-
dria raised his younger brother Ptolemy to the throne,
whom they surnamed Euergetes the Second, to distin-
guish him from the captive king, who was Ptolemy Phi-
لومeter. The conduct of Antiochus brought the two
Ptolemies to a mutual understanding; and they united all
their resources to oppose their ambitious and unnatural
uncle. Still, however, he persisted in his scheme, and
they were in danger of being overwhelmed, when an
embassy from Rome arrested the progress and designs
of Antiochus. The successes of the Roman arms, and
the growing fame of the nation, overawed the king of
Syria, and relieved the Egyptian government. But
the harmony of the two brothers did not long remain.
Dividing the empire, Lybia and Cyrene were ceded
to Ptolemy Euergetes, and the rest was retained by Pto-
lemy Philometer. The former of these districts formed
the island of Cyprus; and when the claim could not be adjusted
between the brothers, the Roman senate favoured the
pretensions of Ptolemy Euergetes; still, however, Phi-
لومeter resisted; and, during the course of the struggle,
his rival brother was taken prisoner. Ptolemy Philometer
restored him to liberty, and gave him back his part of
the kingdom, together with an advantageous substitute
for the island of Cyprus. Thus the brothers were at
peace and friendship with one another; but the reign
of Ptolemy Philometer was not suffered to remain in
tranquility. On the death of the Syrian king, a suc-
cession of changes took place in the management of
the empire; and Alexander Balas, a young adventurer,
usurped the throne of Syria. This sovereign obtained
the daughter of Ptolemy Philometer in marriage; but
so unworthy was he of this alliance, or the throne to
which he was raised, that Ptolemy espoused the cause of
his competitor Demetrius Nicator, and gave him his
dughter, who was married to the unworthy Alexan-
der. In a short time, Ptolemy Philometer died at the
age of forty-one.
Upon the death of Ptolemy Philometer, his Queen Ptole-
my Cleopatra assumed the management of public affairs,

History.

Ptolemy VI. B.C. 181.
the Roman ambassadors, Euergetes and the queen regent were united in marriage, and the son of the late king was to ascend the throne on his uncle's demise. Such an arrangement appeared to be wisely calculated to preserve harmony and order; but can it be believed, that during the marriage festival, the new king stabbed the infant prince in the arms of his mother. Ptolemy was inauspiciously denominated Euergetes, for he was a monster of cruelty and vice, and afterwards received the surname of Physcon, on account of his corpulence and unseemly figure.

From the horrible commencement of his reign, nothing was to be expected but cruelty and crimes. He wantonly banished, or put to death, the principal inhabitants of the kingdom; and the people at large were exposed to insults and destruction. During these scenes of unequalled cruelty, the men of science, who had been cherished in the college of Alexandria, fled from the kingdom; but they carried with them important discoveries and much valuable knowledge into foreign countries and foreign climes. Having invited strangers to settle in Egypt, and found that they also were impatient of his tyranny, he let loose his mercenary troops upon multitudes of people, who were assembled on purpose for his revenge, and unfeelingly put them to death. But being terrified at the popular rage, he left Egypt and sailed to Cyprus.

But previous to this, he had divorced his Queen Cleopatra, and forced her daughter to receive him in marriage. But, how shall we obtain credit for the cruel, nay mad conduct which he now pursued? Finding that his divorced queen had been raised to the throne of Egypt, his fury exceeded all bounds; he murdered his son Memphites, whom she had born to him in marriage, and sent the mangled carcass to afflict the feelings of a mother, already too much agitated and torn. Having raised a well-appointed army, the kingdom of Egypt was soon subdued by his power, and Cleopatra took refuge in Syria, with her daughter and Demetrius the king. Enraged at Demetrius for the protection which he afforded Cleopatra, he raised up Zebina, a citizen of Alexandria, to be a competitor for the throne of Demetrius; and though this youth had no just pretensions to the government, yet upon the ruin of Demetrius, he obtained the Syrian empire. From this time forth, there was no further knowledge of the exiled queen; and after a reign of 20 years, the detestable Physcon finished his earthly career. During the contest which he maintained with his brother, the Roman senate espoused his cause, though toward the close of the competition, they saw reason to support the pretensions of his brother Philemon. When he obtained the throne of Egypt upon the death of this king, the Romans could not fail to see and detest his character. Their intercourse with Egypt was then but slight and casual, but, considering the value of the country, and the disordered state of Ptolemy's government, they appear to have entertained some thoughts of rendering Egypt a province of Rome.

The kingdom of Egypt, which had been long feeble and convulsed, was now more than ever in a precarious and dangerous condition. Ptolemy Physcon had left three sons, Appion, Lathyrus, and Alexander; amongst whom it was highly probable there would be competition and intriguing for the crown; for in Egypt the rules of succession had not been well ascertained, and in various instances, capricious claims had been admitted. Though Appion was illegitimate, he might have aspired to the sovereign power; yet he appears to have been satisfied with the province of Cyrene, and retired in peace to the seat of his government. Lathyrus, it is believed, ascended the throne of Egypt in the order of succession; but the Queen-mother Cleopatra, having sufficient influence to maintain an ascendancy in the government, dismissed Lathyrus to the island of Cyprus, and raised Alexander his younger brother to be her associate on the throne. But so agitated was the state of Egypt, so arbitrary the conduct of Cleopatra, and so varying the interests of these two princes Lathyrus and Alexander, that they were alternately raised to the throne, and dismissed, by their mother's influence, to the more humble situation of governors of Cyprus.

Alexander appears to have been the favourite of his mother; but the preference seems to have been given, because he was more subservient to her will: for no virtuous affection could have influence in the breast of a woman so ambitious and base as Queen Cleopatra. She and Lathyrus were not only at perpetual variance about the affairs of Egypt; but each of them took a part in the interests of Syria, which were a subject of contention between Antiochus of Cyzicus, and his brother Grypus. Each of them employed the influence which their Syrian conquests afforded them, for the purpose of overthrowing each other's power in Egypt. Lathyrus at length prevailed; but his success was more owing to other causes than his own prudence or superior skill.

The conduct of his mother was so shameful and void of principle, that his brother Alexander, notwithstanding all his forbearance, was at length wearied with her crimes, and retired in disgust. He was invited by the queen to return to his duties in the state, for the nation would not be satisfied with her government alone. When he did return, she conspired against his life; but the conspiracy was detected, and she was herself cut off by cruel and unjustifiable means. It could not be disguised that the mother was put to death at the instigation of her son, and though his character was detestable, and self-preservation might be pleaded in his favour, yet to encompass the death of a parent was a crime which could not be forgiven, even by the dissolute and degraded Egyptians. Therefore Ptolemy Alexander was compelled to fly from Egypt, and his brother Lathyrus was recalled to the throne. Scarcely was he invested with the powers of the kingdom, when the affairs of Upper Egypt demanded his attention. You must have observed, that for a series of years the kingdom of the Ptolemies was almost dissolved by contensions and mist ature; and we are not to be surprised, that the remoter parts of the empire should wish to obtain independence and quiet. It is unnatural to suppose that Thebes could be contented with her forlorn condition. She had long been the mistress of Egypt; her glory had been at length tarnished, by the state of government being removed to Memphis, and now that it was carried to a still greater distance in the lately erected city of Alexandria. The whole strength of the government being unmoved, it could scarcely be deemed culpable that she should attempt to become again the habitation of a court, and the head of an independent kingdom. It was natural for Lathyrus, too, to retain his subjects within the influence of his government, and it was a legitimate enterprise to adopt measures for reducing Upper Egypt to its former allegiance. The insurgents were resolute in their defection; and Lathyrus, with culpable severity, reduced the ancient and venerable city of Thebes to a heap of ruins, where the voice of joy and of gladness was never more to be heard. But
Lathyrus himself did not long survive this melancholy
triumph, and he left his kingdom to increase in evils,
and endure greater degradation.

Cleopatra.
B. C. 81.

Cleopatra, the daughter of Ptolemy Lathyris, had
the only legitimate claim to the crown, and she was in-
stantly proclaimed the sovereign of Egypt. Being gentle
and conciliating in her manners, they expected a happy
reign; but there were events in preparation which dis-
appointed their hopes, and exposed Egypt to a long
train of anarchy and sufferings. Rome, from being the
ancient ally of the Ptolemies, had gradually acquired an
influence in the state; and at this time the senate sup-
ported the pretensions of Alexander, the son of Ptolemy
Alexander, late king of Egypt. While his grandmother
Cleopatra, during the last reign, was taking an interest
in the affairs of Syria, she took her grandson along with
her as she embarked for Phoenicia; but left him, to-
gether with her jewels and valuable stores, in the island of
Cos. The whole of these deposits fell into the hands of
Mithridates the Parthian, from whom the young prince
Alexander escaped, and took refuge in Rome.

Sylla, who was then perpetual dictator, supported his
pretensions to the kingdom of Egypt; and coming from
so powerful a quarter, the recommendation could not be
slighted. To make the best accommodation that the
circumstances of the case permitted, it was finally
agreed that Cleopatra should marry Alexander, and that
they should reign together on the throne of Egypt.

But Ptolemy Alexander was too ambitious to have any
partner in the government; and, according to the rude
and corrupt practices of those times, the young and
amiable queen was cruelly put to death. This detesta-
ble crime excited the hatred of his subjects; and, after
a variety of unavailing attempts to suppress his enemies,
he found it necessary to flee from the country. He
took refuge in Syria under the Roman general Pompey;
but seeing no prospect of being restored to Egypt, he
departed to Tyre, where he soon died, and bequeathed
Egypt, as well as Cyprus, to the Roman people.

Upon the deposition of Ptolemy Alexander II. a son
of Ptolemy Lathyris was admitted to the throne, who,
on account of his attachment to music, and skill in play-
ing the flute, was denominated Auletes. But his char-
acter possessed none of those qualities which were ne-
necessary for restoring Egypt to order and obedience.
He appears to have been frivolous in his manners, and
though a sovereign, yet he contended publicly for the
musical prize. The power which Rome had acquired,
rather than the senate formidable to their neighbours;
and Auletes was desirous of obtaining their approba-
tion to his succession in Egypt. The Romans had habitual-
ly acquired an influence in Egyptian affairs; and he
was the more anxious to secure their approbation, be-
cause they had obtained a show of right to the king-
dom of Egypt, by the will which Ptolemy Alexander
had left in their favour.

Though it was not expedient that the Romans should
openly lay claim to the kingdom of the Ptolemies, yet
there was a general unwillingness to sanction the ac-
cession of Auletes. But Cesar, the consul, being deep in
debt, he and Pompey, who was also venal, were gained
to the interests of the Egyptian king, and the Roman
people received him as their ally. In the mean time,
the brother of Auletes was appointed king of Cyprus;
but having offended Closius, a Roman naval com-
mander, he was deprived of the kingdom, and Cyprus was
united to the Roman republic. The facility with which
Ptolemy Auletes had suffered the island of Cyprus to
be separated from the Egyptian dominions, gave great
offence to his people; and being otherwise obnoxious,
both by the meanness of his character, and by the ra-
pacity which he exercised to repay the money which
he had borrowed to lavish upon the leading senators
of Rome, in order to obtain their approbation and sup-
port, rendered him so completely detestable, that his
army deserted his standard, the people were tumultu-
ous, and he was compelled to flee for his life. In this
situation he looked to Rome for assistance, and on his
passage to Italy he landed at the island of Rhodes, and
there he met the celebrated Cato.

That solid and deep-thinking republican blamed his
conduct for leaving Alexandria; and persuaded him to
return without going to Rome. He might find means
to satisfy the discontent of his own people; but the
value of Egypt itself, said Cato, will not satisfy the
avidity of the degraded senators of Rome. He pro-
ceeded, however, to the Roman metropolis; but Caesar,
whose friendship he had obtained, and from whom he
expected support, was abroad on his military appoint-
ments in Gaul. But his cause was taken up, and his
name was perpetuated by the celebrated Pompey, who
had been assisted by the Egyptian king in his war
against Mithridates. He was treated, however, with
greater favour, because Pompey was bound to his in-
terests, by the profusion of gold, which Ptolemy distri-
buted to procure the support of the more active and
leading senators.

In the mean time, a numerous embassy arrived from
Alexandria to state the Egyptian complaints, and op-
pose the restoration of Ptolemy Auletes; but the fugi-
tive king found means to cut off the ambassadors, with
the learned Dion at their head; and, by bribery and
corruption, obtained the forgiveness of the senate for
what he had done. At the same time a decree was
passed for restoring Ptolemy to his kingdom; but by
the address of his enemies, and the superstition of the
people, an oracular response was obtained and acted
upon, by which it was forbidden to employ Roman
soldiers for restoring the Egyptian king. But the en-
terprise was too lucrative not to be undertaken by the
avaricious servants of the Roman republic. By Pome-
py’s advice, Gabinius, the Syrian proconsul, under-
took the business for the reward of 10,000 talents, or
nearly two millions of British money. Under his di-
rection, Mark Antony passed the desert, and, by the
assistance of Gabinius, replaced Auletes upon the throne
of Egypt, though not without much resistance and
blood.

When Ptolemy Auletes fled from Egypt, his daugh-
ter Berenice was invested with the regal power, and
married to Seleucus, a king of Syria. This marriage
was accomplished to add the strength of Syria to the
Egyptian power; but the connection was unfortunate
and transitory. It was Antiochus of Syria whom the
Egyptians desired for the consort of their queen; but
he having died prematurely, his brother Seleucus was
invited to be her partner on the throne. He was no
less distorted in the dispositions of his mind, than he
was unseemly in his personal appearance. Among
other vices, he was covetous in the extreme, and violat-
ing the sanctions of the dead, which was peculiarly
sacred among the Egyptians, he seized upon the gold-
en coffin in which the body of Alexander the Great
had been deposited, and put in its stead one of inferior
value. By these and other means he became obnoxious
to the people, and so detested by the queen Berenice
that, according to the practice of those ruder times, she
devised means, and put him to death. Then she mar-

niece.
ried Archelaus, high-priest of Comana, who was also an able warrior, and was the Egyptian leader, who resisted with so much boldness Gabinius and Mark Antony, when they entered Egypt to restore Ptolemy Auletes.

The money paid to Gabinius was borrowed from Caius Rabirius Posthumius, and he naturally expected payment when Ptolemy had recovered the resources of his kingdom. But the Egyptian king was in every respect worthless and vile. He devised means to cast Gabinius into prison, and the unhappy high dignitary, having escaped from confinement, returned to Rome, and was prosecuted by the senate for having degraded the character of a Roman knight, and for having been engaged in scenes of bribery and corruption. By the eloquence of Cicero he was acquitted of the crimes; but Gabinius, who was the chief instrument of restoring Ptolemy, was found guilty, and condemned to perpetual banishment; but was recalled by Caesar when he obtained the sovereignty of Rome. No sooner was Ptolemy Auletes settled upon the throne of Egypt, than he put his daughter Berenice to death, whom the people had constituted queen, and he was guilty of oppression in every form. But his death ensued after a period of four years; and he left his two sons and two daughters to the care and tuition of the Roman people.

Ptolemy Dionysius was the legal successor to his father in the kingdom; but being too young for managing the affairs of state, he, and the other children of the late king, were under the superintendence of the Roman senate, and the government of Egypt was also conducted by them. But as soon as the young prince was thought to be capable of managing the state, he was admitted to the throne; and he associated with him, in the government, his sister Cleopatra. But their friendship and union were of short continuance; and each having their partisans, a civil war ensued. During the occurrence of these events, the affairs of Rome had suffered wide and important changes. Julius Caesar, a popular and ambitious leader, employed the power which he had obtained, both in his army and amongst the people, to overthrow the Roman republic, and raise himself to the sovereign power. Pompey stood foremost amongst the numbers, who hated and opposed the encroachments of Caesar; but he was daily losing ground, whilst the other as regularly was increasing his influence; and at length, in the battle of Pharsalia, Caesar conquered, and Pompey was put to flight.

In terror of pursuit, and without protection, he directed his course to Egypt, where he hoped for a ready and welcome reception; because, through his influence and schemes, Ptolemy Auletes, the late king, had been restored to his kingdom; but he was betrayed and put to death. The counsellors of the young king were either afraid of giving offence to Caesar, or they were suspicious that Pompey, even in his fallen state, might regain some of that influence which he formerly possessed in Egypt; and either lessen their power with Ptolemy Dionysius, or espouse the cause of Cleopatra, who was now driven from the kingdom; and therefore, without justice or feeling, Pompey was beheaded as he landed on the shore.

Immediately after the victory of Pharsalia, Caesar paraded Pompey; and, with a chosen band of soldiers, landed at Alexandria. There he found his enemy had been put to death, and being presented with his head, he was much afflicted; and instead of being gratified, as the assassins supposed, he wept at the sight, and commanded the remains of Pompey to be honoured.

The kingdom of Egypt, which had long been agitated by intestine divisions, was now in a state of turbulence and misery. Cleopatra, with some of her adherents, fled into Syria, and Ptolemy had assembled an army between Pelusium and Mount Cassius, in order to oppose Cleopatra, who was returning to Egypt with an armed force. On the frontiers, every thing was warlike; in the interior, all was confusion. In the capacity of guardian to the children of Ptolemy Auletes, Caesar being then invested with the supreme authority of Rome, commanded a statement to be laid before him of the differences which continued to agitate the kingdom, that he might pass sentence thereon, and compel the parties to abide by his decision. The power of Caesar was too great to have his will opposed; and therefore advocates for each side were chosen, and every arrangement made to have the matters in dispute brought to an issue. But Cleopatra, being anxious for the success of her own claims, and aware what influence her presence and personal charms might have upon Caesar, set out from Phoenicia, and arriving in the bay of Alexandria, was secretly conveyed into the presence of Caesar.

Ptolemy, having discovered his sister's arrival, was frantic with rage at her access to the arbiter of his destiny, and the whole city was in commotion. To avert the storm which was gathering, and restore the people to confidence, Caesar passed a decree, that Ptolemy Dionysius and his sister Cleopatra should reign jointly upon the throne. And further to conciliate the affections of the people, he restored the island of Cyprus, and submitted its government to the younger son and daughter of the late king. But the friends of Ptolemy were suspicious of Cleopatra's power, especially as she was obviously the favourite of Caesar, and could support her interests by the power of Rome. At the instigation of Photinus, Achillas, the commander in chief, filled the city of Alexandria with troops, and attempted to block up the harbour, that he might thereby cut off the Roman supplies. The attempt was frustrated by burning the Egyptian ships; but the flames reached a part of the city, which was called Bruchium, and its noble library was destroyed. Photinus, the fomenter of these evils, was put to death; but Ganymedes, his associate, a deep designing man, continued to maintain the strife, and combat the Romans.

On various occasions, Caesar was in imminent danger; and upon a time while he was hastening from the Mole of the Pharos, the boat in which he was passing sunk by an over-pressure of soldiers, who fled from pursuit. But Caesar swam to a neighbouring vessel, and his life was preserved. Upon a promise of peace, the king of Egypt was liberated from that bondage into which Caesar had thrown him, while he had drawn the sword against him and Cleopatra. But all his promises were soon violated; and the war acquired new strength from the presence of the king. But the Roman discipline and address overcame the numbers, as well as the rancour of the Egyptians; and Ptolemy himself perished while crossing a bracer of the Nile.

A fair opportunity now occurred of Cleopatra obtaining the sovereign power; but Caesar, attending to the prejudices of her people, joined with her in the government her younger and only surviving brother, who had been formerly appointed to the government of Cyprus. But this nomination was a mere show of limiting the power of Cleopatra; for the young prince
EGYPT.

was but in the eleventh year of his age; and, according to the accredited maxims of those times, he was soon put to death by treachery and poison. His younger sister Arsinoe was sent to Rome, that she might acquire no partisans, nor be the means of any disorders in Egypt.

Cæsar, captivated with Cleopatra.

Hitherto Cæsar had continued in Egypt with the professed intention of settling its affairs; but his remaining at Alexandria after Cleopatra was seized firmly upon the throne, only served to alienate and degrade his attachmment to the queen. In various parts of the Roman dominions, the power of Cæsar was threatened; but he could not be induced to leave Cleopatra till his fortune seemed to be upon the verge of despair. Then his usual activity returned, and from place to place he carried victory and triumphs. Having suppressed the insurrections in Syria, he hastened to Africa, and overthrew the partisans of Cato, and the king of Numidia, in the celebrated battle of Thapsus. Then, having conquered the remainder of Pompey's party in Spain, he returned to Rome, and enjoyed for a while the fruit of his triumphs. But still his affections centered in Cleopatra; and it is said that he had taken some steps to remove an obstacle, which the Roman law placed in his way, for making her his wife. But the Roman people were still dissatisfied with arbitrary power; and Cæsar having become more unpopular, by repeated acts of licentiousness and severity, was murdered in the senate house.

Cæsar's death.

A scene of confusion now ensued at Rome, and it was difficult to say what hardships were to be endured, or what form of government was then to be adopted. Antony, Lepidus, and Octavius, who had assumed the name of Octavianus, formed a coalition, with the professed intention of avenging Cæsar's death; but chiefly with the view of aspiring separately to the sovereign power. Consequently the triumvirate was soon broken, and Lepidus falling into neglect, Antony and Octavius strove for the mastery. But Antony was peculiarly conspicuous at the battle of Philippi, where the cause of the republicans was lost, with the lives of Brutus and Cassius.

Antony in power.

Victorious and full of hope, Antony departed to Syria; and viewing himself as the master of Rome, he travelled into Syria, which, with the other provinces of the East, was committed to his government; and having arrived at Tarsus, he commanded Cleopatra to leave Egypt, and appear before him.

Though the kingdom of the Ptolemies had lately been secured to her by the interest of Rome, yet it is obvious that she did not obey the commands of Antony to acknowledge his authority, but perhaps to pay respect to the avenger of Cæsar; and who knows, but the licentiousness of Cleopatra might induce her to expect another admirer in the Roman hero? The meeting of Antony and Cleopatra was splendid beyond example; they indulged in costly presents, and their feasting were numerous and extravagant. At her solicitation, and to remove every fear of a rival, her sister Arsinoe was put to death. Like Cæsar, Antony was lost amidst the fascinating manners of Cleopatra; and he divorced his wife Octavia, the most virtuous of women, to remove the jealousy, and enjoy the favours of the abandoned Cleopatra. Having subdued his enemies in the East, he returned towards Rome to oppose the growing power of Octavianus, which his own misconduct had tended to enlarge.

Had Antony marched directly to Rome, the power of Octavianus might have been overthrown; but being enamoured with effeminate pleasures, he listened to the voice of Cleopatra rather than the counsels of his wiser friends; and having hazarded a naval battle near Actium, his fleet was vanquished, and he fled first to Lybia, and then to Alexandria. But he was not to be consolated by the presence of Cleopatra, and the consciousness of her own errors disquieted the mind of that virtuous woman. She fled from the presence of Antony, and retired to a sepulchral under the tombs of her fathers. Previous to this, Octavianus had followed up his triumphs over Antony, and was then victorious in the city of Alexandria. Believing a report that Cleopatra had put an end to her life, and seeing himself upon the point of falling into the hands of his rival and inveterate foe, he fell upon his sword. But not having instantly expired, and finding that Cleopatra was still in life, he was conveyed to her retreat, and after an affecting farewell, immediately expired.

Cleopatra could no longer escape the power of Octavianus, and she attempted to win his heart, and gain her liberty; but her attempt was ineffectual: and though she was treated with many marks of apparent respect, yet she was still detained a prisoner, and she had good reason to believe, that the Roman conqueror intended her to complete his triumphs at Rome. She maintained an appearance of confidence and good spirits; but she had taken her resolution, and was determined to die. Although this was suspected, and she was strictly watched, yet she found means to obtain an aspic, by the sting of which her life was taken away.

Thus died Cleopatra, who, to the beauty and gracefulness of her person, added the charms of wit, extensive knowledge, and affable manners. She was the patron of letters, and added a valuable collection to the libraries of Alexandria. She was licentious and vain; but she was born in the midst of a dissipated court, and placed in circumstances peculiarly seductive. While we reprobrate her conduct, we regret that her lot was not more favourable to virtue, and that qualities which might have been pure and illustrious in another situation, had exposed her conduct to the reprobation and dislike of every virtuous mind. See Maneth, Herodotus, Plutarch, Dio/ Siculus, Dio Cassius, Bruce's Travels, Browne, Hornam, Ren. Geog., Arrian, Lucan, Q. Curtius, Eutropius, Valer. Maximi, Prideaux, Justin, Josephus, Cicero, and Cæsar.

By the death of Cleopatra, the dynasty of the Ptolemy's was finished after it had lasted about 294 years, and Egypt was converted into a province of Rome. That the people of that country might continue united to the Roman government, none of the noblemen were allowed to have intercourse with the Egyptian people. The kingdom of the Ptolemies was to be subject to a governor; and that office was conferred upon Cornelius Gallus, who was a person of equestrian rank. And, further to restrain the ambitious views of Egypt, it was not allowed to be under the direction of a procurator as the more favoured provinces were; but the government was under a prefect, nor had he the power of life and death, nor the command of public money. His office was continued but for one year, and all the interests of Egypt were jealously watched by the eye of Octavianus.

But all these precautions did not prevent disorders in Egypt. Gallus, the first governor, enriched himself by oppressing the people; and by inscribing his own name and deeds upon the pyramids and other public buildings, he fell under the suspicion of Octavianus; and,
mislead the people, the Emperor collected the books which treated upon that subject, as far as they could be obtained, and shut them up from the inspection of the nation.

But his son Caracalla was less favourable to Egypt. Caracalla. The Alexandrians exposed his follies and vices to ridicule; and he cut off the followers of Aristotle from their usual support in the schools of Alexandria. He executed this purpose professedly from a dislike to the sentiments of that philosopher, but in reality for the purpose of injuring Alexandria. But this disguised method of shewing hostility was soon exchanged for open and avowed violence. His troops rushed into the abodes of the unoffending inhabitants; and, while the whole city was full of terror and dismay, the unworthy emperor viewed the scene from the temple of Serapis, and smiled with savage pleasure. For several successive reigns, the Christians of Egypt were persecuted; and the nation was agitated by competing claims for the government.

Aurelian. A.D. 117.

The Jews fell under the displeasure of the Emperor Caligula, because they refused to receive him as a deity; and, by the orders of Avilius Flaccus, who was then prefect of Egypt, their sacred places were polluted by the images and statues of the emperor; for, to guard against idolatry, there was no painting or similitude permitted to be seen in the Jewish devotions. But, through the influence of Agrippa, the king-elect of Judea, the prefect was removed from Egypt; and banished to Andros. While Claudius was emperor, the Roman conquests were extended into Africa, and the college of Alexandria was improved in splendour; but Egypt was robbed of an obelisk, which was conveyed to Rome, and placed upon Mount Vatican. In the time of the Emperor Nero, the Jews were still persecuted, and on their part they continued turbulent and unwise, insomuch that, in a future reign, their temple at Onias was completely destroyed.

Aurelius.

In the reign of Aurelius, the affairs of Egypt were turbulent and precarious. Some of the discontented, and perhaps oppressed, inhabitants, had taken refuge in the forest of the Delta; and, refusing to pay tribute to Rome, they resisted its power, and destroyed not a few of its servants. Many Greeks, who dwelt in Egypt, joined this resistance, till they were suppressed by Avilius Cassius. This successful leader aspired to the suverainty of Rome, and would have been successful, if his attempt had not been premature. But the report of the Emperor Aurelius being dead, proving to be false, Cassius and his adherents were vanquished, and some of them put to death; yet the memory of Aurelius was extended to Flavius Calvisius, the prefect of Alexandria, who had surrendered the province into the hands of the usurper. Egypt was also visited by the Emperor Severus, who viewed and repaired many of the national monuments. To restrain the spirit of magic which was common in those days, and supposed to

EGYPT.

History.

extremes; and, now that the church had acquired con-
siderable influence in Egypt and with the Pope, a per-
son soon appeared in the see of Alexandria, who abu-
used his power, and degraded his character.

It was Cyril, the bishop of Alexandria, and vicar
of the Roman pontiff, who, by haughtiness and overbear-

conduet, created for himself a host of enemies. In
the exercise of his power, he encroached upon the authori-
ty of the civil magistrate; and Orestes, the prefect of
Egypt, was assailed and abused by the adherents of
Cyril. But there was a darker shade to be added to
the character of the aspiring and violent bishop. Hy-
patia, the daughter of Theon, a celebrated master in
the school of Alexandria, was no less famous for learning
and elegant accomplishments, than she was for beauty
and virtuous qualities; yet she had offended Cyril, and
her life was the forfeit. She was the friend of Orestes
the Roman prefect, and being unjustly accused of cher-
ishing the irritation between him and Cyril, she was
attacked by the multitude in the streets of Alexandria,
and cruelly put to death. But the ambition of Cyril
was as violent in public life as in private, and his in-
temperate dispute with Nestorius, the bishop of Con-
stantinople, remains against him in the annals of the

A. D. 616. - The western empire of Rome having already fallen,
by the intrusion of the Huns and Goths, the Vandals,
and other warlike and uncultivated nations; the eastern
empire, of which Constantinople was the head, was also
fallen into decay, and the Queen of Persia over-ran dif-
f erent parts of the Roman dominions. She likewise
obtained possession of the principal towns and parts of
Egypt. But her triumphs here were of short duration,
and Persia itself was soon added to the dominions of the
Mahomedan conquerors.

Omar.

A. D. 634. - Omar succeeded to the empire of Mahommed, and in
his reign Egypt was subdued by the arms of the caliph.
Amr Benalas marched his troops into Egypt, and, after
much resistance, got possession of Memphis. Mocaw-
cas, the prefect of Egypt, was hostile to the religious
 tenets of Constantinople; and when the Persians were
besieging that capital, he had revolted from his alle-
giance. For these reasons, Mocawcas supported the
interests of the Mahomedan invaders, and, after many
efforts, and various changes of fortune, the city of Alex-
andria surrendered to the Saracens. The town was
exposed to plunder; but at length the people were ad-
mitted into the protection of the conquerors, and if they
did not become Mahomedans, they were to pay a cer-
tain ratio or tribute. Among other disasters which be-
fell Alexandria, its famous library was destroyed; for
the Saracens were then a rude people, and unaclain-
med with the value of letters. And notwithstanding
what has been asserted by the author of the Decline
and Fall of the Roman Empire, the library was not
only destroyed, but learning must have suffered by
that unfortunate event; for it must have contained many
valuable writings of the Alexandrian school.

Amr.

Amr, the conqueror, was also constituted the gover-
nor of Egypt; and having added to its boundaries, he
likewise regulated its internal affairs, and commanded a
channel to be opened between the Nile and the Red Sea.
When Othman was raised to the caliphate, Amr was
removed from the government of Egypt; but his suc-
cessor Abdallah Bensaid was not acceptable to the
people of that province. He renewed the conquest of
Africa, and was successful in his views; but the suc-
cess was owing to the bravery of Zobeir, and not to the
courage or conduct of Abdallah. But being afterwards
unfortunate, he was removed from the government of
Egypt, and Amr restored to his former station. But
this salutary change was not of much avail, and the
improvident conduct of Othman was hurtful to his domi-
nions, as well as fatal to himself. In the subsequent
caliphate, Egypt was involved in the civil wars, which
were occasioned by the competitors for the dominions
of Mahommed; and Egypt was not composed nor set
at peace till Amr was again invested with the govern-
ment of the country, with the most ample and almost
independent powers.

During the contentions which ensued, Egypt threw
off the yoke of the Saracens; but was again reduced to
submission, when Merwan the son of Hakem was raised
to the throne. In the caliphate of Walid, Corrah Ben-
sharik was invested with the government of Egypt;
but he was licentious in his manners, and outraged the
feelings and the decency of the Christian adherents.
But while he was degrading himself by every species
of folly and vice, Mura, the lieutenant of the caliph's
armies, was traversing Africa in triumph, and had re-
ached the fortress of Ceuta, or Pillar of Hercules, on the
African side. Count Julian, the Gothic commander of
this fortress, not only surrendered it to Mura, but of-
fered to the besiegers of Ceuta the protection of his

It was jealousy and resentment among the Gothic
chiefs, which occasioned this offer to the Arabian war-
ior; for Roderick, the usurper but reigning king of
Spain, had many enemies in his dominions, and he had
stirred up the vengeance of Julian, by his infamous
conduct to the daughter of that chief. Musa hesitated,
for he was fearful of a snare; but one of his confiden-
tial generals was willing to make an experiment; and
having sailed from Ceuta, and landed at Calpe, the
other pillar of Hercules, the Saracen army pitched
their first camp where the impregnable works of Gib-
ralta are erected. The expedition was successful, and
Musa being jealous of Tarik or Tarif, his general set sail
for Spain, and completed the conquests which his fore-
runner had begun. If he treated his successful general
with unbecoming severity, Musa, in his turn, was de-
grated by the caliph, and died under the pressure of
infirmities and cares.

These things happened in the beginning of the eighth century, and the Saracens
obtained the chief possessions and management of Spain,
into which they introduced the literature of the East.

For a considerable period of years, the affairs of
Egypt are scarcely mentioned; for the public mind
and the national records were employed with animo-
sity and violence about the succession to the caliphate.
Formerly the family of Ali, the immediate descendants
of Mahommed, had been overpowered, in attempting
to assert their right to the throne; and the house of
Omnia, by power and good fortune, were raised to
the sovereign power. The Omniaes being in their
turn overthrown by the Abbassides or descendants of
Abbas, the uncle of the prophet retired into Spain,

A. D. 786. - Al rashid was a prince of great fame, and he is well
}
known as the hero of the Arabian Tales; but in the great variety of his vast engagements, Egypt, as a distant province, attracted little of his attention, though he visited many of his dominions sometimes in disguise, and sometimes openly. The disorders of that country, and other distant possessions, called for his interposition; and he invested Ibrahim, the son of Aglab, with the powers of governor and lieutenant over his dominions in Africa upon the shores of the Mediterranean; and Ibrahim found means to render himself independent. Thus he established the dynasty of the Aglabites, the seat of whose government was at Carthage.

During the reign of Al Rashid, there was nothing remarkable in the state of Egypt, excepting a general feebleness of the government, which happened, as we have already observed, in all the remote provinces; but in the reign of his successor Almansur, the Ommiades of Spain attempted to regain the possession of Egypt. But the caliph of Bagdad invested Abdullah Bertaher with a high commission for repelling the invaders, and restoring Egypt to order. Yet the Ommiades were scarcely dispersed, when the Greeks of Constantinople arrived in Egypt with a numerous fleet. Alarmed by this powerful armament, Ahmed Ben Tholan, a Turkish commander, was sent into Egypt to defend the country, and reduce the inhabitants to order. When he had settled the disturbances in that country, he led a powerful army into the East, and reduced under his own power several cities and provinces of the caliph. His son and successor enlarged his dominions from the falling empire of the caliph of Bagdad, until he returned to Egypt in possession of dominions which extended from the south of the Danubian to the confines of Nubia. But the power of the Tholomides was not of long duration, and Egypt again was added to the empire of Bagdad.

The Fatimites.

The Aglabites, in Africa, ceased to reign, and a dynasty succeeded, whose princes were denominated Fatimites; because they professed themselves the descendants of Fatima, the wife of Ali, and daughter of the prophet. This new race of princes aspired to the dominions which the Aglabites possessed in Egypt; but the caliph of Bagdad defended his Egyptian possessions, and put the Fatimites to flight. At this period, Ikshid, the governor of Egypt, laid claim to the title of independent prince; for the feeble and distracted caliph of Bagdad was not able to restrain his pretensions; and the government of Egypt continued for a while under the Ikshidites. Upon the death of the conqueror who gave name to this dynasty, Egypt was governed in succession by his two sons, who were both under age; but the kingdom was under the regency of Cafur, an old and faithful servant. Upon the death of both the young princes, Cafur was himself seated upon the throne; but his reign was of short duration, for he soon paid the debt of nature.

A.D. 969.

The Fatimite caliph, who reigned in Africa, never ceased to harass Egypt, and got full possession of the kingdom, now that the Ikshidite dynasty was ended. Moez Lediniblah transferred his government from Cairo to Carawan; now Cyrene, in Barbary, to a city which his victorious general Jawhar had built in Egypt. This city was called Cahara, or the City of Mars, and is now the Grand Cairo of Egypt. Though former princes had reigned with professions of independence on the banks of the Nile, yet still the caliph of Bagdad, in the capacity of Imam, or chief priest of the Mahometans, had been mentioned in the mosques and prayers of Egypt; but the new caliph of the Fatimite race interdicted this mark of honour, and claimed for himself the legitimate succession to all the honours of Mahommed. An intricate series of claims and disputes took place between the caliphs of Bagdad and Egypt; and if the former had not been far in the decline of power, the latter must inevitably have been overthrown.

But Hakem Bamritlah maintained his authority in Bamritlah, Egypt, and delivered himself from the power and threatenings of the caliph of Bagdad; nevertheless, he did not continue in honour, for the agitation and difficult circumstances of his kingdom seemed to have affected his mind. The incoherency of his conduct appeared in various instances, and at length he claimed divine honours. It is supposed that he was led into this folly, in imitation of Darar, an extravagant fanatic, who was put to death. But his followers were not extinct; and the caliph, running counter to every Mahommedan practice and institution, the fasts, festivals, and pilgrimages, were forbidden; and when it was apprehended, that even the worship of God would have been set aside, Hakem was assassinated, and the former order of things restored.

Hakem's son, Daher, succeeded to the caliphate, in whose reign nothing important happened; but in the following caliphate, there was a multitude of occurrences, which deeply affected the interests both of Bagdad and Egypt. No sooner had the son of Daher ascended the throne, than he assumed the name of Mostanser Billah, and his cares were directed toward his possessions in the East. But the principal anxieties of his government, proceeded from the feebleness and disorders of Bagdad. The Turks, who had lately assemled by fortune, his Syrian provinces, had also encroached considerably on his power; and Nassir, one of those slaves who had risen to power in the government of Bagdad, having met with opposition in some of his extravagant claims, fled into Egypt, to receive the assistance of Mostanser. This application was attended with success; for the caliph of Egypt entertained a hope that he might seize upon Bagdad, and overthrow his rival caliph.

Nassir having conducted his victorious troops to the very gates of Bagdad, the caliph Alcayem solicited and obtained the assistance of Togral Bey, a Turkish warrior and chief of the Seljuicides. In the mean time, Nassir entered Bagdad, proclaimed the caliph of Egypt sovereign of the city, and treated with great severity the emir Almor, as well as other persons of distinction. But Togral Bey approached the city, restored the caliph, and Nassir was put to death. Thus were the hopes of Mostanser Billah not only frustrated with respect to Bagdad, but, upon his reverse of fortune, his Syrian provinces revolted, and he was dispossessed of every foreign possession. To his foreign disappointments, famine and pestilence were added; and the whole was followed by an invasion of Egypt by Naseraloulah, a Turkish general, who had taken refuge and found protection at the court of Cairo. The caliph was unexpectedly besieged in his palace, and, being altogether unprepared for such an attack, he was compelled to purchase his safety at an extravagant price. After seeing himself disgraced, and his country plundered, he was relieved from his afflictions, and closed his eyes from the sorrow of his kingdom.

Abuleassem, surnamed Almostali Billah, was seated on the Egyptian throne. But the affairs of Egypt embra- a.D. 1096 ced at this time little more than domestic quarrels, with some feeble excursions into Syria and Palestine. Caliph succeeded caliph in common succession; but
every new sovereign had his power diminished, till the vizier, or prime minister, was in every thing caliph excepting in name. During the reign, if it might so be called, of Hafedah Ledinillah, the grandson of Mostanser, his vizier Redwan was saluted at Grand Cairo by the title of king. His presumption, indeed, in procuring this appellation from a party of his supporters, was followed by dislike and violence, and he was driven from the country; and finally put to death. Amid these internal commotions, the caliphs themselves were sometimes put to death; but still the viziers increased in power.

At length the appellation of vizier was not sufficiently dignified for the prime minister of the Egyptian caliph, and therefore they now assumed the name of sultan; and the dynasty of the Fatimites was drawing to a close. In 1164, Shawer, a person of consideration, was raised to the confidence of Aladil, the caliph of Egypt; but a competition for power having arisen between him and Aldargam, they had recourse to arms, and Shawer being defeated, took refuge with Nureddin, the prince of Syria, and solicited his assistance. The prince of Syria sent an army into Egypt under the command of Asoddudin, and Aldargam was soon overthrown. But Shawer being reinstated in power, neglected to fulfill his engagements with Nureddin, which occasioned several mutual attacks. In the mean time, the armies of the crusade had laid siege to Grand Cairo; and the caliph, with his whole court, being in danger, Nureddin was invited to give them assistance, which he readily consented to do; but, before his arrival, the siege was raised by the influence of bribes and high promises. When Asoddudin, the general of the Syrian prince, arrived at Grand Cairo, he was received with demonstrations of joy; but Shawer, conscious of his own faithlessness, and fearing the displeasure of Nureddin's general, formed a scheme of putting him to death. But the plot was discovered, and Shawer himself beheaded. Asoddudin was made vizier in his stead; but having died in the course of a few weeks, he was succeeded in office by his nephew Saladin, whose fame became great in the annals of the East.

The new vizier kept up a show of submission to the prince of Syria, though he did not intend to continue in a subordinate condition. In the mean time, Nureddin ordered Saladin to omit the name of the caliph Aladil-Sedinillah in the public prayers, and to substitute the name of the caliph of Bagdad. But when the order arrived, the Egyptian prince was breathing his last, and insensible of the disgrace. In the person of this caliph, the dynasty of the Fatimites was ended.

Upon the death of Aladil, the caliph of Egypt, Saladin, being in possession of the chief power in his character of vizier, seized upon all the wealth of the late prince, which was various and valuable. He threw his whole family into confinement, and adopted every measure which his wisdom could devise, for establishing in his own person the supreme authority of the state. He maintained a show of obedience to Nureddin, the prince of Damascus, but was secretly determined to acquire an independent rule in Egypt. This intention, though disguised, could not be concealed from the powerful and declining Nureddin; and, while he seemed satisfied with the conduct of Saladin, he was raising a numerous army to resist and overthrow his power; but in the mean time, he was seized with a sudden illness, and died at Damascus.

But the death of this prince did not deliver Saladin from danger; for Nureddin's successor was both able and willing to give him just cause of alarm. In these circumstances, Saladin wished to secure a retreat, and for this purpose he sent his brother Malec Turunsheh into the kingdom of Nubia; but finding it desolate and barren, he returned to Grand Cairo, and thence he was dispatched with a numerous army into Arabia Felix. There he was successful, and reduced a considerable part of that country under the subjection of the Egyptian vizier. Saladin having enlarged his dominions, and confiding in the means which he had devised for becoming master of Egypt, was determined to assume a name suitable to his views. Not being a descendant of Mahommed, he could not be denominated caliph, which implied the sacerdotal as well as the kingly office. On this account he chose the name of sultan, and left the office of pontiff, who had the charge of religious affairs, to be filled up by a descendant of the prophet.

Though Saladin was acknowledged as the sultan of Egypt by many of the neighbouring states, and even received the sanction of the caliph of Bagdad, which gave him a name and influence among the followers of Mahommed, yet he was not secure from intestine commotions. The friends and adherents of the Fatimite caliphs raised a rebellion in the kingdom, and a pretender to the throne collected an army of 100,000 men. These, however, were soon defeated by the power and address of Saladin; but no sooner was he freed from this alarm, than he was threatened by the soldiers of the crusades. William II. king of Sicily, had engaged in the Christian wars, and laid siege to Alexandria both by sea and land: But the enterprising spirit of Saladin frustrated his views. With a rapidity of movement which was peculiar to the energetic mind of the Egyptian sultan, he marched to the relief of Alexandria; and the crusaders, with a sudden panic, fled from the siege, leaving their stores, baggage, and engines.

At this time the government of Damascus was under a regency; for Malec Alasleh was under age, and the government of affairs in his minority was not acceptable to the people. Amidst these discontents, Saladin was requested to accept the sovereign power of Syria. Having arrived at Damascus, he found little difficulty in becoming master of the country; but he professed to assume the government in the name and for the interest of the young prince. Having settled the affairs of Damascus, he marched with a successful army through various parts of the country, while his growing prosperity excited suspicions; and the ministers of Malec, the prince of Damascus, entering into a combination with some of the neighbouring powers, sought an opportunity to check the career and disappoint the designs of Saladin. A battle ensued; but the Syrian forces, together with all their allies, were defeated, and the sultan of Egypt was left master of Syria.

Saladin returned from his eastern conquests, and began to aggrandize and fortify the city of Grand Cairo. He encouraged the schools and literature of the country; but was drawn away from the pursuits of elegance and domestic improvements, to the din of arms and the ravages of war. Having obtained possession of Syria, he was anxious to acquire Palestine; and therefore he led a numerous host against the armies of the crusade, who had assembled for the defence of the Holy Land. But there he met with the most obstinate resistance; multitudes of his army perished in the field of battle; and when he was forced to return towards Egypt, a still greater number died in the desert, from hunger, thirst,
and disease: yet still the views of Saladin were toward Syria and the East. At the commencement of this campaign, his army was defeated both at Aleppo and Mossul; and, in the mean time, the Christians of the crusade had assembled a fleet in the Red Sea, which threatened the cities of Mecca and Medina; but Abubeker, Saladin’s viceroy in Egypt, fitted out a fleet under the command of the brave and experienced Lulu, which opposed the European expedition, and gave fresh vigour to the exertions of Saladin. In the spirit of conquest, he entered the provinces of the East; and to trace his progress, would be to follow him like lightning from field to siege, and from siege to battle.

Having run a triumphant course through Syria, he entered Palestine with victory and terror. Having obtained possession of Aleppo and Mossul, he aimed a blow at the Holy Land. For the space of three years, Saladin continued to gain advantages over the armies of the crusade. Various places of strength having fallen, Tiberias was at length taken, and Lusignan, king of Jerusalem, was desirous of meeting Saladin in the field. The armies met upon the banks of the Jordan, and victory was declared in favour of Saladin. The king himself was taken prisoner, as well as Arnold, lord of Carac. The king of Jerusalem was treated with respect, but Arnold was put to death by Saladin’s own hand, because he had inflicted many miseries on the followers of Mahommed. Ptolemais, Neapolis, Caesarea, and other cities, fell into the power of Saladin. Finding nothing to oppose his course, he marched directly toward Jerusalem, and besieged the city. The garrison was numerous, and made a desperate defence; but after Saladin had made a breach in the walls, and was on the point of entering the town, the commander made offers of capitulation.

But Saladin refused to accept of the terms, and vowed that he would sack and destroy the city. His cruel threatenings roused the spirit of the Christians, and a herald declared, that they would first put 5000 mussulman prisoners to death; and, that no European might be exposed to their revenge, they would also destroy their wives and children. That no booty might be found, they would destroy everything valuable in the city; and, having levelled the rock which the Mahomedans held sacred, they would sail out in a body upon the besiegers; and if they were not victorious, their destruction should be accomplished by an unexampled experience of blood and misery. This desperate resolution moved Saladin to more reasonable terms; and the garrison, as well as the citizens, were spared by paying a stipulated sum of money.

In this embattled state of the Christian armies, a third crusade was determined on in Europe; and the emperor of Germany, together with Philip II. of France, and Richard I. of England, having arrived in Palestine, encamped before the city of Acca or Ptolemais, whilst many European ships rode in the harbour. In this city, Saladin had assembled a numerous army; and the powers of Europe were combined to defeat him. Richard I. of England was of great courage, and therefore was surnamed Cœur de Lion; and his skill in war, added to his prowess, had rendered him the most famous general of the age. If there had been as much harmony as there was power among the different armies of the crusade, the city of Ptolemais must soon have fallen; but, after all the distractions in the views and counsels of the allies, Saladin was compelled to capitulate. The garrison were allowed to march out with the honours of war; but a sum of money was to be paid to the besiegers.

The sultan of Egypt refused to pay the ransom; and historians tell us, that 5000 prisoners answered for it with their lives. The siege was extremely bloody; and it is not supposed that fewer than 300,000 persons on either side were cut off during the conflict; and the flower of Europe, as well as Egypt, Asia, and Syria, perished in the combats. Ptolemais, or Acca, became the residence of the hospitalers of St John, and, since that period, the town has been denominated St John d’Acre.

Of all the European potencies, the king of England only remained; and, having laid siege to Ashkelon, he took possession of that city. Upon this event, Saladin hastened to Jerusalem; and Richard followed him to the holy city. The king of England held it in close siege; but when the hour arrived that the city was to be delivered up, the besieging army retreated, and the enterprise was abandoned. The cause of this sudden and extraordinary conduct has never been well explained; and different authors have presented different views of the subject. It may justly be supposed to have been involuntary on the part of Richard; for his courage has never been questioned; and the value which he set upon his honour could not permit him to tarnish it by unworthiness of conduct. The retreat of the army, it is said, overwhelmed him with grief; and his misfortune was increased by the discord and jealousies of the combined army. The Duke of Burgundy, who was left in Palestine by the king of France with 10,000 soldiers, is said to have been as jealous as his master of the fame and valor of the English king; but, even in his retreat, Richard was formidable. He concluded a truce with Saladin for three years and upwards; various places of strength were dismantled; the whole sea-coast from Jaffa to Tyre was surrendered to the Christians; and the pilgrims of Europe, travelling to Jerusalem, were to be under the protection of the powerful Saladin. But scarcely had the king of England returned to his country, when the health of Saladin began to decline; and he finished his life about the 55th year of his age, and after he had reigned in Egypt 24 years. See Abulpharag, D’Herbelot, Rinaldi, Will. Tyr. Vertot, Sa- nut, Jac. de Vitriaco, and Dr Wilson’s Hist.

Alaziz, the second son of Saladin, was appointed to the government of Egypt; but, not being contented with the portion of his father’s dominions assigned to him, he made successful inroads into Syria; but died suddenly in the midst of his triumphs. Upon his death, several important changes took place with respect to the affairs of Egypt and Syria; but nothing worthy of notice till the reign of Alcameal.

When this prince was raised to the throne, he was well received by the Egyptians; but he found the state of public affairs full of disorder, and attended with danger. The Mahomedans and the Christians were plotting each other’s destruction; and the Christians were at variance among themselves. In this state of internal disquietude, the soldiers of the fifth crusade landed in Egypt, and laid siege to Damietta. The united forces of Egypt and Damascus could not overcome the European army; but Alcameal offered such terms of accommodation as were acceptable to all the chiefs of the crusade, except D’Albano, the Pope’s legate.

Such influence had the see of Rome then acquired, that his single voice prevented the negotiation. The
The siege was continued, and the town of Damietta fell. Elated with this success, they pushed into the interior of the country; but were vanquished by the Egyptians, and were compelled to sue for mercy. The sultan of Egypt became powerful in Syria, as well as at home; and, when Frederick II. of Germany found it necessary to return to Europe, he entered into a league with Alcameh, which was wise and profitable for both.

Alamel died at Damascus, and Aladel, one of his sons, was raised to the throne; but Nojmoddin, his eldest brother, laid claim to the kingdom. A bloody contest would probably have ensued; but, in the meantime, Aladel died or disappeared; and his brother Nojmoddin was peacefully proclaimed sultan. He, too, acquired influence with the most powerful party of the crusades; for Richard, the earl of Cornwall, perceiving that the sultan of Egypt was more powerful than the Syrian lords of Carac and Damascus, entered into an alliance with Nojmoddin, and renewed the treaty which Frederick of Germany had made with Alcameh his predecessor. By this covenant, the Christians were protected, and the views of Nojmoddin encouraged, in opposition to his Syrian rivals.

In this settled state of affairs, Nojmoddin passed into Syria, and, with the help of some uncultivated tribes, determined to overpower his eastern enemies. That part of the crusading armies which was favourable to the lords of Syria, joined them in opposing the sultan of Egypt; but Nojmoddin overthrew them with great slaughter. In the mean time, a host of warriors from Europe arrived in the port of Damietta, with Louis IX. of France as their leader. In the absence of the sultan, and when the nation was unprepared for this unexpected attack, the armies of the crusade entered Damietta. The news of this event were quickly carried into Syria; and Nojmoddin having raised the siege of Damascus, hastened to Egypt to protect his kingdom, but he died by the way, and left a vacancy in the government when a vigorous administration was particularly wanted.

The country received a seasonable relief by the address of Shajir Aldor, the favourite female of the late sultan. Pretending that Nojmoddin was indisposed on his journey, the principal lords of the country were induced to swear allegiance to his only son Turan Shaw. The veil was then taken off, and the young prince was proclaimed sultan, upon his arrival from Damascus with a numerous army.

The European soldiers had by this time penetrated far into the country; but they paid dearly for their rashness; and Louis himself was taken prisoner. Turan Shaw had the name of Sultan, but none of its powers; for Shajir Aldor, and her adherents about the court, directed in reality the affairs of state. The young sultan was sensible of his situation, and determined to assert his proper rights. Being strictly watched, Shajir Aldor was aware of his intention, and he was violently put to death.

The young prince having been assassinated, Shajir Aldor was declared to be sovereign of the country. She was prayed for in the mosques, and her name was impressed on the coins. This active and designing woman was raised to the throne by the power and influence of the Mamelukes. These were a body of Turkish slaves, who had gradually acquired authority at the Egyptian court. When Saladin usurped the sovereignty of Egypt, he durst not entrust himself to the national troops, but placed about his throne a powerful body-guard of slaves from Kipza, whom the Moguls acquired in war, and sold into bondage. Successive sultans increased the power of these attendants by new privileges; and, upon the death of Nojmoddin, they had in reality the disposal of the sovereign power.

Ibeg, one of the Mamelukes, who, from their power in the state, were called emirs, was chosen to be the prime minister, or rather regent of the kingdom. But still the people were dissatisfied with the government of a woman, and the management of a foreigner. In this situation of affairs, Shajir Aldor was deposed; and Musa, a descendant of Alemel, elevated to the throne. But his reign was short as well as turbulent; and, in the midst of internal commotions, the young sultan was removed from the throne; and, with his government, the reign of the Ayubites was terminated.

Ibeg, who had reigned with Shajir Aldor, was proclaimed sultan by the Balarite Mamelukes, and he immediately espoused Shajir Aldor; but, through jealousy, and an idea of ingratitude, she hired assassins, and Ibeg was put to death. By a party of the Mamelukes, Nurededdin Ali was raised to the throne of his father Ibeg, by the surname of Almansur; and Shajir Aldor was put to death. About this time, the Moguls had overrun all the Saracen possessions in the East, except Yemen and Egypt; and the power of the caliph was almost at an end in Bagdad. It was in this perilous conjunction of affairs that the young sultan began his reign in Egypt; and in that situation he was overthrown and deposed by Cutuz, an artful and ambitious chief.

This warlike prince entered Syria with triumph; and, for a time, was formidable to his enemies: but Bibars, one of his generals, acquiring influence with the Mamelukes, deposed Cutuz, and was proclaimed sultan in his stead. It was pretended that the merits of Bibars had been neglected; but, in truth, the reason is to be discovered in the power of the Mamelukes, and the feeble state of the government. For, as the army, in the decline of the Roman empire, created emperors at their pleasure, so did the Mamelukes of Egypt, at this period of its history, raise whom they would to the office of sultan. To give his usurpation a more legitimate colouring, Bibars acknowledged the pretensions of Ahmed, the professed son of Dalber Billa, a caliph of Bagdad; and he was acknowledged as imam, or pontiff of the Mahomedans in Egypt. Bibars received the benediction of this Mahomedan pontiff; and by that means acquired greater influence among the people. In truth, he was a successful warrior, as well as a benefactor to the dominions which he acquired; and, at the time of his death, his empire extended from the interior of Africa to the river Euphrates.

From this time till the year 1293, there were rapid changes among the sultans of Egypt; but though the government was unstable, yet the nation was powerful; for the Mamelukes were brave and warlike. When Naser Mahomed was proclaimed sultan, he was only in the 9th year of his age, and suffered various reverses of fortune. Thrice he had abandoned the throne of Egypt; twice by compulsion, and once by choice. But in the progress of events, being firmly established in power, he exercised his authority, as well as his active mind, to correct the abuses of the state, and restrain the exorbitant influence of the emirs and lords of the court. He improved the fertile fields of the Delta; threw streams of water into the city of Aleppo, and repaired the canal as well as the reservoirs of Alexandria.

Upon the death of Naser, Abubeker his son succeeded.
Egypt.

ed to the throne; but so rapid were the changes of royal succession, that twelve descendants of Naser Mahommed successively extended their reign through the period of forty-one years. During the short and turbulent reigns between Bibars and Naser Mahommed, and while the Sultan Calib was on the throne of Egypt, the city of St John d'Acre was taken from the Christians. The attack was violent, and the defence brave; but the Mussulmans obtained possession of Acre, and the whole land of Palestine, after much treasure had been spent, and innumerable lives lost in the wars and victories of the crusades. Soon afterwards, the knights templars departed into Europe; but those of St John formed a settlement in the island of Rhodes. From this situation they made frequent inroads into Egypt; for, although the knights were comparatively weak, yet the distracted situation of Egypt permitted them to retire from the coast, without the severe vengeance which they might have inflicted; but indeed Egypt was in the utmost state of distraction; and a revolution in the government could not be avoided. If the Ayubite dynasty was superseded by the Baharite, the Baharites, who surrounded their throne, the Baharite sultans were also supplanted by the Circassian slaves, who had been cherished at court, and permitted to acquire uncontrollable power. The sultan Hagi, who was but a child, was deposed by the influence of a Circassian chief; and the Baharite dynasty was terminated in Egypt, after it had existed about 128 years. See Abulfarag, Deyvignes, Olivier Scholast. in gest. Dei francois D'Hericleot; and Dr Wilson's Hist.

The Circassian slaves, whose chiefs had in their turn become masters of Egypt, were called Borgites, because, in the capacity of soldiers, they had been dispersed through the different fortresses of the country, to keep in check the people, who had long been in want of subordination; and these fortresses were called Borges. Barcok was the first of this dynasty on the throne of Egypt; but so powerful were the adherents of the deformed family, that Hagi was soon restored to the kingdom. But his renewed power was of short duration, for Barcok suddenly recovered his situation, and the Borgite dynasty was established. Scarcely had he overcome the internal enemies of his kingdom, when he was threatened by a formidable power from without. Tamerlane the Great, who had formed the new empire of the Moguls, and denominated the Cham of Tartary, was desirous of adding Syria to his dominions; and the sultan of Egypt marched with an army to meet him at Damascus. At the approach of Barcok, Tamerlane retired; and, directing his course towards India, his arms were attended with great success.

In the mean time, Bajazet, at the head of the Ottoman armies, and the rival of Tamerlane, was spreading terror upon both sides of the Hellespont, and had carried his arms to the very gates of Constantinople. Indeed, he was determined to take possession of that city, and establish his government upon the ruins of the Roman empire. For this reason, he solicited the friendship of the Egyptian sultan, and the blessing of the caliph, who was then residing at Grand Cairo without any civil authority, but only as imam of the Mahomedan faith.

About this time, Barcok died; and his son Pharage, surnamed Abulsaadat, reigned in his stead. When this prince obtained the government, he was but ten years of age; and the affairs of the kingdom were managed by a regent. In these circumstances, the national commotions were continued; and his Syrian dominions rose in rebellion. But Abulsaadat, under the influence of his native vigour, took the reins of government in his own hand, recovered the provinces which had rebelled, and put his whole kingdom into a state of order and obedience. In this situation of affairs, Tamerlane returned from India, and found that his rival had been extending his power, and was more formidable than ever.

These ambitious and terrible warriors were determined on each other's destruction. Bajazet laid claim to the assistance of Egypt, because he had entered into a formal alliance with the sultan; but he did not receive the expected support, because he had not been faithful to the terms of agreement; and we may add, that the power of Tamerlane was another reason with the sultan of Egypt, for withholding aid from his rival Bajazet. These two powerful chiefs met once and again in the field of battle, when Bajazet was finally overthrown, and taken prisoner. Having overcome his rival, the ambition of Tamerlane was more unbounded than ever. He intended to ravage the south of Europe across the straits of Gibraltar, and continue his course through Egypt and Syria, till he arrived at the seat of his government in the East. But there was one power of which he stood in awe, and which prevented the project which his ambition had laid. The knights of St John, now established at Rhodes, and enriched by the spoils of the forfeited Templars, were formidable to the neighbouring powers, and maintained a mighty preponderance in the scale of nations. Though small in numbers, their strength was great, their fame extensive, and their courage well tried.

In these circumstances, it was not expedient to attack the knights directly in the island of Rhodes; but he laid siege to Smyrna, and reduced it to ashes. He was drawn away, however, from any further attempts upon the power and interests of that religious order, by dangers which were threatening him in the East. A powerful prince, whom Tamerlane had subdued in his Indian expedition, appeared again with renewed strength, and was laying waste the kingdom of Persia. Thither he directed his course, but his power was much diminished through a long succession of obstinate engagements; and, having met his enemy in greater power than was expected, they entered into terms with mutual agreement; and Tamerlane, having withdrawn from public life, retired to Samarchand, and there, in a few years, ended an active and victorious life. In the mean time, the distractions of Egypt still continued; and the sultan Pharage Abulsaadat, being weary with continual broils and confusion, retired from the dangers of public life, and surrendered the throne to his brother Abdolaziz, but to assume it again.

This happened in the year 1405; and there was little more than a rapid succession of feeble monarchs, till the year 1517, when the Borgite dynasty was overthrown; and the kingdom of Egypt was converted into a province of the Turkish empire. During this period, there were many broils, and much warfare between the sultans of Egypt and the kings of Ithrones. The Portuguese, who had acquired some settlements in India, alarmed the governors of Egypt, who had long been enriched by the merchandise of the East; and ineffectual efforts were made to overthrow the power of the European invaders. In the mean time, Europe itself was in commotion; and, upon the 29th of May 1453, Constantinople was taken by Mahomed II; the sultan of the Turks. This success opened his way.
to the kingdom of Egypt; and Tuman Bey, the last of the Circassian or Borgia dynasty, was basely put to death at Tavifs, one of the gates of Grand Cairo.

The race of princes who were now seated upon the throne of Constantinople, and had added Egypt to their dominions, derived their origin from the Scythian or Tartar tribes, and were afterwards denominated Turks, from the word in their own language which denotes a helmet. Selim, though a younger son, got possession of the Turkish government, by deposing his father, and putting to death his elder brothers. The same ambition which impelled him to deeds so cruel and unnatural, induced him, in a way more honourable for a warrior, to establish his power, and extend his empire. He successfully invaded the kingdom of Persia, engaged the Egyptian forces at Aleppo, and, after various successful efforts, carried his victorious course to the banks of the Nile, and easily became master of the country, which had long been agitated by internal commotions, and was then in a revolutionary state.

He continued for a considerable time in Egypt, and settled the form of government, after the manner which had been adopted by the Turkish sultans. He converted with him to Constantinople the caliph, or spiritual head of the Mahometan religion. Upon his death, another was appointed in his stead; but at his demise, the order of caliphs terminated, and a mutiny was substituted, who had the supreme direction of the Moslem faith; while the ulema, or chosen body of men, are invested with the power of interpreting the Koran. Imams, or persons subordinate to the mutfi, are sent into the different provinces, and four of them were appointed to Egypt. In the early times of the Turkish or Ottoman government, there were only two Beys, who, in the capacity of chief governors, presided over the dominions of the Turks. One of them had the command of the European provinces, and the other was entrusted with the command of Asia Minor. As the Ottoman empire was extended, the number of the Beys were increased; and each of those in chief command was called Beyler-bey, or Prince of Princes. At first there was a Pasha of Egypt, with sixteen Sanjaks under his authority; but in process of time, the Sanjaks were exchanged for twenty-four Mamelukes, who also assumed the name of Bey, or princes, to whom the government of the various provinces was entrusted.

In the most perfect form of the Turkish government in Egypt, it consisted of a divan, or council of regency, composed of those who commanded the military bodies, and whose president was the Pasha or viceroy. From the Mameluke beys, who commanded the provinces, were chosen the Sheik al Belled, or governor of Grand Cairo; the Janizary Ağa, or commander of the Janizaries; the Defterdar, or accountant-general; the Emir al Haga, or conductor of the caravans; the Emir al Said, or governor of Upper Egypt; and the Sheik al Bikkeri, or director of the sheriffs. In subordination to these, there were cashiphs, or deputies, and other officers of inferior note.

Soliman I. succeeded his father Selim; and he not only began his reign by crushing rebellion in the provinces, and adding dominions to his empire, but his name was terrible among the nations. He was the competitor of Charles V. and overthrew the power of the knights in the island of Lliodes. But even in his time the factions in Egypt were not at rest; and in the more feeble reigns of his successors upon the throne, the Ottoman power in that country was much impaired, and the form of government at last changed. The beys, who superintended the 24 departments in Egypt, collected the revenues of their respective districts; and by that means acquired an influence which was not intended. The heads of the seven military corps and the pasha became avaricious, and courted the favour of the beys, who could enforce the payment of tribute with severity, or remit it in part, according to their pleasure.

By indulging the members of the regency, the beys increased in power till they obtained the complete disposal of public affairs. Every bey had originally a few Mamelukes or slaves at his command, for enabling him to make his authority respected in the province where he resided; but as the power of the beys was enlarged, they increased their attendants, and in proportion to their number of slaves, so was their strength. When a vacancy occurred in the government of the provinces, the most powerful bey had his favourite Mameluke appointed to the office: this election increased his authority; and, by pursuing a similar course, the most active and powerful beys acquired a continually increasing influence in the government, and their Mamelukes became the only efficient soldiers in the state.

The members of the divan having become subservient to the pleasure of the beys, the beys got possession of every important office, with the exception of the vice-regal appointment. But in their career of devastation, the pasha of Egypt also became subject to the Mameluke beys. The Sheik Albelled, or governor of Grand Cairo, was chosen from amongst the beys, but he was approved or rejected by the pasha. The Sheik Albelled was the constitutional organ through which complaints were made to the Grand Signior, when the pasha violated the rights of the community; but to remove him from his office could only be done by the sultan himself. But in process of time, when the divan fell under the control of the beys, they dismissed them at pleasure; and when a new one was appointed, if they discovered by their spies, that he was entrusted with any mandate inconsistent with their views or authority, they never suffered him to approach Grand Cairo, but intimidated at Constantinople, that another pasha must be chosen.

In these circumstances of the Egyptian government, an active youth among the slaves who were brought from the neighbourhood of Mount Caucasus, grew up to great influence and fame in the house of his master (Bismah), who was a boy of the Janizaries, like other Mamelukes, this young slave became a Musulman, and received the name of Ali. Having gone through different offices in the house and service of his master, he was raised to the office and rank of a bey. Upon the death of Ibrahim, to whom he owed his power and elevation, considerable commotions existed; and in the year 1763, Ali Bey obtained the office of Sheik Albelled, by which he was invested with the chief authority of the state.

In the struggle for power, Ali Bey was more than once obliged to flee from Egypt, and seek refuge in Palestine or Syria. He became obnoxious to the Turkish Divan, and the Grand Signior sought his destruction. But in the year 1768, the court of Constantinople proclaimed war against the Emperor of Russia; and while the Ottomans were employed in defending their provinces against the northern invasions, Ali Bey was not only active in reducing Egypt to obedience; but he sent an army into Arabia Felix, for purposes of conquest and aggrandisement. The troops of Ali, under the conduct of Mahommed Bey, were successful against the Turkish garrisons; and they took possession of Gaza, Tatta,
and Shechem, or Naples. They even reached Jerusalem, and having arrived at St John d’Acre, they formed a junction with the troops of the celebrated Sheik Daher. The forces of Ali entered Damascus. But after tarrying a few days, his general Mahommed hastened to Grand Cairo, and compelled his master Ali Bey to take refuge in Palestine, where his arms were attended with success, being supported by the Sheik Daher.

Osman had been constituted Pasha of Damascus, and invested with extraordinary powers by the divan of Constantinople, that he might oppose and subdue the Sheik of Acre. Ali Bey and the Sheik Daher fearing equally hostile to the Ottoman power, entered into a treaty to support each other in their views and pursuits. The Egyptian Bey had attempted to secure the assistance of Russia, by negotiating with Count Alexis Orlov, the commander in chief of the Russian forces in the Archipelago; but the negotiations had been attended with little success, until a Russian transport, under British colours, commanded by Captain Brown, appeared off Jaffa, and assisted the forces of Daher and Ali Bey to get possession of that town and fort. By these and other means, Daher obtained considerable power.

But though the Sheik Daher and Ali Bey had been so far cordial in their co-operations, yet their interests might soon interfere, and their friendship be dissolved. This might be a sufficient reason of itself for Ali Bey to go in quest of possessions which were likely to be more permanent; and both his interest and inclination led him towards Egypt, where he had once been in power. But his former general, and now competitor, Mahommed Bey, was still in great power, and met him with a numerous army, in the desert which lies between Gaza and Egypt. The armies engaged, and Ali Bey, being wounded, was taken prisoner. His rival Mahommed seemed to receive him with great respect. For at the first interview, even in his fallen state, his former authority might have some remaining impressions, even upon the mind of the revolted general; but upon the third day the unfortunate Ali died, and not without suspicions that his death was occasioned by undue means.

By the death of this powerful chief, Mahommed Bey was left without a rival in the kingdom of Egypt; but in the fluctuating state of public affairs, he was aware that competitors might soon arise, and he was well assured that the divan of Constantinople would endeavour to recover their power in Egypt, as soon as they could withdraw their forces from the wars in which they were engaged with the Emperor of Russia. For some time past, no Pasha had been admitted in Egypt from the court of Constantinople, nor any tribute remitted to the Grand Signior. But Mahommed Bey, though hostile to the power of Constantinople, made extraordinary professions of friendship, and transmitted to the Grand Signior a large sum of money. Both parties dissembled; the reigning Bey of Egypt intended to manifest his independence as soon as circumstances would allow, and the court of Constantinople were determined to take the first opportunity of reducing Egypt to obedience; but in the mean time, they made a show of attachment to Mahommed, and raised him from the office of Sheik Albeled to that of Pasha, or viceroy of the Sublime Porte.

To ingratiate himself still more at the court of Constantinople, he marched an army into the East, under the pretext of subduing the Sheik Daher, who was inimical to the Ottoman authority, but in reality to obtain such conquests in the East, as would render him formidable to the power of the Grand Signior. Having gone in person to Syria, his army was attended with success; but he was seized with a fever, and died on the second day of the disease.

When Mahommed’s death was announced in Egypt, A. D. 1776, the country was in commotion, but the principal competitors for power were the boys Ibrahim and Murad. After various attempts to obtain the ascendency, it was at length agreed that the powers of the state should be held in common by the two contending chiefs. Ibrahim was to continue in the office of Sheik Albeled, and Murad was raised to the situation of Defterdar, or accountant-general. About this time, peace was concluded between the courts of St Petersburg and Constantinople, and, as might have been expected, the Grand Signior was determined to restore his power in the province of Egypt.

By the active and prudent services of Prince Potemkin, the Empress of Russia had obtained from the Grand Signior a vast extent of territory, which included the Crimea, together with the provinces of Circassia, Georgia, and other districts. The fleets of St Petersburgh were permitted by treaty to traverse the Black Sea; and as all these circumstances weakened the Ottoman government, it was the more necessary to recover Egypt, with its resources and tribute.

A fleet belonging to the Grand Signior arrived at A. D. 1758, Alexandria in the month of May, and landed an army of 25,000 men. The forces of Ibrahim and Murad Bey were drawn out to oppose their progress, and the armies met between Rosetta and Grand Cairo. The dexterity of the Mamelukes, who always fight on horseback, threw the Ottoman army frequently into confusion; but the skill and perseverance of Hassan Pasha, finally triumphed over the irregular though intrepid warfare of the Mamelukes. Ibrahim and Murad Bey withdrew by treaty into Upper Egypt. Hassan returned to Constantinople, and Beker was sent into Egypt with the honourable distinction of a pasha of three tails. Notwithstanding his power, he was but ill received, and found it impossible to collect the tribute, or preserve the country in order. But these irregularities soon gave place to designs and achievements of greater moment. The French directed an expedition against the province of Egypt, which was followed by warlike exertions, both of Great Britain and Constantinople. See Cant. Mign. Revolt of Ali Bey, Brown, Volney, and Life of Potemkin.

After the republican armies of France had vanquished Holland, shaken the power of Austria, overthrown the states of Venice, and trampled upon the independence of Italy, many inferior states sued for protection; and at Campo Formio, upon the 17th of October 1797, a treaty was entered into between the Emperor of Germany, and the Republic of France. By this convention, the Austrian Netherlands, as well as the Venetian islands in the Levant, together with several districts of Italy, were all ceded to the French nation; and although Venice, with several territories of importance, were granted to the Emperor of Germany, yet they did not restore him to his proper rank in the scale of Europe. Elated with these conquests, France had been threatening the independence of Great Britain, and attempted to wound her on the part of Ireland, where many discontented were already brooding.

After the peace of Campo Formio, the public were more than ever amused with the designs of France.
against Great Britain; but while the attention was directed to that quarter, preparations were secretly making at Toulon for a great and important expedition. The fleet was large, and the soldiers of every description amounted to 40,000 men. The command of the fleet was bestowed upon Admiral Brueys, and the command of the army was entrusted to General Bonaparte. The fleet sailed about the end of May; and having landed at Malta, got possession of the island by fear or treachery. Having arranged the affairs of that settlement, the French fleet set sail again upon the 19th of June, and directed their course towards Egypt.

These movements of the French were not unknown to the British government, and Admiral Sir Horatio Nelson was appointed to the command of a squadron to watch the motions of the French fleet. Having looked into the harbour of Toulon, and found they had escaped, he immediately sailed toward Egypt, whether it was supposed they had directed their course. Having learned at Malta that they had departed for Egypt, he crowded sail and stood after the fleet of Brueys. The French admiral steered his course along the northern coast of the Mediterranean Sea, while Nelson kept near the African shore. On this account, he arrived off the coast of Egypt before the French fleet made their appearance; but not finding it expedient to wait upon that station, he steered his course into the Levant. But soon after his departure, the French fleet appeared upon the Libyan shore, a few leagues to the westward of Alexandria. The friends of the Grand Signior, and the Mameluke beys, were equally alarmed at the arrival of the French; for if they got possession of the country, both the one and the other would be divested of their power.

In this situation, no time was to be allowed for the forces of Egypt to be collected in numbers; and, therefore, the landing of the French forces was instantly begun at Marsab. Bonaparte himself led the way; and without waiting till the whole forces were on shore, the troops began to March toward Alexandria on the second of July, between two and three o'clock in the morning. They met with considerable resistance, and the city refused to surrender; but the French army burst into the town, and a dreadful slaughter ensued. Generals Kleber and Menou were wounded, and several French officers of distinction lost their lives. Having reduced Alexandria to obedience and order, Bonaparte directed his troops to march for Grand Cairo; while, at the same time, he ordered a flotilla to sail up the Nile and meet the army at Ramannah. In the meanwhile, Admiral Brueys moored his fleet on the coast of Aboukir, with the view, if possible, to have them afterwards removed to the old port of Alexandria, which is the safest harbour in Egypt.

The troops under general Desaix marched across the desert, and other divisions followed the same route. They suffered much from hunger and thirst, as well as from fatigue, and arrived upon the 19th of July at Ameldinar, near the upper point of the Delta. By this time there had been a general rendezvous of the French troops; and having seen the beys appearing in force, they resolved to give them battle. The Mamelukes retired, but in the afternoon they formed in order of battle, and an engagement ensued. The Mamelukes were received with a sudden and steady fire of musket shot, when many of them fell; but they rushed on, and were received by well-directed bayonets, which covered the field with blood and dead bodies of the slain.

The plunder of Murad Bey's camp yielded a seasonable supply to the French army, by furnishing them with camels, baggage, and cannon, together with other articles suitable to their wants; and they also obtained considerable sums of money, with many costly ornaments. In consequence of this action, the French got possession of Giza, with the adjoining country, and the island of Roda. On the following morning, the principal inhabitants of Grand Cairo offered to surrender the city, provided that property, lives, and privileges, were respected and preserved. These conditions they were encouraged to expect, from the proclamation of Bonaparte on his taking Alexandria, in which protection was promised to the Egyptians, and respect professed for the Ottoman religion and government. It was asserted in this manifesto, that the object of the French expedition to Egypt was to suppress the turbulent beys, and restore the legitimate influence of the Grand Signior; but the disguise was too thin to conceal the real intention, and it was unquestionably evident, that the French government were desirous of subduing the country, and adding it to their own dominions.

When Bonaparte entered Grand Cairo, the pasha fled under the protection of Ibrahim Bey; but to keep up an appearance of confidence in the French, the Caya remained at his station, and professedly entered into Bonaparte's views. Murad Bey, with the remains of his troops; fled toward Saceara, and Ibrahim, his colleague in the government, marched with his followers into the eastern parts of the Delta. The motions of each of these chiefs were strictly watched, and it was found that Ibrahim was using his utmost endeavours to increase his army, and render the people hostile to the French. Bonaparte pursued Ibrahim with a numerous army; but the fugitive bey was successful in escaping from the power of his enemy. The circumstances of Grand Cairo did not permit Bonaparte to be longer absent from that city; but he was alarmed, as he was returning, by the report of an engagement which had taken place at Aboukir, between the British squadron and the French fleet. The news were found to be true, and a commenced was made of the disappointments and defeats by which the French forces were compelled at length to abandon Egypt.

The fleet of Admiral Brueys had been disposed in a French manner near the shore of Aboukir. Some fleet British frigates in search of Admiral Nelson's ships, were seen off the coast of Alexandria upon the 21st of July, which gave the alarm; and upon the 31st of the same month, the fleet itself was observed from the Roads of Aboukir. The French ships were moored at a proper distance from the shore, and placed in a curved line, according to the direction of the deep water. The headmost vessel was placed near a sand bank, the line of battle was flanked by frigates, and the van protected by a battery on a small island. No contrivances could have been better formed for placing the French fleet in an exquisite state of defence; but danger and difficulty raised the spirits of Sir Horatio Nelson; and in such situations, his fertile genius opened up astonishing resources.

Shortening sail on a sudden, he directed a part of his squadron to pass between the French fleet and the sand bank, which the republican admiral had viewed as the great security of his vessels. While a part of the British ships penetrated in this manner between the enemy and the shore, others moored opposite them within Nelson's victory at Aboukir.
a small distance; and the French being exposed to a cross and destructive fire, the British were victorious. Having dropped further down on each side of the enemy's line as their success allowed them, the fleet of Admiral Brucey was either destroyed or taken, excepting two ships of the line and two frigates. The Cul-oden having run aground, was prevented from having a share in the action; and thus the British admiral, with eleven ships of the line, and one of 50 guns, had to contend, and contended successfully, with 13 ships of the enemy, all of them of equal, and some of them of superior force. The French admiral had also four frigates, while the British commander had only one brig to employ in expeditious movements. L'Orient, the flag-ship of Admiral Brucey, carried 120 guns. The admiral himself was killed during the action; and his ship having taken fire, was blown to pieces.

Admiral Blanquet succeeded to the command, and several of the officers perished in the conflict. The British lost Captain Westcott, and 15 other officers. The French had upwards of 8000 killed and wounded, while the British loss scarcely amounted to nine hundred.

Sir Horatio Nelson was made a peer of Great Britain, by the title of Baron Nelson of the Nile, and Burnham-Thorp in the county of Norfolk. He was afterwards raised to the dignity of viscount; and after the celebrated victory where he lost his life, additional honours were accumulated on his memory; and his brother William succeeded the hero by the names of Baron Nelson of the Nile and Hilborough, Viscount Merton, and Earl Nelson of Trafalgar; and was added the foreign title of Duke of Bronte.

The court of Constantinople were quite transported with the success of Nelson, and they lavished upon him many honours. Money was also distributed among the seamen of the British squadron. In the mean time, Bonaparte arranged a constitution for the province of Egypt, somewhat resembling the Turkish model; but while the people had the appearance of choosing the principal officers of state, the power of the government was really in the hands of the French agent. Bonaparte met with much discontent of Aboukir, but his presence could be of no avail in that part of the country. The British squadron had sailed from Egypt, and the Mediterranean Sea was swarming with British vessels. Besides, he had an expedition in view, which was conceived in France to be of great interest.

Upon the death of Sheik Daher, Ahmet Aljezzar was nominated and appointed pacha of St John d'Acre. For many years the merchants in Europe had been enlarging their share of the Mediterranean traffic; and the divan of Constantinople was jealous of those encroachments. Aljezzar exercised his power to check the growing commerce; and he had been peculiarly severe upon the adventurers of France. Soon after the battle of Aboukir, the Grand Signior proclaimed war against France; and this formed a pretext for Bonaparte carrying his arms into Syria, which he had formerly been determined to do. His army consisted of 12,000 men, and 10,000 of them were effective troops. He had Generals Kleber, Bon, Lannes, and Regnier, to assist his views, and execute his plans. They met with several obstacles on their march; and had some engagements, but always with success. They first took Alarish; then Jaffa, with several places of inferior consideration; and in the month of March 1799, they took possession of an eminence on the east side of the city of Acre, and upon the 20th opened trenches within a few yards of the wall.

The Pacha Aljezzar was terrified at the approach of the French troops; for the news of their uncommon successes had reached the whole dominions of the Grand Signior; but he was encouraged and kept at his post by the advice and assistance of Sir Sidney Smith. That enterprising officer had been appointed by the British government to co-operate with a Turkish squadron, in bombarding the city of Alexandria, and seizing the French vessels which were in the harbour. Finding that his efforts could be of little avail upon the coast of Egypt, he directed his course to St John d'Acre, on board the Tigre, accompanied with the two frigates, Alliance and Theseus. He was fearful lest the Pacha Aljezzar should yield to the formidable troops of France; and he arrived in time to prevent the failure of which he was apprehensive. Under the direction of Sir Sidney Smith, the troops of Bonaparte were baffled in various attempts to take the town by assault.

A part of the French troops, under Kleber and Junot, found it necessary to leave the siege of Acre, and march towards the banks of the Jordan. When they were hard put to it, Bonaparte himself marched with additional forces to the assistance of Kleber, and afforded effectual aid. Having accomplished his purpose, he returned to St John d'Acre, and renewed the siege with vigour. He made a lodgment in one of the towers, but was repulsed with great loss by the soldiers within, and the British vessels which were moored in the roads.

In the course of a few days, the Turkish fleet made its appearance under the command of Hassan Bey, and it consisted of thirty sail. This addition of strength to the forces of Aljezzar encouraged the Pacha, and sunk the hopes of the French general. After a variety of severe conflicts, in which many valuable lives were lost on either side, Bonaparte was forced to abandon St John d'Acre, after a siege of sixty days.

Having resolved to depart for Egypt, he concealed Bonaparte's design, by incessantly firing upon the town; and in the night-time made preparations for a safe escape. Upon his retreat to Jaffa, he sunk the heavy artillery, which could not be taken along with them in their retreat; and put the howitzers and small cannon on board some small vessels, and thereof with the wounded soldiers, to be conveyed to Egypt. But the heavy ordnance was discovered; and the vessels with the sick and wounded were taken at sea. Troops of cavalry harassed his soldiers on the rear, and bands of Arabs attacked them on every quarter. By fatigue and slaughter, the road was strewn with the bodies of the dead. The troops of Bonaparte burnt the villages as they passed, destroyed the fields of corn, and marked their route by desolation.

In the mean time, Desaix had pursued Murad Bey into Upper Egypt as far as Syene; but though victorious, he could not subdue the Mamelukes, who moved from place to place with incredible swiftness. When Bonaparte returned to Egypt, he found Mamelukes among the pyramids of Giza, but was not able to bring that active bey to a general action; for he retired into the province of Fayum. In the mean time, a Turkish fleet had arrived in the bay of Aboukir, with an army of 8000 or 9000 men. The news were distressing to Bonaparte; and the more so, as he was apprehensive that Sir Sidney Smith, who had defeated his views at St John d'Acre, was present with the Turkish fleet, and ready to assist them with all his activity and skill. But the French commander in chief determined upon an immediate trial of strength and fortune. He marched
his army, with rapid movements, toward Alexandria; and thence he led on his forces to attack the Turkish camp.

Both wings of the Grand Signior’s army were assaulted at once by detachments in advance, and General Murat with his cavalry darted upon the centre. The lines were thrown into confusion, and most of the Turkish army were either killed in the field, or drowned in attempting to reach their ships. The bravery of the Ottoman soldiers, and the determined skill of the French, made the conflict dreadful. After gaining so complete a triumph, General Bonaparte returned to Grand Cairo. There he attempted to tranquillize the people, and to establish a regular and subservient government. He had formerly professed himself attached to the Mahommedan faith; and here he celebrated a grand festival of the prophet with much solemnity. Having finished these arrangements, he returned to Alexandria, professing that the situation of public affairs required his presence, but really with an intention to embrace an opportunity of returning to France.

In the port of Alexandria there were two frigates lying at anchor, and ready for the sea. Some hopes, aided by a natural wish, induced the friends of Bonaparte to encourage an expectation, that the commander in chief was meditating a return to Europe. No intimation was given, not a hint dropped; but upon the morning of the 24th of August, by the dawn of day, his attendants, trembling with expectation, were commanded to wait his pleasure upon the sea-shore. Instantly they were on board, and the vessels under sail, with a fair wind, steered their course along the coast of Africa. At length, having made for Corsica, they anchored in one of its bays, on the first of September. Upon setting sail from that island, they were seen and chased by a British squadron. Gantheaume, who commanded the frigates, proposed to run back to Corsica; but Bonaparte enjoined him to steer for a port in France. The darkness of the night favoured their escape; and upon the 14th of September 1799, they arrived safely in the port of Frejus.

Never was a plan conducted with so much secrecy, and productive of such great events. A note was conveyed to General Kleber, which he was enjoined not to open, till twenty-four hours after the frigate had sailed. In that note, he appointed him commander in chief of the French army in the East, and it contained rules for the general management of public affairs. When Bonaparte appeared at Paris, he was not conscious for leaving his command; nor was the falling authorities call his conduct in question. Change after change had taken place in the French government, according as successive parties had lost their influence; and he arrived in France upon the eve of the seventh revolution, when the Abbé Sieyes was projecting a new constitution for a new party, who were attempting to rise into power. Discontentment ran through every department of the state; and the public successes had been somewhat counteracted, by the reverses in Italy, and the approach of Suvarrow with his hostile troops.

At this momentous conjuncture, Bonaparte joined in the project of Abbé Sieyes, and a form of government was established, with a senate and various nominal authorities. To captivate the people, it had some names and appointments similar to the popular government of ancient Rome, and the office of first consul was vested in Bonaparte. But neither the name nor the authority were commensurate with his ambition; and having at length acquired additional influence, he was proclaimed emperor of France. Considering the elevation to which at this time he was raised, and the state of degradation into which he has now fallen, we shall quote the following passage from a character which was drawn of this extraordinary man in the height of his power.

"Viewing Bonaparte in the exalted station of emperor where he now stands, we shall neither be dazzled by the splendour of his rank, nor inflamed by envy at the greatness of his success; but we shall endeavour to glance, without partiality, at the steps of his military career, and form a true estimate of his character and conduct. As a soldier, he is possessed of undaunted courage, and no man ever questioned the daring intrepidity of his soul; but he is too violent in his passions to enjoy that self-command, and hold those deliberate councils, which distinguish a great and characteristic an empire. Few generals have equalled Bonaparte in point of fame or extent of conquests; and it is not our wish to deprive him of any part of his well-earned trophies. But it does not appear that his merit as a general, is fully commensurate with his progress as a conqueror. The Italian states have long been destitute of that martial spirit, which glowed in the legions of Rome; and having descended from the height of military glory, they have sunk into the lap of indolence, and laid themselves down on the couch of dissipation. They were tainted, too, by the prevalence of democratic sentiments, and their resistance to the French army was rather apparent than real. They were not unwilling to become captives to those distinguished heroes, who promised them liberty and seducing favours.

"The armies of Germany were harassed by the numerous forces of France; for when both were fatigued by severe combats, the French generals brought up extensive corps of reserve, and poured fresh troops upon the exhausted forces of the enemy. But it has also been suggested, that many of the Germans were dazzled with the professed, but false advantages of the French revolution. As examples of Bonaparte’s violence in times of irritation and difficulty, we shall not appeal to instances of indiscreet management in affairs of state; but we shall turn our recollection to St John d’Acre, and bring to our remembrance the hopeless attacks upon the town and fortress towards the end of the siege, when blood was spilt, and lives sacrificed to disappointed ambition and frantic rage. Even the battle of Marengo was indebted for its success to the effects of a daring attempt, which has met with praise, because it was prosperous; but if it had not terminated in a happy manner, the rashness of the proceeding would have exposed the general to pointed blame. Whether Bonaparte and his family will be secured in the honours of a throne, or whether, in the course of events, they shall be hurled from their grandeur, and levelled with the dust, are arrangements of Providence, which lie concealed in the destiny of heaven."
This temper of mind has made its appearance in various parts of his conduct. It was peculiarly predominant in the arrangements, which preceded the battle of Leipsic; and for him it was more fatally displayed, when he refused the terms of accommodation so frequently offered by the allied powers; and continued his infatuated projects, till, for the benefit of the world, but to his own disgrace, he was driven from the throne, and consigned to a residence in the Island of Elba. And to sum up the whole, "heaven gave him a degree of military skill, but without the recommendation of personal bravery; an activity prodigious, but without aim; a will untameable, but without discernment. All his disasters—all the disgraces with which he has been overwhelmed, have sprang from the same causes which produced his triumphs. Nothing was able to soften the character, to correct the false judgment, or to elevate the corrupt soul of this Corsican soldier."

The court of Constantinople were amused with pretensions on the part of Bonaparte; and he hinted to Kleber, who succeeded him in the command in Egypt, that he should still offer to negotiate with the grand Signior, but retain the commercial influence of the country. But the British interest prevailed at Constantinople, and the overtures of the French were rejected. In the meantime, a Turkish division were landed on the coast of Egypt, and entrenched on the sea-side, between the Nile and lake Menzalah. They were attacked by the French, under the command of Verdier, and but few of them escaped. Intimation being given, that no treaty at Constantinople could be made without the consent of Great Britain, commissioners from all the parties opened a conference on board the Tigre, and an armistice was signed.

Soon afterwards, upon the 24th of January, A.D. 1801, a treaty was entered into, by which the French were bound to leave Egypt in a given time; but their private property was to be preserved, and various arrangements made for a safe and honourable return to France. In the meantime, orders had been issued from the court of London, to enter into no convention by which the unconditional surrender of the French army was not acknowledged; and due attention paid to the interest of the Turks. Yet when the treaty of Alarish was communicated to the British councils, the whole was ratified, and orders issued to carry it into effect; but the French commander refused to abide by the terms of agreement. Some deficiencies in the conduct of the Ottoman court, and the first determination of the British, which was to require a surrender of the French army, as prisoners of war, were assigned as reasons by Kleber for not adhering to the terms of the treaty.

These, without other considerations, might have operated on the general's mind; but such objections would soon have been removed, if they had not been strengthened by the recent prosperity of the French affairs. At Grand Cairo and its neighbourhood, a Turkish army, which had marched from Syria, was subdued by Kleber; and, under the new order of things, the internal situation of France was improved. Notwithstanding every effort, the people of Egypt were not tranquillized, and Kleber, the French commander in chief, was assassinated upon the terrace of his own garden at Grand Cairo. Menou succeeded to the command; and he was determined to submit to any hardship, rather than relinquish the conquest of Egypt. He wished to recommend himself to the favour of the first consul, and enjoy the honour of retaining Egypt in the possession of France. In full expectation of receiving supplies from Europe, he carried forward the public works which his predecessors had begun.

But the court of London had planned a secret expedition: Lord Keith was Admiral of the fleet, and Sir Ralph Abercromby commander in chief of the army. It is uncertain what object the fleet was originally appointed, but intervening circumstances finally directed the expedition to Egypt. It touched at Malta, on its way to the place of destination; and was to wait for the arrival of Turkish troops at some of the islands in the Levant. The haven of Marmaricke was fixed upon for the place of rendezvous; but after waiting long, the supplies from Constantinople were scanty and ineffectual. Too much time had already been wasted, and the object of their enterprise must be attempted. To conduct the army from St John d'Are over land to Grand Cairo, would have been the easiest way to penetrate into Egypt; but the French were in possession of Alexandria, and it would have been hazardous to take a station in the centre of Egypt, and permit the direct communication with Europe to be cut off. It was therefore resolved upon, in a general assembly of the officers belonging to the expedition, that they should sail directly for Alexandria.

Early in the morning of February 22d, A.D. 1801, the signal was made for unmooring, and in the evening the whole fleet was under way. During part of the voyage, the weather was stormy, and a Greek vessel foundered. Upon the first of March, in the evening, a signal was made that land was in sight, and in the morning the fleet anchored in the bay of Aboukir. The weather was too tempestuous to permit a landing, and Major McKerris, who had been sent to examine the shore, had been unfortunately killed by the enemy. Abercromby himself reconnoitred the shore in a small vessel, and took every precaution to effect an easy landing. When the sea became sufficiently calm, the first division prepared to land at an early hour in the morning. It consisted of 5000 soldiers, under the command of majors-general Moor, Ludlow, and Coote, together with brigadier-general Oakes. But these preparations could not be made without the observation of the French; and they were ready to receive them with artillery, a large body of soldiers, and a number of cavalry. Though the Fury and Tartarus bomb vessels, with sloops and gun boats, were appointed to protect the landing of the forces; yet they suffered dreadfully from the fire of the French, who opposed them on the shore.

But the British troops displayed the most undaunted valour; and though they were scattered, and could attack the enemy only in detached parties, yet the French forces, after making a stout resistance; under the command of General Friant, were forced to retire. During the course of the day, the most of the troops were landed, and met with no more resistance; for the peninsula of Aboukir was mostly abandoned to the British. Daily skirmishes were happening between the two armies, but no regular engagement took place till the 13th of March. Upon the advance of the British forces, the army of General Menou were discovered in a strong position upon a range of sand hills. Their right extended to the canal of Alexandria, and their
left was supported by an extensive range of ruined buildings. The position was strong, but it was the more necessary on that account, that the British should possess it, and the army received orders to be in readiness for marching by five o'clock in the morning.

When within gun-shot of the enemy's lines, the French advanced with rapid movements; but they were received with determined bravery, and were driven back from station to station till they took their stand near Alexandria, upon the heights of Nicopolis. It would have been desirable to have driven them from that station, and it is believed that the business might have been accomplished; but there were circumstances at that time which induced the British general to decline the attempt. Both armies had suffered severely in the action, though the loss was less serious than might have been expected. Upon the landing of the British forces, General Menou was at a distance in the interior of the country; but being apprised of the danger, he hastened to Alexandria, and arrived from Grand Cairo with 9000 men upon the 20th of March. He determined upon an immediate attack, being confident of success; and Sir Ralph Abercromby was informed by a friendly sheik of the Arabs, that the attack was to be made on the following morning. Every arrangement was made which was suitable to the prospect of so important an engagement.

The army was strongly encamped in the same favourable position which it had taken up after the late engagement, and was disposed of in the following manner. In the centre of the first line were Major-general Ludlow and Coote, with the Royals, two battalions of the 54th, and the 92d regiment. About a quarter of a mile in advance, upon the right, Major-general Moore was stationed with the corps of reserve, which consisted of the 28th and 58th regiments; the 23d, the 42d, and the flank companies of the 40th, together with the Corsican rangers. The left wing reached the canal of Alexandria, which was composed of the 8th and 18th, the 13th and 90th regiments, under the command of Major-general Cradock. Upon the left, near the lake of Aboukir, the staff was placed; and the whole extent of the army was about a mile in length.

In the second line, upon the right, were the Minorca, De Rolle and Dillon's regiments, commanded by Brigadier-general Stewart. In the centre were the 30th, the 4th, and 89th regiments, under the command of Brigadier-general Doyle. Upon the left was Brigadier-general Finch, with the 20th regiment, and both the mounted and dismounted parts of the 12th dragoons. Also the 27th, 50th and 79th regiments, which were commanded by Lord Cavan. The cavalry of reserve were placed behind the troops of General Moore, Captain Maitland was stationed with gun-boats near the beach, and the fleet was cruising off the port of Alexandria.

The French army, in the strong holds of Nicopolis, was arranged in the following manner. The right wing was composed of the 18th and 85th, the 25th, 61st, and 75th demi-brigades, commanded by General Regnier. In the centre were the 21st and 32d demi-brigades, with two grenadier companies of the 25th, and three of the second light battalions, entrusted to the command of General Rampon. The left, under General Lanusse, consisted of the 4th and 18th, the 60th and 88th demi-brigades. The army extended with its right wing towards the canal of Alexandria, and with the left it approached the sea. Behind the centre was a powerful body of cavalry, commanded by General Roise, and in the rear of the whole was a large park of artillery. Early in the morning of the 21st of March, all the troops were under arms; and every officer was at his post. The intelligence communicated by the Arab chief might be untrue; but it related to too important a concern to be neglected. But his information was as correct as it was valuable; for soon after three o'clock in the morning, the report of musketry was heard on the left; and the noise of cannon immediately succeeded; but Sir Ralph Abercromby justly considered it as a false alarm. From the situation of the troops and the nature of the ground, that was not the quarter from which a discerning general would make his attack. Scarcely was this conclusion drawn, when shouts of defiance and clashing of arms were heard upon the right. It was a misty morning, and the division of General Lanusse had almost approached unperceived the position of General Moore. Upon the sea-shore, the French troops made an attempt to enter the ruins occupied by the British 58th regiment; and it was not till they were quite at hand that Colonel Houston could see them so distinctly, through the haze, as to distinguish them from his own men, and direct his fire with safety. General Silly's brigade was engaged with the 28th regiment, and at every point the battle was severe. The 23d and 42d regiments flew to the relief of their fellow soldiers, and the foe was repelled.

General Rampon, with the centre division of the French army, penetrated through the British lines, but was forced to retire with considerable loss. While the French were everywhere giving way, General Roise was commanded to charge the British upon the right, and his cavalry were to be supported by the infantry of Regnier. The first charge, conducted by General Boussart, was bravely sustained, and a second by Roise himself was not more successful. Being repulsed in every quarter by British bravery, the French army retreated, and took up their late position upon the heights of Nicopolis. A French standard, inscribed with many mottoes of victories and trophies, was taken by Anthony Lutz, a private soldier in the Queen's German regiment. This standard was the subject of much contention; but it seems, after every enquiry, that the standard was first taken by Major Stirling of the 42d regiment, and given in charge to Sergeant Sinclair; but the sergeant being wounded, the standard was lost and retaken by Anthony Lutz. Each of the persons concerned had great merit for their bravery in the hour of danger; but Lutz was rewarded with a pension of £20 a year, as being the most suitable boon for his situation in life.

Upon the 21st of March, 12,000 French troops were on the field of battle, whereas the British force was little more than 10,000 men. The French cavalry were well mounted, whereas the horses of the British army were of an inferior kind, supplied by the Turks; and as the French had been in possession of Egypt for a considerable time, they were everywhere better prepared than the British army could be, who had landed but lately on the beach. But British valour and perseverance overcame every difficulty, and taught the republican soldiers of France what they were to expect from the soldiers of Great Britain. Generals Lanusse, Beaufet, and Roise, did not survive the late engagement, and the loss of the French was immense. Six British officers were killed upon the 19th of March, Major Ogle died by the bursting of a shell at the landing of the troops, and Ensign Warren and Mead fell also on that memorable occasion. On the 21st of March, which terminated so honourably to the British name,
Sir Ralph Abercromby, their tried and much-esteem ed commander-in-chief, died after the battle, on board the Foudroyant, Admiral Keith's own ship; and his death was occasioned by the wound of a bullet which entered his thigh, took its direction toward the groin, and could not be extracted. He was lamented by his country, and beloved by his army. His body was deposited in the north-west bastion of Fort St Elmo, in the island of Malta. A monument was erected to his memory in St Paul's church, London; and the king was pleased to command, that the funerary French standard, taken by de Lutz, should be deposited on his tomb. The lady of the departed hero was dignified by the title of Baroness Abercromby of Aboukir and Tullibody, which remained to the heirs male of her deceased Lord. Other remembrances accompanied these honours, and the national feelings were indulged by these merited tokens of public favour.

Upon the death of Sir Ralph Abercromby, Major-general John Hely-Hutchinson, being the second in command, succeeded in course to the office of commander-in-chief. The part he had to act was perilous. To push forward immediately to Alexandria would have been dangerous, and to remain inactive would have been inglorious. To establish a correspondence with the Grand Vizier, who was directing his course to Grand Cairo, and to obstruct the communication of the French with that important city, it was necessary to reduce Rosetta and the strong post of Ramlamiah. Rosetta was of great consequence for defending the navigation of the Nile, and conveying what was necessary to Grand Cairo; and when it was taken, the care of the place, and the reduction of Fort Julian, were given in trust to the Right Hon. the Earl of Dalhousie. The city of Alexandria being put into a respectable state of defence, and the communication of Grand Cairo being rendered more difficult by the water, which was thrown into the old bed of the lake Mareotis, which extended far into the desert, the British and Ottoman troops were attended every where with success.

A party of the French advancing from Alexandria, were attacked by General Doyle and Major Wilson; and being already harassed by the Arabs, they surrendered themselves prisoners, upon the promise of being permitted to return to France. A considerable number of French troops were assembled at Grand Cairo, and a detachment was sent to engage the army of the Grand Vizier, and drive them back to Salehiah. An engagement ensued, and the Turks were victorious. Immediately after this victory, the Grand Vizier encamped at Benerhasset, where Major-general Hutchinson, and the Capitan Pasha went to visit him, and concert measures for the siege of Grand Cairo. Though several skilful British officers were ready to assist the Grand Vizier with all their talents; yet General Hutchinson was fearful of a Turkish army meeting the well-trained troops of France; therefore, as the Grand Vizier advanced on one side of the Nile, General Hutchinson made progress on the other. Seeing these powerful preparations, General Belliard, the French commandant of Grand Cairo, proposed a conference for surrendering the city.

Brigadier-General Hope appeared for Great Britain, Mahommed Pasha for the Vizier, Isaac Bey for the Capitan Pasha, and Osman Bey for the Mamelukes, who were still formidable, though held in check. Generals Morand and Douzelot, with Tareyre, a chief of brigade, were employed in behalf of the French. Captain Taylor was secretary to the conference, and, in the course of six days, a convention was signed for surrendering Grand Cairo. Vessels, and every necessary provision, were furnished for facilitating the departure of that division of the French army; and in the first week of August they sailed from Egypt for their native country. In the mean time, Menou was providing for his army at Alexandria; and General Coote was providing for the British interests both by sea and land.

While transports with supplies for the French troops were not permitted to land, the British forces before Alexandria had received reinforcements and other supplies from Europe. But, after all, Menou refused to comply with the terms which Belliard had accepted at Grand Cairo, and vowed to triumph or perish in the fate of Alexandria. During these transactions, General Hutchinson had been created a Knight of the Bath, and appointed Lieutenant-general of the Mediterranean. As Menou refused to surrender, it was necessary to adopt measures for driving him from Alexandria. The most convenient place for an attack appeared to be the peninsula of Marabu, on the west of Alexandria. This scene of action was fixed upon by General Coote, and he was appointed to conduct the operations, while Sir John Hutchinson commanded the camp to the eastward of the city.

The troops under the command of General Coote were about 4000 rank and file, with a due proportion of artillery and engineers. They pushed along in boats on the lake Mareotis; and to facilitate their landing, a diversion was made by the troops of General Finch, and a successful landing was effected. To distract the attention of the French, General Hutchinson made an attack on the enemy's whole line, upon the heights of Nicopolis, while the western division of troops had taken the fort of Marabu, and then pushed forward toward Alexandria. The French in this situation were strongly posted; but their lines must be forced, or Alexandria could not fall. Upon the 22d of August, therefore, the British troops were under arms by dawn of day, and moved forward in separate columns. Lord Cavon, with Generals Ludlow and Finch, had the principal command of the corps and divisions of that day. Upon the right of the army was the lake Mareotis, with four gun-boats; and on the left the old harbour of Alexandria, with six sloops of war. As the army advanced, so did the vessels on either side, keeping rather in advance, to harass the enemy, and protect the British in their march.

The French soldiers retired, and the British having advanced, formed an encampment upon the ancient Nicopolis. Both sides of Alexandria were invested by the British troops; an accession of ships in the old harbour poured destruction upon the city; and Menou, after various attempts to procrastinate, in the hopes of receiving supplies from home, was compelled to capitulate, upon the same terms which General Belliard had accepted for Grand Cairo, and which General Menou had formerly rejected with scorn. Here, also, Brigadier-General Hope was the person employed to adjust the capitulation; and on the 2d of September the French surrendered. Sir John Hely Hutchinson was created a British peer; and Lord Keith, who had already an Irish title, was raised to a seat in the British House of Lords. General Coote was invested with the order of the bath; and the Grand Signior conferred many favours upon the principal officers both by sea and land. All the regiments who had been in Egypt were allowed to carry a sphyx upon their colours. Upon the 18th of September, the keys of Alexandria were
EGYPT.

392

delivered to the Turks, but a division of British soldiers were retained, for a time, to garrison the city. There was a deadly hatred between the court of Constantino - ple and the Beys of Egypt; and it was thought to be expedient, as well as humane, to see that the Ottoman soldiers did no injury to the humbled Beys.

The officers of the Grand Signior had determined to ensnare the principal Beys, and carry them to Constantinople; but the plot was discovered, and many lives were lost. The British interfered, and the Beys entered into an agreement to retire into Upper Egypt, within a limited part of the country. But this was only a temporary arrangement; and it must have been obvious, that they would seize upon the first opportunity to return to the fertile plains of the Delta. Their spirits were broken, but their designs were the same; and they must have been anxious to regain their influence, and, if possible, to become masters of the country which they had long been accustomed to keep in control. Accordingly, in 1806, Osman Bey Bordossi, together with Ibrahim Bey, and other chiefs of inferior note, were still in possession of Upper Egypt, and apparently faithful to the treaty they had made, while Elfi Bey, who had then risen to great power, possessed the left side of the Nile, from Sacare to Rosetta. Occasionally the Arabs under his command pushed forward between the lake Mareotis and Aboukir, threatening the city of Alexandria; while Pasha Mahomed Ali, the representative of the Grand Signior, remained inactive at Grand Cairo, and his Albanian soldiers were without pay, and in a state of mutiny.

The authority of the Grand Signior was obviously in a weak condition, when it could not repress the incursions, nor overthrow the power of the turbulent Elfi Bey. Notwithstanding the benefit which the British nation had conferred on the court of Constantinople, in driving the French from Egypt, and restoring the country, without exception or reward, to the Grand Signior; yet the intrigues of Bonparte, who was then subverting kingdoms, and destroying wise and ancient alliances, had found access to the councils of the Grand Turk, and rendered the nation hostile to Great Britain. In this situation, an expedition was fitted out against Constantinople, and another directed to the coast of Egypt. The Egyptian expedition sailed from Sicily on the 6th of March, under the command of Major-General Alexander Mackenzie Fraser. It consisted of the 35th regiment, a battalion of the 31st, and another of the 78th, together with De Rolle's regiment, four troops of the 20th dragoons, three companies of artillery, and two of artificers,—in all about 5000 men, under convoy of the Tigre and Apollo.

In the night of the 7th, or the second night they had been at sea, the Apollo, with nineteen transports out of thirty-three, which were employed in conveying the troops, parted company; while the Tigre, with the other fourteen, anchored to the westward of Alexandria, on the 16th of March. They learned by the Wizard sloop of war, which had been sent forward to receive instructions from Major Misset, that the French consul at Alexandria was endeavouring to prevail upon the governor to admit a body of Albanians for the defence of the city; and that it was necessary, to ensure success, that an attack be made upon Alexandria without delay. Having made the necessary preparations, the British force moved forward in the evening of the 18th, and forced their way through a paled down entrenchment with a steep ditch, which ran from Fort Des Bains to Lake Mareotis. They almost reached, with little loss, the gate of Pompey, which they found barricaded, and the walls lined with armed men. As the party did not exceed 1000, it was thought too hazardous to risk an engagement, and therefore the general directed his troops to the neighbourhood of Aboukir, and took up a position upon the very ground, which Abercrombie's troops occupied on the declared 21st of March. A flag of truce was sent into Alexandria, and the town, with two frigates and a corvette, surrendered to the British arms; and, what is remarkable, were taken possession of upon the morning of the 21st, the anniversary of the memorable victory obtained by the British over the French six years ago. On the 19th, the Apollo, with the nineteen transports, arrived on the coast of Egypt, and entered the bay of Aboukir.

It was stated to General Fraser by Major Misset, his majesty's resident in Alexandria, that the city would be reduced to famine, unless Rosetta and Ramlanik were taken possession of by the British troops. With the concurrence of Admiral Sir John Duckworth, some British troops, with the Chasseurs Britanniques, under Major-Generals Wauchope and Mead, were detached and appointed to perform that service. They possessed themselves of the heights of Abourmandour, which commands the town, and suffered no loss; but having entered the town, they were severely attacked from the houses in all quarters. General Wauchope was killed, and General Mead severely wounded. They retired to Aboukir, and from thence to Alexandria; and, upon the urgent representations of the magistrates and people of Alexandria, another attempt was made to occupy Rosetta, but the enterprise was again unfortunate. The detachment marched by the wells of Aboukir and the village of Edko; and having taken possession of Allamet, a village where the enemy occupied a post, they marched on to Rosetta, and drove the Turkish soldiers into the town. It was summoned to surrender; but the summons was despaired, and General Stuart, who commanded the troops, was obliged to retreat to Alexandria, with the loss of about 1000 men, killed, wounded, and missing. This enterprise was unfortunate on two accounts; first, because powerful reinforcements had arrived for the Turks from Grand Cairo, which gave them an advantage; and secondly, because the Beys had not joined the British, as they were led to expect. They were anxious that neither the Turkish nor British forces should be masters of Egypt; for they were desirous themselves of independence; but on the present occasion, they were unable to obtain it, and therefore leaning to the strongest side, they surrendered, and made a treaty of peace with the viceroy of Egypt.

The British ministers had been misinformed with respect to the Turkish forces in Egypt, as well as the disposition of the Beys; and not having supplies at hand to give them the necessary support, when pressed by superior numbers, the expedition was rendered of no effect, and the enterprise was abandoned. Much has been said of the advantages which might be derived from Egypt as a province; but it is a question whether a settlement in that country would be of real benefit to Britain; as the trade of the Mediterranean is sufficiently open to us in the time of peace; and the Indian commerce, which of old flourished in Egypt, is more conveniently carried on by a different route. But the government of Egypt is miserable and depraved, and stands much in need of some renovating power to reduce it to order and happiness.

Part II. Statistical Account of Egypt.

Properly speaking, Egypt is a part of Africa, being included within the same natural division of the globe; but, from its particular situation, and the importance which it once held in the scale of nations, it is generally described in a more independent and particular manner. It is bounded on the east by the isthmus of Suez and the Red Sea, on the south by Nubia, on the west by Libya, and on the north by the Mediterranean Sea. It commences on the south about 23° 45' of north latitude, and at Rosetta terminates at 31° 27', being in length about 500 miles, from south to north; and some parts of it 250 in breadth, comprehending the greater and lesser Oases. But this extent is merely nominal in point of value: the principal parts of the country being the Delta, or lower part of Egypt; and the valley of the Nile, in the higher parts of the country, which is comparatively of a small breadth, being bounded on both sides by high hills or abrupt banks.

The mountains upon the east of the Nile extend to the Arabian Gulf, and are only inhabited by Bedouins, or travelling Arabs, who pitch their tents here and there, as circumstances require; for water is scarce, and vegetation scanty. Across these mountains is a dreary road to Cosseir, which is a sea port of the Arabian Gulf; but the intercourse between that and the Nile is neither ready nor frequent. The principal towns and villages are upon the eastern side of the Nile; for, in going westwards, you soon meet with a sandy desert, with here and there occasional spots of verdure, which are called Oases, or islands, among the sand, when they amount to a size that deserves the appellation. Even Alexandria is hemmed in by the burning sands of the sterile desert; while the Delta is a most luxurious tract of land. The soil is rich, being of a pure black mould, unctuous, and stands in need of little or no manure. It is called the Delta, from the shape which it bears to the letter in the Greek alphabet of the same name.

It is evidently formed, at least in part, of an alluvial soil; but we cannot suppose, that the earth to any depth was formed by the deposition of matter carried down by the streams of the Nile. In the early state of the earth's surface, more loose earth might be carried down by the streams than there can be at present; but we are not persuaded, that any accession of this nature could be sufficient, in a given time, to convert a bay of the sea into an expanse of land. We are rather to suppose, that when this world was brought into shape, it consisted of sea, dry land, and marshy districts. When these swampy parts lay low, and bordered upon the sea, they would be occasionally overflowed; and hence a comparatively small addition of alluvial matter might gradually raise them above high water-mark, and permit them to become dry and arable land.

It is not, however, unlikely that shallow places of the sea have been forsaken by the water, which could soon and easily be cultivated. We do not mean, that the waters of the sea have been diminished in quantity; for if this were the place for such discussions, it might be shewn, that the rains and streams are sufficiently adequate to supply the quantity which is lost by evaporation and absorption. Chemical operations which take place in the atmosphere, contribute more, perhaps, than the rarefied fluids of evaporation, to produce those abundant rains, which supply the springs and streams of water that run into the sea, and maintain its bulk. While the quantity of water remains the same, certain portions of the sea may be converted into valleys, by the water of the ocean being drawn off to supply new spaces; or, in other words, to form new branches or arms of the sea. Convulsions of nature are supposed to have opened up new valleys, or considerable expanses of low lying lands, into which the waters of the ocean ran, and converted them into seas. Such is supposed to have been the case with the Red and Mediterranean seas, and with several bays and inlets on the continent of America. And this may account for such alluvial flats as the Delta of Egypt, and many other districts of the world, which have evidently been derived from the sea, and still exhibit remains of marine productions.

The Delta of Egypt may be higher above sea water-mark at present than it was in early times, from the effects of the earth accumulated by the annual decay of luxuriant vegetable productions; but we believe, that the progress in this respect is extremely slow, if at all perceptible. As much earth may be washed off by the streams which overflow it, as is deposited by these waters, or occasioned by vegetable products. The difference of cubits in the rise of the Nile, which was necessary at different times to water the Delta, sufficiently for producing luxuriant crops, are rather to be ascribed to different lengths of the cubit, than to any visible difference of the height of the Delta above the general channel of the Nile.

This river requires particular notice, from its importance to the fertility and general prosperity of Egypt. In times of ignorance, many absurd ideas were entertained respecting the origin and source of this celebrated river. About 7° south of the boundaries of Egypt, two rivers unite their streams, to form the copious waters of the Nile. One of these is called the Bahir Alabiad, which rises in the district of Donga, belonging to the Gebel Alcomari, or Mountains of the Moon, in the 8th degree of north latitude. It is also called the White River, from the tinge which its waters acquire from the nature of the channel over which they flow. The latter is the Bahir Alazrek, or Blue River, whose waters are clear; which has its origin from some springs in the province of Geesh, in the 11° of north latitude. The White River takes its rise about 3° nearer the line than the Blue River; and the former is three times the size of the latter; and yet Mr Bruce ascribes the origin of the Nile to the province of Geesh rather than to the Mountains of the Moon.

There have been more disputes and sarcastic humour on this head, than the merits of the case deserve. One part of the waters of the Nile rolls its course from the Mountains of the Moon, and another from the province of Geesh; and the question is merely this, which of these places is to be esteemed the source of the Nile? It is far from being uncommon for a river of note to derive its name from the smaller of two branches which compose its streams; and the argument would hold equally good, whether the difference be six or six hundred miles. That the waters of the Nile have their original source in the Gebel Alcomari, is certain; but the question is, how and when the Nile derived its name? The word Nile, in some of the Eastern languages, means the Blue River; and as the Bahir Alazrek, which rises
The Lake Sherun, supposed to be the so much celebrated Meris of old, is now of small moment, and affords but a scanty subsistence to a few miserable fishermen. This lake is near 40 miles in length, and six in breadth; and some have supposed that the Bathaun, which appears to have been artificial, was the Meris of the ancients. As to the Babib-Delta-Ma, or river without water, it seems to have been originally a channel for conveying water from the Nile to the adjoining plains, which, in happier times, were well watered and fruitful. The higher and unwatered parts of Egypt are extremely barren; but the banks of the river are capable of high cultivation, and the fruitfulness of the Delta has been long and justly celebrated.

The appearance of the Delta is luxuriant; but the palm and the date tree, to be seen everywhere, is uniform and fatiguing. The orange groves about Rosetta have been much celebrated; and that perhaps is the most delightful scene upon the Nile. Wheat and barley are produced in profusion, with little agriculture, and that of the simplest kinds. Oats are scarcely known in the warmer countries; and the Delta abounds with rice, lentils, and maize. Dates and oranges, citrons, and various kinds of pulse, are common productions, in the well cultivated parts of Egypt. Two or three different kinds of crops may be obtained annually.

The Egyptian sycamore was probably imported from Arabia, and is much valued for its shade, as well as for its fruit. It grows with little moisture, and flourishes on the frontiers of the sandy desert. The date, the palm, the bread tree, the pistachia, and the Oriental plane, are highly ornamental in the vicinity of their towns; and the cypress overshadows the tombs of the dead. The caper-bush also grows profusely among the ruins of Egyptian buildings; and the henna is abundant, from which the women prepare the yellow dye for tinging their nails. The papyrus, once so famous and common in Egypt, is no longer found in its borders, unless it be the cyprus papyrus of Limnea; but the lotus, sacred to their gods, is found in abundance in all the canals and shallow pools, when the streams of the Nile retire. In Egypt, too, are found the almond and the apricot, the fig and the orange, the pomegranate and the peach. Melons and gourds grow to perfection, and are highly valuable for food. Cotton, and the sugar-cane, together with the plantain, and other productions of different countries and climates, have been imported to Egypt; and as they thrive well with so little care, they would be of great importance under different treatment; and with proper cultivation, Egypt might flourish with the most favoured climates.

The situation of Egypt upon the globe makes it always warm; and at certain seasons the heat is intolerable. From March till November, the mercury in Fahrenheit's thermometer rises in the shade to 86 or 88 degrees. This being the case in the Delta, the heat is more intense in Upper Egypt, where the earth has little, and in some parts no vegetable clothing, but abounds in arid sands and burning rocks. In this situation, the thermometer never indicates a lower temperature than 59°, and seldom less than 52°, even in the coldest season of the year. This excessive heat is partly occasioned by the distance of Egypt from the ocean, and by the moderate height of its hills; for in the bosom of the line, where the mountains are high, the cool air descending from these high regions refreshes the country, and moderates the climate. And we may add, that the air is never cooled by copious rains; for if we ex-
cept occasional showers on the coast of the Mediterranean Sea, which happen in the months of December, January, and February, scarcely a drop of rain falls through all the extent of Egypt. A slight shower in any other part of that vast country is a rare occurrence, and seldom seen by the most aged and observing.

This peculiarity in the circumstances of Egypt, must be accounted for by natural causes; and though we cannot pretend to detect every arrangement which tends to produce so striking an effect, yet there are certain causes obvious to reflecting and philosophical minds, which are sufficient to shew in what manner this occurrence takes place. "The tendency of the air," from the cooler regions, "to fill up the rarified space between the tropics, not only produces the monsoons and trade winds, but also assists us to offer a reason for the deficiency of rain in the districts of Egypt. Being partly within the extent, and altogether within the influence of the northern monsoons, the clouds of that quarter are hurried toward the equator from the month of April to October, and, being carried both rapidly and high, none of them descend upon Egypt, where there are no lofty mountains to attract them, nor do they let fall on its surface any part of their burden, but leaving it unvisited and dry, they hasten to the mountains of Abyssinia, and there deposit their watery stores. The heated and rarified air between the tropics necessarily ascends into the higher regions of the sky; and, yielding to the thicker atmosphere, by which it is displaced, it is driven towards the northern mountains to be loaded with vapours, and to return in a lower direction toward the equator." (Dr Wilson's History of Egypt, vol. i. p. 19 and 20.) But though rain seldom falls in Egypt, yet the dews are exceedingly copious, and refresh the ground.

The comforts of Egypt are diminished, by being subject, in some degree, to that suffocating wind of the deserts, which spreads terror and desolation. It is called the sumiel, the sinnoum, and the chamiss. It is announced by a lowering, troubled sky, and sometimes by a hissing noise. Its heat may be compared to that of a newly opened oven, and its effects are always distressing, and sometimes insupportable. It hardens the skin, and destroys the vegetable growth. It affects the lungs by its pernicious qualities, produces convulsions, and sometimes death. It is felt in Africa, India, Syria, and Arabia; and it reaches Italy in a more modified condition, where it is called the sirocco, and is guarded against with anxiety and care.

Every where the human race are subject to diseases, and in Egypt some of them appear in their worst forms. The leprosy, with which the people of that country are frequently affected, does not seem to be so virulent as that which was spoken of in old times. But the diseases of the eyes are violent and dangerous; and a considerable part of the people are occasionally affected, and sometimes so severely, that some of them lose one, and others both of their eyes. The British soldiers brought this disease with them to Europe; and it is to be hoped that the attention of our experienced surgeons has paved the way for moderating the dangers of the disease. The sources of this affection are not well ascertained, though it has been supposed, that it is owing to the small dust with which the air is impregnated, and especially to the nitrous particles with which the soil of Egypt abounds. It may partly be ascribed to the habit of sleeping in the open air, and being exposed in the daytime to the excessive glare of the reflected sun. Guarding against these inconveniences, will promote the health and comfort of the inhabitants. But of all the diseases which affect this or any other country, the plague is the most alarming. Like other fevers, it is supposed to proceed from miasmata, or putrid effluvia, and it spreads its infectious matter in the air. A high degree of heat, as well as the application of cold, is said to abate its violence, and remove its effects. It has frequently been found, that the free access of cold air has removed the symptoms; and we have no doubt that using the cold bath would be found to be efficacious.

There is no room for mineralogy in the district of the Delta, nor does the valley of the river, in any part of its course, afford subjects for the investigation of that science; but the mountains and higher grounds on each side of the river, yield many curious specimens of the fossil kingdom. The rocks, which form the banks of the lower part of the Nile, are all calcareous, and those on which the pyramids stand abound with shelves, but above the town of Esneh they consist of freestone of various qualities. The chain of mountains on the right, or Arabian side of the river, furnish granite, porphyrites, porphyry, and traps. Here too are found porphyrites, porphyrin, and various kinds of breccia. It was a species of the pudding-stone of which the colossal statue of Memnon was formed at Thebes, which, according to ancient tradition, emitted various sounds at the rising or setting of the sun. Granite or primitive rocks are found in Egypt, but they chiefly prevail toward the southern parts of the country. One of the mountains toward the Red Sea, is called the Mount of Emeralds, and precious stones had formerly been obtained from that part of the country; for those of the best quality are still called by the Persians, the emeralds of Alsaid. Among the fossil specimens of Egypt are found felspar, hornblende, lapis-lazulis, marble with veins of silver, mica, amethyst, cakedony, carnelian, onyx, Jasper, sienite, &c. In the isthmus of Suez there are various silicious fragments, which serve as a bed for those curious Egyptian pebbles, which, when cut, exhibit portraits, branches of trees, ruined buildings, and other imitations of nature. Egypt does not abound in metals, yet iron as well as manganese has been found there, and it is obvious that lead and copper had formerly been worked in its mines.

The animals of Egypt are little different from those of other countries in a similar situation. The native horses are well made, and by proper care might be rendered highly valuable; but they are rather neglected for the Arabian horses, which the Turks prefer on account of their fleetness and spirit. Upon the rich pastures of the Delta, the ox, the cow, and the buffalo are found in perfection. Sheep and goats have also their proper pasture, and are found in numbers. Bees, insects, and reptiles, are also abundant; and the lakes, as well as the sea and the river, abound with fish. In this country the ass is of considerable beauty, as well as strength, and is employed for riding and various useful purposes. The ibis, so much revered in Egypt formerly, is not to be found in that country at present; but from the bodies which were so carefully preserved by the ancient Egyptians, it appears to be a curlew, and not a species of the stork.

Few countries abound so much with ruins as Egypt. Antiquities, which do not only shew its former importance and glory, but is a sad memorial of the reverses and degradations to which human affairs are constantly exposed. The situation of Canopus and Zanis, with other places of note, may be sought for in the Delta; but the prin-
capital memorials of ancient times are to be found in the more early inhabited places of the country. The remains of Denderah, anciently Tentyris, indicate a greater variety of ruins and wrecks of former arts than any other place of Egypt. Though it does not appear to have been the capital of any district, yet it must have been a highly favoured residence, and under the special protection of the kings and nobles of the country. But the ruins of Thebes are peculiarly the objects of our attention, as deriving a higher degree of interest from the antiquity of the city, and the rank which it held as the seat of royalty and science.

Yet even here one might be astonished to find such scanty remains of a city, so great and so famous; but ancient towns, and even the most celebrated cities of remote times, contained few buildings which were calculated to stand the ravages of time. Excepting temples, palaces, and other public edifices, the other buildings were composed of mud or some perishable materials, which were easily swept away by the current of events. And this may be assigned as the reason why cities, like the far-famed Troy, have been entirely destroyed, and the place where they once stood scarcely ascertained. The situation of Thebes is sufficiently known, but little more of it remains than the ruins of its public buildings, its vaulted receptacles for the dead, and some huge specimens of statuary, which command our admiration. The colossal statue of Osymandius, with the two figures, one on each side, which are supposed to represent his wife and daughter, are still seen, and have often been described. Near the same city, an enormous figure, 75 feet high, is described as the celebrated statue of Memnon. Though all these representations are only founded on conjecture, of one thing we are certain, that whosoever this and the preceding statues represent, they belong to ancient times, and are memorials of the progress which in those days had been made in the fine arts. The excess which their proportions bear to the productions of nature, is a proof of rudeness of conception, and a deficiency in taste and imitation. Still, however, in the remotest times, Egypt was eminent for its knowledge and acquirements.

The paintings in the tomb of Thebes have wonderfully preserved their colours, and are specimens of Egyptian ingenuity. They have also a tendency to exhibit the fashions and designs of furniture which were known in those early times. Since the French and British expeditions, we have imitations of Egyptian vases and carpets, chairs and couches, as well as other articles of Eastern production. The ruins of the temple at Carnak, and the magnificent remains of Luxor, are curious and astonishing; but they are neither so chaste nor elegant as the designs at Esnah, Edfu, or Tentyra. Though all the Egyptian relics are ancient, yet there is a difference in their style, and an evident progress from the more rude to the more refined. Girgeh, which is now the capital of Upper Egypt, is comparatively a modern town, and not productive of antiquities; but it derived its name from a monastery dedicated to St. George, more ancient than the town, and built in an early part of the Christian era. The Isle of Philae, at the entrance of the Nile into Egypt, is interesting for many ancient remains, which have been well exhibited by M. Denon, in his splendid and faithful account of monuments, remains, and antiquities of Egypt; and Elephants cannot be passed over without notice.

Memphis has suffered so completely in the lapse of ages, that, like many other ancient cities, it is a question of some curiosity where it was situated. It is most probable, that it stood between the pyramids of Giza and Saccara; and as it was of great extent, its suburbs may have stretched themselves toward both those places, and comprehended within its bounds Mohammon and Metraheny. Upon this supposition, those ancient depositories of the dead, which are found at the pyramids of Giza and Saccara, may have been the burying-places of the dead; without the walls of the city, according to the practice of ancient times, and in this situation, there have been discovered vast excavations and numerous mummies. In the article of antiquities, we speak not of Damietta and Rosetta, though they were ancient stations upon the branches of the Nile; but they were rather the resort of sea-faring men, than the abodes of literature or science, and consequently afforded few works of splendour or art to be handed down to succeeding times.

Although Alexandria was built for the accommodation of trade, and became the emporium of foreign merchandise; yet it also became the residence of kings, and flourished with grandeur and the arts; and now, in its forlorn condition, it exhibits many curious remains, which command our reverence, while they excite our regret. The ancient Pharos was a superb building, worthy of kings, but it has long ago been utterly destroyed; and the present Pharos is an inferior fortification, at the end of a causeway projecting into the sea. Upon the shore, to the eastward of this tower, are two obelisks or Cleopatra's needles, above 70 feet high; one of them continues erect upon its base, while the other has been overthrown, and was partly sunk in the sand, till Lord Cavan, after the British victories, had it raised from the earth, with the view of transporting it to London. Not being able to have his design accomplished, he deposited various specimens of British and Turkish coins in the hole of the pedestal, where the shaft had been inserted, and covered them with a marble slab, upon which was inscribed an account of the British exploits in subduing the French and recovering Egypt for the Grand Signor. These obelisks are inscribed with hieroglyphics, which might assign them a very ancient origin; but it is impossible to determine whether they have a just claim to such antiquity, or whether they were constructed to adorn the royal buildings of the Ptolemies, and afterwards dedicated to Cleopatra. As to the hieroglyphical figures, they may only have been imitations, and performed with the view of giving the obelisks an air of antiquity. But to whatsoever age these or other obelisks of Egypt may have belonged, it will continue to be a matter of astonishment, how such vast pillars were hewn out of the rock, conveyed to their place of destination, and in those times of little knowledge in mechanics, how they were elevated, and placed securely in an erect attitude.

Nearly on a line with Pharos, without the walls of Pompey's ancient Alexandria, and not far from the lake Mareotis, pillar is the magnificent pillar of Pompey. Its height is about 90 feet, whereof the pedestal is 10, the base above 5, the shaft rather more than 63, and the capital completes the rest of the measurement. Its principal parts are of the Corinthian order, though the proportions and ornaments are of a mixed species. This superb monument has been ascribed to Ptolemy Philadelphus, in memory of his beloved Queen Arsinoe; and others have assigned it to Ptolemy Euergetes. A few have supposed, that it was erected for the Emperor Adrian or Severus, while the power of Rome prevailed in Egypt; but the Greek inscription upon the column dedicates it.
to the Emperor Diocletian, under the government of Pontius, the prefect of the country. Ignorance might ascribe its origin to different persons of note, and flattery might dedicate the building to persons of influence or authority, in the same manner as Sonnini indulged a hope, that the pillar in question might in time be denominated the pillar of the French. But why should not the name lead us to the founder? It is called the pillar of Pompey, and might be erected to his memory; for we know that Caesar not only lamented his death, but ordained honours to his memory, and, by the assistance of Cleopatra, his favourite, he might easily accomplish the thing which he desired, although expensive and superb. But Dr White of Oxford supposes, that it was originally connected with the temple of the god Serapis; and if his conjecture be true, its erection must have been in the time of the Ptolemies, and it might afterwards be named in honour of Pompey; and his head, which was presented to Caesar, might be deposited there, and the building afterwards held sacred to his name.

The vaults in Alexandria are monuments of ancient designs for public convenience. The celebrated well of Joseph, at Grand Cairo, is of the same description, and the mikwees at Roda for measuring the rising of the Nile, is a building of considerable elegance, and a remnant of the Saracen grandeur.

The pyramids of Egypt have been more taken notice of than any other ancient monuments of that country. Of the various pyramids of Giza, on the Lybian side of the hill, and nearly opposite to Grand Cairo, there are three, which, for their size and notoriety, more especially demand our attention. The height of the highest has been differently represented, and owing to incorrectness, or different standards of measure, it has been stated at all the gradations from about eight hundred to five hundred feet. But perhaps the height of the three greatest pyramids may be stated in the following manner:—the first at 477 feet high, founded by Cheops; the second at 428 feet, ascribed to Chephrenes; and the third, which Misherin is supposed to have built, is about 160 feet high. St Peter's church at Rome is 437 feet high, and therefore is 40 feet lower than the highest pyramid of Memphis. St Paul's, in London, is 344 feet in height, and consequently is 193 feet lower than the first pyramid, and 93 feet lower than St Peter's church at Rome. The stones of the pyramids are shaped in the form of prisms, and there are various passages and chambers within; at least such have been found in the largest one at Giza.

Further to the south there are other pyramids, which shoot far into the deserts of Lybia, and are generally called the pyramids of Saccara. These erections appear to be more ancient than those about Giza. They are less perfect, and some of them are formed of unburnt bricks. The most ancient bricks of Egypt were only dried by the heat of the sun; and that they might stick more closely together, the clay was mixed with chopped straw; and hence the Israelites, while in slavery in Egypt, made use of straw in making bricks. There are also pyramids in India, and one at Benares is formed of earth and covered with bricks. A pyramid at Medin, in Egypt, is formed of different stories, every one less than another, as it rises in height; and in this manner, it is said that the followers of Buddha constructed their pyramids in India. Such was the form also of the tower of Babel. The antiquity of the pyramids is not easily ascertained, and Diodorus Siculus says, that in his time some of them were 1000 and others 3400 years old. Neither are men agreed in their conjectures about the original design for which the pyramids were built. The greater number are of opinion, that they were erected for the tombs of kings and conquerors, which should hand down their memory to the latest posterity, and preserve their remains inviolate. Others have imagined, that they were meant for altars of the gods, and that their tapering form was in imitation of flame, as the Persians and other nations worshipped fire. It is well known, that the Brahmins consider them as connected with religious ceremonies. While others imagine that they were constructed as a permanent memorial of the proper length of the cubit, of which it is said, that all their dimensions contain a certain number of multiples. But one thing is certain, that they were constructed on scientific principles, and give evidence of a certain progress in astronomy; for their sides are accurately adapted to the four cardinal points.

The present inhabitants of Egypt may be divided into Copts, Beduin Arabs, Mamelukes, Europeans, Musulmans, and Jews. The Copts are descended from the original inhabitants of the country, who in early times dwelt in caves, and their descendants are very different in their appearance from the native Africans. Their eyes are dark, and the nose frequently aquiline; and though the hair be sometimes curled, yet they are evidently a different race of people from the negroes. The present Coptish race have a dusky complexion like the Arabs or Indians, and seem to be the same race of people as those of which the mummies are preserved. The Egyptians, and the people of Hindostan, appear to have one common origin. The Persians and Indians, the people of Egypt and Ethiopia, are said to be descendants of Ham, the son of Noah. Different sons of that patriarch are thought to have separated into Ethiopia, India, and Egypt, &c.; while others maintain, that the latter country was peopled from Hindostan. Several circumstances point out the Persian Irac, and the high country above Thibet, together with other adjoining places, as the regions of the world which were most early inhabited, and from which the people sprung who settled in Egypt, India, and other early civilized countries of the East.

Egypt having suffered so many changes of circumstances and masters, was exposed to the intrusion of different people; and we have found, that its present inhabitants are of different nations. The Beduin Arabs are a wandering class of Arabs, distinguished from their countrymen, who have become stationary in some situation or other, and join in trade, or in cultivating the fields and other arts of life. The Beduin Arabs are still in the pastoral state, like the patriarchs of old; but they have not their simple and pure manners, nor the moral and religious principles for which the Jewish patriarchs were renowned. Many relics of ancient habits are still preserved among the Beduins, but they are a predatory race of people, and stand much in need of religion, good laws, and civilized usages. They chiefly dwell in the higher parts of Egypt, removing their tents and their herds, their cattle and their camels, to the vicinity of wells or streams of water, where they find drink, as well as better pasture; and at certain seasons they are permitted, upon specified conditions, to descend into the lower parts of Egypt, where their herds feed on the luxuriance of the Delta; but they never penetrate far into the country, for they are always ready to dart into the wilderness, when they have committed any act of violence or injustice, which
they frequently do, and which would bring upon them the vengeance of the inhabitants and laws.

The Mamelukes are a race of people whose origin has already been explained, and who were introduced into the country by their Turkish masters, in the capacity of slaves, and having become numerous, acquired so much property and influence, as to threaten the existence of the Mahomedan government in Egypt. Their numbers are still maintained by slaves imported from the unpolished countries of Georgia, and the neighbourhood of Mount Caucasus. But since the grand signior was restored to his former power in Egypt, after the intrusion of the French into that country, the influence of the beys has been exceedingly reduced, and the number of the Mamelukes is upon the decline. The rest of the inhabitants are Jews and Mahomedans, or Christian merchants, who reside in the principal parts of Egypt, for the benefit of trade and commerce.

The fertility of Egypt has long been celebrated, and the number of its inhabitants is proportioned to its produce. The simple manner of living which the native inhabitants observe, is well fitted to increase the population, for it is a well known fact, that the inhabitants of a country increase in proportion to the ease with which their food and accommodation can be procured. In the most prosperous and highly favoured condition of Egypt, when the people lived in ease and safety, under a powerful race of native kings, the population must have been more numerous than in its future state of distraction and violence; more especially under the injudicious government of the Turks: but the number of inhabitants assigned it in very ancient times, appears to be extravagant. Notwithstanding the excessive population of China, which may be in a situation similar to the ancient condition of Egypt; yet we can scarcely believe that Egypt ever contained, at one time, 20,000,000 of people, or even 7,500,000, as other authors have maintained. Grand Cairo, which is supposed to comprehend more than the eighth part of the people of Egypt, is not said to contain 500,000 persons, but, perhaps, the whole may be fairly reckoned at 2,500,000.

To give us an idea of its ancient population, we are told, that it contained from eighteen to twenty thousand towns; but the most of these, if that number did really exist, must have been only scattered villages of small extent and little population. For although Egypt is a country of considerable extent, yet the places which are capable of cultivation are but limited, and, making every allowance for the times of its greatest prosperity, could not have comprehended more than an extent of 6000 square miles.

Among all the improvements which have pervaded every department of life, the art of agriculture has, perhaps, made the least general progress. At any rate, there is much to be done even in the most enlightened countries in Europe. And if there be such deficiencies, where nature needs so much aid, and where knowledge has made so much progress, how lamentable must be the defects in more favoured climates, where nature does so much of her own accord, and where the human mind remains in a state of inferior activity! In Egypt, as well as in other countries of this description, the state of agriculture is low; and yet, from its natural fertility, it has often been found to give ample supplies to other countries. The government of Egypt, and the condition of its people, are unfriendly to great exertions either of body or mind, and, consequently, the manufactures of Egypt are few and inconsiderable.

The country of itself produces an abundance of salt from the different mines, and though not pure, it obtains a ready and extensive sale. Much of it is tinged with a red colour, mixed with a portion of calcareous tares; and by the inhabitants of the country it is called natron.

This becomes an article of commerce, with little labour to the people. But they have considerable manufactures of sal-ammoniac at Giza and Rosetta. But their chief manufactures consist of linens, woollen, and silk goods. They spin their yarn with the distaff, and are altogether unacquainted with machinery, which is so valuable and effectual in Europe. The fine linens of Egypt were formerly in the highest estimation, and far excelled every other manufacture of the kind; but now the linens of that country are chiefly of a coarser texture, and fit only for the more common purposes of life. The fine linens have yielded to the manufacture of muslin, which is generally worn by the higher classes of the people, being not only more fine and showy, but better fitted for the nature of the climate. Among their woolen goods, they form beautiful carpets, upon which they sit in the divan, or in the halls and houses of the great. Their silk is chiefly brought from Syria, and is manufactured into goods after various patterns, such as tafetas and satins; but all their goods of this sort are inferior to those which are brought from India. The Egyptian dress is a shirt, bound about the middle with a kind of girdle, with an upper loose garment, more or less warm, according to the season.

The polishing of flints and precious stones is a considerable business in Egypt, but is chiefly performed by Jews, and the Copts are excellent merchants, clerks, and accountants. Formerly the Egyptians excelled in the art of dyeing, and they imparted colours to glass and crystal of such exquisite hues, that it was difficult to distinguish them from valuable stones. Glass is at present manufactured in Egypt, but it is chiefly of an inferior kind. Their mirrors are small, and glass windows are seldom used in the country. Glass beads of diversified colours form an article of traffic, but they are made at Venice, and are transported to India and the interior of Africa, where the women adorn themselves with these bawbles, as the ladies in Europe and Constantinople do with jewels and diamonds. The Egyptians might excel in the making of glass, because their country affords the best materials which that manufacture requires: but they are deficient in the knowledge of that art; and the fuel which they employ being only straw or other feeble combustibles, is not of sufficient strength to melt with propriety the articles which are necessary for forming elegant glass. With the exception of a few trifling articles, they have no manufacture of iron-ware, and every thing valuable in the art of cutlery comes from the markets of Britain, France, or Germany.

Few situations are more convenient for commerce than Egypt; and it was this conviction which induced Alexander the Great to found the city which he called after his own name, and which he intended to be the capital of his conquests. His quick discernment enabled him to see the means which it possessed of being a commercial centre for Asia, Europe, and Africa. His unexpected death prevented the execution of his schemes, both civil and warlike; but under the government of the Ptolemies, Egypt acquired the commercial ascendency which Alexander foresaw, and which its situation was calculated to bestow.

The princes of this new dynasty encouraged a spirit of enterprise; and from the ports of the Red Sea vessels
launched out in pursuit of new countries and new commerce. Being small, and the sailors unacquainted with the principles of general navigation, they were obliged to sail along the coasts, and move cautiously from one point to another, seldom or never losing sight of land. But with all these disadvantages, they made considerable advances in trade and riches. Moving along the coast of Africa, they darted over to Madagascar; and some of them entering the Persian Gulf, conveyed their goods by the Euphrates to the Persians and other people of these regions. Some penetrated to the mouths of the Indus, visited the coast of Malabar, and reached the Island of Ceylon. There were a few who passed over to the coast of Coromandel, and reached the Ganges.

These Egyptian adventurers exported to India silver and iron, copper and lead, together with some kinds of glass. They also furnished them with woollen goods and other articles of inferior importance. And in return brought from India ivory and ebony, silks, and printed or stained linens, pearls, and precious stones, cinnamon and nutmegs, frankincense and diverse valuable perfumes. To facilitate the conveyance of that merchandise to Alexandria, a canal was cut, from the Red Sea to one of the branches of the Nile; but when that enterprise was unsuccessful, the goods were landed at the port of Berenice, and conveyed from thence across the country to the Nile. To accommodate the travellers and caravans, wells were dug, and resting places provided by royal munificence. By caravans, the different countries of Africa threw the riches of their trade into Egypt, and Alexandria became the most valuable centre of merchandise in the world. It was owing to the riches derived from this traffic, that the sovereigns of Egypt maintained their greatness amidst so many indiscretions, and that Cleopatra, when the empire was shaken to its foundations, was still able to be so splendid and profuse.

Every nation that enjoyed the means of commerce with the Mediterranean, derived pleasure as well as profit from the commerce of India, and, by trading at Alexandria, added to the wealth and importance of Egypt. When Carthage was destroyed, and Corinth was no more in its glory, Egypt increased its means of accumulation, and supplied the whole Mediterranean by its own shipping. Rome became a favoured nation, and while it supplied the increased luxuries of the state from the ports of Egypt, it afforded a source of wealth to the Ptolemaic princes, by its great consumption of the merchandise and luxuries which were brought from India. When the Romans became masters of Egypt, the country continued to flourish in trade; but the Romans, being warriors rather than merchants, were not calculated to promote the commercial prosperity of Egypt.

In the process of time, Egypt was subdued by the Saracens; and the particular circumstances of their empire occasioned an extension of the trade with India. A communication was opened between that country and Constantinople, by means of the rivers Indus and Oxyx, in connection with the Caspian and Euxine Seas. The trade which was formerly carried on through the Persian Gulf and the Euphrates, was afterwards conveyed by Palmyra to the Syrian coast. It was this trade, perhaps, which raised Palmyra to so much splendour, though situated in a desert; and when circumstances occasioned its ruin, the trade of the Persian Gulf was conveyed by Aleppo to Constantinople. Since the discovery of the Cape of Good Hope, the Indian trade with Egypt is considerably diminished; but perhaps it might have been more attended to, if Egypt had not become a province of an overgrown but feeble and degraded empire. It still carries on a trade with India, and the goods are landed at Suez or Cossir, and conveyed from thence to Grand Cairo, and other parts of the country. Various caravans convey passengers and goods from Fez, Tunis, and Algiers, as well as from other parts of Africa; and the caravans, which convey pilgrims to Mecca, are also employed in the merchandize of India and Arabia. If Egypt were under the influence of a well-regulated government, it would become a nation of high importance, both in point of splendour and the arts, as well as in the place of commerce, well fitted to hold communication with all places of the world. In its present circumstances, its trade is much interrupted; but when the Mediterranean is open for commerce, it exports many valuable articles, not only to Constantinople, the coast of Barbary, and other places belonging to the Grand Signior, but also to Venice, Marseilles, and Great Britain. Among these articles may be comprehended Mokah coffee, myrrh, various kinds of gum, cinnamon, with a great variety of drugs, mother-of-pearl, dates, opium, frankincense, and rice; to which may be added, linen clothes, buffalo and ox hides, and camels skins. From the same or similar parts, they receive woollen clothes, both superfine and common; iron and lead, together with various articles of cutlery and sharp-edged tools. Silks are even imported into Egypt of a different kind from what is manufactured among themselves, and printed cottons of showy patterns; to which may be added, tobacco, copper, quicksilver, and, in short, every article of the arts, which the ingenuity of other nations have produced.

The villages of Egypt pay a fixed revenue to the Grand Signior; and the lands were formerly let for life, upon condition of providing annually a certain number of soldiers. These were obliged to arrange themselves under the banners of the provincial governor, who, on that account, was called the Sangiacs, and the number of the troops was varied as circumstances required. Now this undefined manner of providing soldiers is abolished; and the country at large is obliged to supply the Grand Signior annually with 3000 troops, if required. Another branch of revenue to the court of Constantinople is the custom-houses, which are established in various parts of Egypt; and the last source of income is the capitation-tax upon all those resident people who are not Mussulmans, and that tax is called harak. The present situation of Egypt in these respects cannot be explained. It has scarcely recovered itself from the threatening influence which the bey had acquired, and from the shock which was given it by the French invasion. The feeble authority of the Porte over its distant provinces, is not calculated either to make them productive or happy; but we believe Egypt has improved of late, in obedience to the orders of the Grand Signior, and, if well managed, is able to yield a considerable revenue.

The earliest form of government, which we find amongst the Egyptians, was strictly monarchical; and it appears to have been as unlimited as any before or since that time. We are not to enter upon a discussion of the advantages or disadvantages of the various modes of government, which have had their times and their changes among the nations of the world. We believe that in this, as well as in every other respect, extremes are dangerous; and it seems to require no proof;
that the most happy form of government lies between the extreme of absolute power, and that of pure democracy. In a mixed state of privileges and power, where the people check the tendency of the rich and dignified toward increased authority or absolute rule, and where the prince and the nobles restrain the turbulence, and chasen the innovations of popular movements, there is the best chance for moderation of government, and stability of happiness.

In some respects an absolute government is better calculated to raise monuments of national glory. Having the whole powers of the state at his command, the unlimited monarch can bring them more quickly into action, and direct them to bear with greater certainty on any individual point. With a secrecy and expedition which no popular government can obtain, he carries into effect the purposes of his will, though great or difficult. Hence the pyramids, the labyrinth, and other works of great difficulty and labour in Egypt, were accomplished by its absolute kings; but in the performance of these works, the oppression of absolute authority was felt. To procure money for such vast designs, the impostes were grievous, and in some cases, where the necessities of the state were supposed to require it, the feelings of the people were hurt, by having the money allotted for the public services diverted into the channel of common life. In such cases, the labour of the people was excessive; and we know the children of Israel cried by reason of their task-masters, who were severe and unrelenting. A monarch of Egypt boasted, that his slaves and captives only were employed in public labour, and that no native Egyptian had been engaged in works of such toil; but whatever an individual of influence and national delicacy might do in saving his subjects, yet a severer master might employ severer means; and even where bondmen and captives can be cruelly treated, the government is not correct; nor the arrangements such as justice or humanity require.

But, however, the government of Egypt may be said to have been always of an unlimited nature. Through every successive change, it still maintained the character of unrestrained monarchy, till it became a province of the Turkish government; and then it had a divan, at the head of which is a pasha, or deputy-governor, with some appearances of a deliberative council. But this form of government, though apparently allied to a mixed and limited authority, was notwithstanding exposed to very arbitrary exactions. And yet the arrangements were so disjointed and feeble, that the government was neither steady nor secure, for, amid the tumults of an ill-regulated state, the court of Constantinople nearly lost its authority. In this condition, the turbulent and ambitious boys were striving for the supreme command; and since they were subdued, we suspect that the liberties of the people are neither accurately defined nor well secured, so that the government of Egypt is still absolute, and unfriendly to order and happiness.

Egypt was celebrated for wisdom of old, and the learning of that country attracted to its schools the wise and inquiring of other nations. We are to estimate its pre-eminence, not by a comparison with the present state of erudition, but by considering the rank which it then held in the scale of knowledge. India, Babylon, and even Phcenicia, lay claim for no considerable share of literary glory. But the principal competition seems to subsist between India and Egypt. Each of them has its supporters, and it would be presumptuous, as well as unwise, to decide the contest from the nature of the documents which have hitherto been furnished. It is more becoming to say with the poet—

"Non meum inter voce tantas componentes illis."

Yet we may suppose, that both of them flourished about the same period, and that there must have been an intercourse, less or more frequent, between the two nations. If we were disposed to argue strenuously in favour of Egypt, we might say, that there was a period in its early history, when the learned, the wise, and the noble, were compelled to seek refuge in other countries, and many of them might land in India.

The season to which we have an eye, was the time when Cambyses desolated Egypt, destroyed its temples, and overthrew its venerated order of things. For a succession of years, the natives were oppressed; and during such events, it was natural for men of eminence and spirit to leave a country which was unworthy of their presence, and to take refuge in more favoured abodes. It may also be observed, that the madness of Ptolemy Physcon drove from his kingdom many of the wisest and most literary persons; and they, too, might seek and find protection in the East.

Though the system of morals could neither be pure nor accurate, under the circumstances in which Egypt was placed, yet there are many reasons which lead us to suppose, that the great principles of moral conduct were known and inculcated there. The principles of justice appear to have been defined with considerable attention, and the laws of the country fairly dispensed. The duties which were due to one another, were as well regulated as the distributions of rank and influence in an absolute government could allow. But still there were many sentiments and practices which we should condemn; and to shew the untractable nature of the human mind, we have many deficiencies to deplore in the most exalted state of knowledge and virtue.

The Greeks are supposed to have obtained the beginning of their mathematics from Egypt; but if we may form our judgment from what is related of Thales and Pythagoras, we shall not have reason to form a high opinion of their mathematical learning previous to the time of the Ptolemies. In the schools of Alexandria, that science was carried to an eminent height; but the ancient state of learning at Thebes, and other schools of the country, appear to have been confined to a lower sphere. It is told, with some interest, that Thales was taught to measure the height of the pyramids by the length of their shadows; and that Pythagoras offered a hecatombe in devotion, when he discovered the relation which subsists between the hypothesis of a right-angled triangle, and the sides of the figure which contain that angle. Other instances may be added to the same effect; but still it must be acknowledged, that Egypt was eminent in her time, and her philosophers appear to have made considerable progress in the science of astronomy. The overflowing of the Nile was an object of much national importance; and, in connection with it, they observed the heliacal rising of the dog-star, which enabled them to fix the commencement of the year, and make considerable approximations towards ascertaining the length of its duration.

Thales divided the sphere into five zones, and in many respects improved the astronomy of Greece. Pythagoras intimated a belief, that the planets moved about the sun as their centre; and if these philosophers
made further progress in knowledge, than the Egyptians themselves had done, yet still the origin of their requirements may be traced to Egypt. And though the current of science must have been enlarged by tributary streams, yet the spring is to be found in the banks of the Nile. The Egyptians had made some improvements in the art of metallurgy; and the golden calf, made by Aaron in the wilderness, is a monument of his skill. No nation can have advanced far in civilization and the arts of life, without having also cultivated the art of music. Certain tones and inflections of the voice, being agreeable to the ear, are cherished and diversified according to the skill and ingenuity of those who are lovers of harmony. It has always been customary to mingle music with festivals and rejoicings; and though the scanty remains of Egyptian history furnish us with few materials for ascertaining their musical attainments, yet upon the architectural ruins of the most ancient edifices of that country, instruments of music are represented in various states of progress, from the most simple to a highly improved form of the harp; and where music is cultivated, poetry has always been considerably improved.

The arts of surgery and medicine were simple and defective in such ancient times, as those of which we are writing; and in Egypt the inflexible adherence to ancient practices was unfavourable to the progress of the healing art. In the ancient state of Egypt, no remedy was to be applied, nor any application recommended, but such as were approved of in their sacred books. But such restrictions were gradually removed; and in the schools of Alexandria considerable progress was made in medical studies. Yet, even in early times, there were some arrangements, which tended strongly to the perfection of those arts. The medical practice was divided into various departments, and some studied the diseases of the eyes, others the teeth, the ears, and other distinct parts of the human frame. The practice of divination was common in all the ancient countries of the East, and it was even applied to the healing of diseases.

Writing. The Coptic, or ancient language of Egypt, is almost extinct, but perhaps might be found in its purity in the manuscripts remains, which are said to be deposited in the monasteries of that country; and the Arabic is now in considerable use in Egypt, though different languages are spoken by the people of different nations who sojourne there. We have no means of ascertaining to what degree of improvement the Coptic was carried by men of genius in the ancient schools; but to Thoth or Mercury are ascribed the most important improvements of early literature and science in Egypt. Whether by Thoth we are to understand an eminent scholar, who contributed largely to the advancement of knowledge, and by whose name every literary improvement was dignified; or whether by Thoth be intended the general means of knowledge in Egypt, is an inquiry which cannot be satisfied. It is enough to know, that by Thoth, or some adequate persons or means, various advances were made in literary pursuits; and amongst these we may enumerate the art of writing and recording events. Dates and inscriptions were originally cut upon the rocks, and in a more portable manner, though not very commodious, upon stones and bricks. Shepherds and rural nymphs eulogize the names and praises of their lovers upon the barks of trees; leaves, too, were inscribed with verses; and the Papyrus of Egypt was formed and compacted into sheets, and obtained great celebrity, as valuable materials for forming books. To this succeeded parchment, or skins of animals, variously prepared; silks also were employed for the purpose of inscriptions; but the most valuable article hitherto invented, is paper, made of cotton or linen rags.

We cannot enter into the history of alphabetical writing. Like every other simple art, it was the produce of much generalizing, and many experiments. To express sounds by certain symbols, and to combine these into words capable of communicating the whole thoughts and intentions of the heart, could not be a work of rude times, and implies considerable skill and experience. The most natural way of communicating an idea in a state of unlettered simplicity, would be to give signs instead of words, and to draw a picture or representation of the things signified. Hence hieroglyphies, or picture writing, appears to have been the earliest method of entering ideas upon record, or communicating sentiments, without words or bodily signs; for, perhaps, knotted cords, which are still used in some ignorant, and mark the constellations in the Chinese zodiac, may be considered as an additional step of improvement. Picture writing appears to have been common in ancient times. When the Spanish ships, first appeared off the coast of Mexico, an alarm was raised by figures and representations, transmitted to the seat of government; and in the islands of the Pacific Ocean, hieroglyphical writing is universally known.

But in Egypt that species of writing has been more celebrated, because it was carried to a higher pitch of perfection. Before the use of alphabets was known, it was practised in the ancient schools of Thebes and Atonum; and when cultivated as a science, and practised on an extensive scale, it was necessary not only to express simple ideas by a picture representation, but also to communicate abstract notions and various qualities. The simple representation of the eye only expresses that bodily organ, but when shewn in a cloud and seen from above, it denoted the inspection of the Divinity. A serpent wrapped up in circular foldings, and the end not easily seen, denoted the perpetual duration of God. The representation of a figure, with several heads and eyes looking to every quarter, represented his universal observation; and the head of a hawk, with its keen eye, pointed out the penetrating knowledge of God. This leads us to understand why the statues of the ancient gods in Indus have many hands and many heads; and what is to be understood by the figures of monstrous animals, like the sphynx, which nature never formed. They are all connected with hieroglyphical sentiments, and intended to communicate various qualities and dispositions of the mind.

In the same manner, a sceptre was employed to denote power, a lion to give an idea of strength, and a dog of fidelity. These hints are sufficient to shew the nature of hieroglyphical writing; but it must be obvious, that, in the course of its application, it became exceedingly complicated; and the allusions being often arbitrary, they must, in some cases, have been difficult to be understood. In the course of time it fell into disuse, and, excepting the general notion which has been discovered of its nature and tendency, the particular knowledge of the art is lost; and the hieroglyphical writings, though seen distinctly by the eye, are the same to us as a sealed book. Another circumstance which has tended to conceal the meaning of hieroglyphical inscriptions, is the progress which was gradual.
ly made from picture writing to arbitrary marks. The representation of an ear would everywhere imply hearing, and a foot or a hand would denote action; but a mark assumed at pleasure, to signify an object or abstract quality, could only be known, where the original intention and arbitrary assumption was communicated. Most of the hieroglyphics, which are found in Egypt, appear to be allied to this description; and with the knowledge of the arbitrary signs and marks, which were adopted to express ideas, the meaning of the writing itself is forever lost to the world. In connection with these arbitrary signs, the formation of the Chinese language seems to be placed; and from that circumstance, the difficulties which attend the learning of it appear to flow. According to Hager, new dynasties sometimes introduced new characters; and thus the extent and the difficulty of the language were increased. It appears from Staunton’s Embassy to China, (vol. ii. p. 576.) that approximations have been made toward converting the Chinese characters into letters, or elementary sounds, after the manner of alphabetical writing. Whenever this method shall become general, the Chinese language will be as easily acquired as other foreign tongues.

Religion.

Neither having come into the world by our own power, nor being preserved in existence without other resources than our own, it is natural to inquire about the Being who made, and the Providence which preserves us. Even in a rude state, whilst sentiments of an acute or very rational nature are not to be expected, we should deem it impossible for the human mind to be destitute of all those feelings and views which enter into religion; and hence, no nation has ever been found without some ideas, more or less legitimate, concerning the existence and nature of God. Even without the knowledge of our sacred books, we think it impossible, that an unbiased and enlightened mind could imagine, that the Supreme Being would form his rational creatures without an adequate knowledge of spiritual things. Their instincts are in immediate operation; and though their religious views might be comparatively imperfect, yet we may be well assured, that he who takes care of the body would provide also for the mind. The book of Genesis, which is by far the earliest record of ancient things, represents the original state of man as enlightened in the knowledge of God; and the most ancient information which is handed down respecting his religious condition, represents to us the acknowledgment of one pure and supreme cause. Of this there are many indications besides the celebrated inscription at Sais. The first temples, too, were built of unpolished stone, without any image or sculptured figure; and this not only in Egypt, but in other countries.

But a pure and spiritual worship, abstract ideas, and the exclusion of every material object from our view, is a difficult exercise of the mind, and requires a higher tone of exertion than could be easily maintained in more rude and corrupt times. To aid the imagination, and cherish the devotional affections, emblems, or symbols, of the divinity, were admitted into the worship of the Deity. An unformed mass of stone was probably the first memorial of the divine presence; and it is said, that there are African tribes who still worship such massy blocks. Perhaps the large stones which have raised so many conjectures in our own country, may have been objects of worship in the time of the Druids, or at a more early and less informed season. In this state of the human mind, more striking appearances of nature would naturally attract the notice of men, and be viewed as appropriate memorials of the divine perfections. Hence, the sun, the moon, and the stars, held their station in the list of those objects which suggested religious ideas; and we know, that those parts of nature were much and generally worshipped in the East.

Taught to consider everything as coming from the Deity, his presence would naturally be acknowledged in every operation and blessing of nature; and hence the woods and the streams became sacred; vegetables and plants were deified; and, in Egypt, divine honours were paid to some of the brute creation. We can easily see how the hosts of heaven, which commanded admiration, might be objects of divine regard; we can feel how the shady grove, or the deep forest, might excite veneration in a sultry climate; we can figure to ourselves, how a spring of water might raise grateful emotions in a thirsty land; or how copious rivers, like the Nile and the Ganges, might be worshipped, and praised in, as agreeable services to the munificent Author of such delightful streams; but we cannot easily comprehend how the bull and the cow, or such animals as the crocodile, the ichneumon, the cat, and the ibis, could command such reverence and solemn rituals as they did in Egypt.

It is difficult to comprehend how Osiris, whether the representation of a hero or the sun, should be worshipped under the figure of an ox; but we may suppose, that such sacrifices as these were offered for the bountiful supplies of nature, in yielding the means of subsistence, and even the luxuries of life. The cow, and other animals, in one period of the Egyptian history, were common sacrifices; and it may be difficult to shew, how this animal, as well as others, became afterwards so sacred, that to take away their life was the highest crime. It is generally understood, that the earlier race of men subsisted solely on the fruits of the earth, and that the use of animal food was introduced at a much later period. It would appear, that a religious sect had sprung up in Egypt, as well as in India, to counteract this innovation in point of food; and as religious scruples take the most lasting as well as firm hold of the mind, the prohibition to use animal food, would naturally be extended to the taking away of the life of the brute creation, excepting in cases which circumstances, or ascertained forms, would prescribe. It is probably on this account that the Hindoos confine themselves to vegetable food.

The people, in the early improved countries of the East, appear to have had many sentiments and manners, in common; and we presume, that the Egyptians, at one period, had their manners and habits similar to those of Hindostan. Each of them were divided into different castes; both of them venerated the ox and the cow; and the same superstition, with respect to this worship, is found in Thibet. The consecrated bull, which was most venerated in Egypt, was distinguished by many peculiar marks, and of a fine figure. It was called Apis, and was worshipped at Memphis. The other bull was black, was denominated Mucirs, and kept at Heliopolis. These animals were treated with much pomp, and maintained at great expense. Their death was lamented with bitterness, and observed with many marks of public mourning. Various ceremonies were observed in finding a successor; and the consecrated calf was introduced into its situation with much pomp, and certain ceremonies not to be commended.
Osiris was said to represent the sun, and Isis the moon. If the cow and the bull were sacred to Isis and Osiris, the ram was worshipped at Thebes in honour of Jupiter Ammon; and the sheep were considered as sacred animals. Pan was venerated at Mendis by the symbol of a goat. Amnis was painted with a dog's head, and accounted the divinity of sanguine and watchfulness. In short, there were a diversity of divinities under different appearances, and honoured with different sacrifices, but all of them alluding to the bounty and productive qualities of nature. To these we must oppose the worship of Typhon, who was considered as the author of evils and misfortunes. Like the fountain of good, the source of evil was described by different names; and to these beings the crocodile, and other forbidding animals, were devoted. Different cities had peculiar divinities, who were worshipped there, and under whose protection the people were supposed to be placed.

The public festivals were celebrated with exceeding splendour, and vast multitudes assembled to solemnize the rites. The scenes at Juggernaut may give you an idea of some of those Egyptian revels; and there, too, indecent rites were allowed. But the most afflicting scenes which have ever degraded the ceremonies of idol worship, were the human sacrifices, which were frequently offered to appease the wrath of offended divinities. To Typhon were such sacrifices presented; and as the red-haired were chosen for this purpose, and the Egyptians being of a dark complexion, Greeks or strangers were frequently obtained. Perhaps this distinction of colour was made on purpose to save the natives from such a fate. This barbarous custom was continued in Egypt till the reign of Amasis; and it was not till the time of the caliphs, that the peculiar practice was laid aside of sacrificing annually a virgin to the Nile, when a mock ceremony was substituted. Heliopolis and Thebes were peculiarly marked for this dark superstition. Every ancient nation, excepting the Jews, were guilty of such horrors; and still prisoners of war are sacrificed in the South Sea islands, and in some parts of Africa, Asia, and America.

Heroes were worshipped in Egypt, and eminent persons were raised to the rank of gods. At first it was merely veneration for great characters after their death; but it was an easy and natural transition, in a country where the objects of worship were so multifarious, to suffer great respect and high veneration to pass into prescribed forms of divine worship. When the Romans took possession of Egypt, they did not change its religious rites; but Christianity obtained its votaries there, as well as in other parts of the Roman dominions; and when the Saracens subdued it, they imposed upon the inhabitants, as far as possible, the religion of Mohammed. Both Jews and Christians are allowed to reside in Egypt; but the only authorised religion of the country is still the religion of Mohammed.

The ancient temples were large and costly buildings, and, in point of splendour, outshine every other edifice. Various circumstances contributed to give them this pre-emience. The priests of Egypt were the princes of the land, and had great influence over the national revenues. The whole national feeling was favourable to the dignity of the public worship; and the temples, together with the tombs of the illustrious dead, were the principal works upon which they bestowed much labour or expense. To this assertion we must not be understood as making an exception in favour of royal palaces, for it does not appear that any fabric of this nature could bear a comparison, either in point of dignity or extent, to the temple, which were erected in honour of the gods. The holy place, where the sacred animal, the representation, or the statue of their divinity was placed, was comparatively of small extent. At Butas, at Suis, &c. the sanctum sanctorum was of one large stone, brought from the granite quarries of Elephantum. The vast compass of the temple buildings was employed in porticos and vestibles, open courts, curious windings, and private abodes. In connection with the temple itself, were the lodgings, or sumptuous dwellings of the sacred order; and the whole constituted a grand assemblage of various apartments and expensive buildings.

In this respect, an important difference subsisted between the temples of the Greeks and Romans, and those of the Egyptian people. The views and constitutions of Greece and Rome admitted an increasing series of divinities, and a vast profusion of temples was scattered through the various cities and towns of their respective dominions; whereas, in Egypt, though the gods were various, yet their worship appears to have been consistent with each other, excepting the offerings, and sacrifices which were presented to the hateful beings who were supposed to be the authors of evil. Selon, if ever, was there more than one temple in a city of Egypt; because these buildings were erected by the state, and not by the people, who were neither permitted to deliberate nor have a choice in sacred things; and while this appears to intimate, that their divinities were more diversified by names than in reality, it enabled them to render their religious fabrics more spacious and splendid. Through the whole Egyptian constitution of sacred things, there were doctrines and rites which were concealed from the vulgar eye, and held back from uncultivated minds; and, while the multitude were invited to join in the public festivals and duties of religion, certain orders and individuals were only initiated into the mysteries, which it was then thought wise and prudent to conceal from the vulgar. And hence those interior and subterraneous apartments, where these instructions were given, and the secret ceremonies observed. These mysterious places were kept secret, and not exposed to the public eye.

Among the things of a serious and important nature which claim our notice, and mark the character of nations, is the care which is shown toward the dead, and the reverence maintained for the tombs of their friends. In this respect the Egyptians were conspicuous for attention and reverence. We cannot enter upon the consideration of the various methods by which, in different ages of their country, they manifested their attention to the dead; for though the number of bodies preserved in a peculiar manner, and denominated mummies, have led us to suppose, that this was the general mode of disposing of their dead, yet we can scarcely imagine, that through such a length of time as the ancient Egyptian kingdom subsisted, the manner of treating their departed friends was uniformly the same. Other nations have pursued various methods; and, though the ancient Egyptian manners were not given to change, but, by national prejudices, were peculiarly permanent, yet in a long lapse of time, different methods must have been adopted for disposing of their dead. The operations necessary for the formation of mummies, are not consistent with a very rude state of society. They require preparations, and a degree of knowledge, which imply improvements in the arts of life.

Having taken out the brains and bowels, the body
was anointed with oil, and deposited in nitre for a certain time. Then the cavities were filled, and the whole perfumed with aromatic drugs; and, being wrapped up with fillets of many folds, and the face covered, so as to retain its natural shape: the whole was preserved to defend it from the air. In this situation it was put into an open coffin of sycamore wood, or a kind of pasteboard, and carefully painted. Bodies thus prepared were sometimes deposited in the houses of the dead, but more commonly in the vaults of public buildings, or in excavations hewn out of the rock. But neither in Egypt, nor in any other part of the East, do coffins appear to have been much in use of old times, and the mummies which are deposited in open coffins, may either be supposed to have been persons of a superior rank, or they may have been prepared in a later period of the Egyptian history, when changes had been introduced in the manner of preserving the dead.

As a part of the Egyptian code of laws, and a means of promoting virtuous conduct, we are told, that an inquest was held upon the dead; and according to their character, so were the ceremonies of their funeral prescribed. Infamous characters were either not permitted to be buried at all, but as criminal and degraded persons are still, among the ruder nations of the East, cast out into the streets and fields, and left without burial, so among the Egyptians they were denied those sepulchral rites, which were considered as marks of merit and approbation. There was a time in Egypt, when persons, perhaps those of distinction, were buried in the islands of the lake Moeris; and if the profane were not permitted to receive such a testimony of respect, it might give rise to the fable of Charon ferrying the souls of the departed over the Styx and Acheron; and not being permitted to receive into his boat the spirits of those whose bodies had been denied the rites of funeral. The present name of the lake is Charon, and that, in the Coptic language, signifies a ferryman; which gives countenance to the allegorical story which has now been mentioned. If the tomb of Osymandias was really so magnificent as it has been described, and if the pyramids were intended for the burying place of kings, then there is a further appearance, in these stupendous buildings, of the excessive care which the Egyptians manifested about the state and protection of the dead.

The houses which they dwelt in when living, were frail buildings, composed of perishing materials; and even the palaces of kings were inferior in splendour to the temples of the gods; but the receptacles of the dead were more permanent in their nature; and princes as well as potentates, aimed at perpetuity in the places of their rest. And they have not altogether aimed in vain; for the sepulchres and tombs of Egypt are the principal remains of architectural greatness. Though a distinction was made, and that perhaps wisely, between the righteous and the wicked at their death, yet their friends and relations were permitted to remove the disgrace attached to their unburied connections, by certain compliances and forms, which were necessary for having their dead removed from their sight. And, in conformity with this arrangement, their souls might be represented by the poets as wafted by Charon's boat to the place of their final destination, after the rites of sepulture had been performed, or a certain lapse of years had been completed. Who is unacquainted with the feelings which are excited, when beloved friends are removed by death? In every nation, the power of these feelings is expressed in a particular manner; diversified, in part, by attending circumstances, and constitutional temperament; but among the Jews, as well as other nations of the East, all the plaintive passions were uttered with loud lamentation, and sometimes by wounding their bodies, and afflicting themselves cruelly. These severities were continued for a longer or shorter space of time, according to the rank of the deceased; but in every situation the mourning was loud and violent.

The benefits arising from the knowledge of other countries, are not bound by the gratification which it yields; but they open up a field for imitating what is valuable; and have a tendency to make us contented with our own lot, when it is not inferior to the general condition of others. The provision for happiness throughout nature is wise and abundant, but much depends upon knowledge and virtue; and it ought to give us satisfaction, in being so highly favoured as a people. The degraded state of Egypt, should show us the advantage of good laws, and of such means of improvement as enlarge the mind, and promote the welfare of nations. It is our duty to do all in our power to better the condition of others; and it is our interest to improve the benefits we ourselves enjoy, which are every way great and valuable. EIGHTH.

507.09152: in the new notation of Farye, it is $507.09152$ or $11f + 49m$ (see Plate XXX. of Vol. II.); it is equal in concordant elements to $3.4ths - III, 16th$: in diatonic elements to $2T + 2s + 3s = 11f + 27c + 20s = 7s + 4s + 2s$.

Some of its others are, 8th $= 2n + 12h = 4th + 5th = VIII - 1, = 7th - II, = 11th + IV, = 12th -- VI, = VIII $= 49c + 26s + 11f$, &c. By tuning upwards from C, three perfect minor fourths, and downwards thereof a perfect major third, this interval is correctly produced on Mr Liston's organ, and is his Cb.

**Eighth Comma-deficient Major, (VIII),** or grave octave ($VIII - C$), or grave major eighth, has the ratio $\frac{63}{64} \times \frac{64}{65} = 0.9998 + 12f + 52m$: its common log is $0.70436503213 \approx 0.704365 \times VIII \approx 54.79762229c \approx 3.4ths - 3rd - I = 2T + 3t + 2s, = 12f + 28c + 21t, = 9s + 29c + 12f$. It is C on Mr Liston's organ, and is tuned above C thus, 4-4ths + IIII + VIII; it is the lesser incominest eighth of some authors.

**Eighth Comma-deficient Minor, (8'),** or grave minor eighth, ($8 - C$), the apto-fifteenth eighth ($VIII - P$), and deficient lesser flat eighth, &c. of different writers. Its ratio is $\frac{63}{64} \times \frac{64}{65} = 0.9998 + 11f + 48m$: its common log is $0.7248878,3537 \approx 0.724887 \times VIII \approx 50.31511022c \approx 5.4ths - 2III - 5ths, = T + 5t + 3s, = 11f + 26c + 19s = 48c + 26s + 11f$, it is C'b of Liston's scale, and may be tuned above C, either by 7-4ths + 2VIII, or 5-4ths + 2V.

**Eighth Comma-redundant Major, (VIII),** acute eighth, or redundant eighth of some authors, has the ratio $\frac{63}{64} \times \frac{64}{65} = 0.9998 + 11f + 54m$: its common log is $0.6935749,7245 \approx 0.693575 \times VIII \approx 56.79762229c \approx VIII + C = 8.3d + 2III - 4th, = 4T + 1 + 2s; = 12f + 20c + 28s = 54c + 29s + 12f = 7th + T$. It is C on Mr Liston's organ, and may be tuned above C thus, 2V + 3d + 4th: it is the greater incominest eighth of some authors.

**Eighth Defective of Holden,** is an interval not belonging to the diatonic system, because involving the prime integer 7; its ratio being $\frac{21}{22} = \frac{21}{22} = 0.982607066 + 11f + 51m$: its common log is $0.7058094.2887$. It is $507.09152$.

**Eighth Diminished-major, (VIII - C),** called by some writers the Greater Flat Eighth, the Comma-redundant Minor Eighth, ($8 + C$), the Imperfect Diapason, and by Liston the Acute Minor Eighth ($8'$), &c. is an interval whose ratio is $\frac{63}{64} \times \frac{64}{65} = 0.9998 + 11f + 50m$: its common log is $0.7190191,7310 \approx 0.719019 \times VIII \approx 56.79762229c \approx VIII + C = 8.3d + 2III - 4th, = 3T + 4t + 1 + 2s; = 12f + 20c + 28s = 54c + 29s + 12f = 3th + T$. It is C on Mr Liston's organ, and may be tuned above C thus, 2V + 3d + 4th: it is the greater incominest eighth of some authors.

**Eighth Diminished of Liston (8 - C),** or diminished minor eighth, has a ratio $\frac{63}{64} \times \frac{64}{65} = 0.9998 + 10f + 46m$: its common log is $0.7398225,7015 = 0.8644292, = 48.22558 \times c, = 3d + 5-th = 7III, = 2T + t + 4s = 10f + 26c + 19s = 46c + 23s + 10f = 7 + 5$: it may be tuned thus, 6th + 2-4th - IIII, on Mr Liston's organ.

**Eighth Double-deficient, (VIII - 2c),** is an interval whose ratio is $\frac{63}{64} \times \frac{64}{65} = 0.9998 + 5f + 12f$: its common log is $0.7097500,6812 \approx 0.709750 \times VIII \approx 53.79762229c \approx 5-4ths - III - 3-3ds, = T + 4t + 2s, = 12f + 27c + 20s, = 51c + 29s + 12f = 3T + 2t + 2L$: on an organ with a sufficient number of pipes, like Mr Liston's, it may be tuned thus, 5-4ths - V - 2-3ds.

**Eighth Double Superfluous, (VIII + 2c),** is an interval whose ratio is $\frac{63}{64} \times \frac{64}{65} = 0.9998 + 12f + 55m$: its common log is $0.6881793,4057 \approx 0.688179 \times VIII \approx 57.79762229c \approx 5-5ds - IIII - 3-4ths, = 5T + 2S, = 12f + 31c + 24s, = 53c + 29s + 12f = 7T + 2t + 2S$: on Mr Liston's organ it may be tuned thus, 3V + 2-3ds - 5-4ths.

**Eighth Minor Comma Defective, (VIII - C),** or the double tritone (2 IV), is an interval whose ratio is $\frac{63}{64} \times \frac{64}{65} = 0.9998 + 12f + 52m$: its common log is $0.7088749,2909 \approx 0.708875 \times VIII \approx 54.88888888c \approx 2-3d + 4-11$ = 11 - 4ths = 3-4ths = 7T + 3s + 1, = 13f + 80c + 232s, = 56c + 32s + 13f = VIII + T, = VII + 11, = 9th + E, = IX - F. On Mr Liston's organ it is e's, and may be tuned thus, VI + III.

**Eighth Superfluous of Bohetrieder, (VIII + P),** apto-fifteenth eighth, or the superfluous diapason of some writers. Its ratio is $\frac{63}{64} \times \frac{64}{65} = 0.9998 + 12f + 55m$: its common log is $0.684511,7361 \approx 0.684511 \times VIII \approx 59.078777,765 \approx 59.0787 \times VIII \approx 61.0887777,205 \approx 61.0887777,205 \approx 59.0787777,205 \approx 61.0887777,205 \approx 61.0887777,205$. It is C on Mr Liston's organ, and may be tuned thereof thus, 4V + 2-11 = 2-3ds.

**Eighth (supposed) of Mersennus,** this author, from an erroneous calculation, concluded the octave to be equal to 58: which was not the major comus: but which is $0.58396 \times 181532 \approx 12f + 55m$, and its common log is $0.685739,9260$. (s).
EISENACH, the Irenacum of the ancients, is a town of Germany, in the duchy of Saxe Weimar, and formerly the chief town of the principality of Saxe Eisenach. The town is situated in an agreeable and fertile valley on the river Nesse, and was founded in the year 1070. The streets are regular, and are well paved and lighted, and the town contains several good houses. The principal objects of curiosity at Eisenach are the ancient castle of Wartburg, in which Luther was confined, in 1521. It is situated about two miles from the town, on the top of a high mountain, and is now in a state of ruin. It is nearly an hour's walk from the town to the top of the mountain, and the highest part of the road is cut through the rock. The walls, the ceiling, several ornaments, and the ancient hall of the chancellors, are now filled with hay. The signal tower, the subterraneous prisons, the chambers inhabited by the ancient landgraves of Thuringia, and the chapel of the pious Elizabeth, are still shown. The view from the castle is very fine and extensive. Among the surrounding rocks, there are two remarkable for their elevation and their form. The English garden belonging to M. Reese is upon the heights which surround Wartburg, and is well worthy of being visited. There is a very large and good library, belonging to the grammar school, which was founded in 1707, by the Duke John William. There is also a college, a seminary for divinity, and an orphan hospital. Eisenach carries on a very active commerce, and possesses manufactures of white lead, serges, shags, ribbons and starch. The population of the town is between 8000 and 10,000. For a particular account of the castle of Wartburg, see the second edition of the description of it published by M. Thun: East Long. by astronomical observations, 10° 20' 15", North Lat. 50° 55' 55". (w)

EISLEBEN, or Isselben, is the name of an ancient town of Saxony, and capital of the district of Mansfeld. It is situated on a hill near a small stream called Kleppenbach. The town is divided into the old and new. The old town, which was a flourishing city so early as 1024, has three parish churches, a grammar school, an ancient castle, and 700 houses. The town consists of one parish, and about 300 houses. The church of St. Andre contains several curious monuments. The pulpit of Luther is still shown, but it is used only three times a year, on public occasions. The church of St. Peter, the institution of M. de Burgsdorf, and the Hotel de Ville, with its roof of copper, are the other objects worthy of notice. The house in which Luther was born has been used, since 1772, for the public school. The mantle and the hat of the reformer are still shown to strangers. There are mines of copper in the neighbourhood. The people are principally employed in agriculture, and in the manufacture of salt and potash. About two leagues from Eisleben is a saltwater lake, and, from the top of a small hill, formerly a Trajan pagan tomb, there is a fine view of the two lakes. Population about 6000. See Kurze Nachricht von Luther's Haus, &c, vom Rector Hopf ner, Eisleben, 1790, 8vo. East Long. 11° 44', and North Lat. 51° 40' (w).

EISTEDDFOD, the name given to the annual congress of the British bards, which was formerly held under the sanction of the Welsh princes, at one of the royal residences of Aberfraw, Mathraval, or Caerwyw. See Evans' Tour in Wales, and the articles Bard and Wales.

EKEBERGIA, a genus of plants of the class Dendrid, and order Monogynia. See Botany, p. 211.

ELAGNUS, a genus of plants of the class Te trandra, and order Monogynia. See Botany, p. 126.

ELCHARUS, a genus of plants of the class Pol yandra, and order Monogynia. See Botany, p. 296.

ELAIS, a genus of plants of the class Diocia, and order Hexandra. See Botany, p. 319.

ELASTICITY. See Mechanics, Physics, and Pneumatics.

ELATE, a genus of plants of the class Monocia, and order Hexandra. See Botany, p. 225.

ELATERIUM, a genus of plants of the class Monocia, and order Monandria. See Botany, p. 319.

ELATINE, a genus of plants of the class Octandria, and order Tetragna. See Botany, p. 205.

ELBA, an island in the Mediterranean Sea. It is situated off the Tuscan coast in Italy, from which it is separated by the channel of Piombino—this channel being about ten miles broad in the narrowest part. Its form is extremely irregular. In circumference it may measure nearly seventy English miles. It is mountainous in its general aspect. The plains and valleys which it contains are of small extent. It is surrounded with a salubrious climate, a good soil, and numerous springs of excellent water. Its vegetable produce consists of natural grass, corn, vines, olives, chestnuts, almonds, figs, walnuts, oaks, myrtles, and a great variety of aromatic and evergreen plants. Pears, also, apples, cherries, peaches, and prunes are produced; but they are wild and insipid. Lemons, pomegranates, and oranges thrive here, though not in great perfection. There is a great want of forest trees or large wood. Kitchen herbs are almost entirely neglected. The husbandry of the island is conducted in a most skilful and slovenly manner; so that the crops of corn do not supply the inhabitants with more than three months consumption. The vintage, however, is more than sufficient. It takes place in September. The grapes are of an excellent quality. Two kinds of wine are made from them; red and white. The white is the common wine that is consumed in the island, and is seldom or never exported. The red is made in small quantity, but is extremely delicious. Two sorts of desert wine are produced, viz. Vermont and Cileatico, both of which are of an exquisite flavour, and highly esteemed. In Elba, as in the other parts of Italy, the use of the press is unknown in the manufacture of wine.

Elba has been long celebrated for its iron. Virgil calls it, "Insula, inequumus chalybum generosa metallica." There are several mines of this metal throughout the island; but the principal one, and the only one that is now worked, is that of Rio near the village of Marina, on the eastern coast. It consists of an entire mountain, which is about three miles in circumference, and so abundant as to afford a supply to Corsica, Genoa, Naples, Tuscany, Romagna, and Piombino. About 1250 quintals are sold annually, each quintal consisting of 83,333 lb. of siena. There are daily employed in exporting it to the neighbouring coasts 120 Elbese vessels of from 40 to 100 tons. The price is various according to the quality of the ore: it generally runs from 50 to 52 scudi per quintal. It is an established rule, that the Corsicans have the first choice; and that the Duke of Tuscany is allowed the best parts of the ore called ferrata, for which, however, he pays an extra price. The ferrata is so called on account of its metallic appearance. Its cavities are filled with those crystals, about which chemists have written so much. The other ore to which any importance is attached is micaceous, not so rich as the ferrata, and is
called *lucella*, from the shining of the little scales of which it is composed. Mines of copper, also, exist in Elba, but these are not open. The opinion that the island produces gold, silver, and lead, has been common, but Thiebaut de Bernanoud maintains that it is a mistake. There are quarries of loadstone, granite, and marble, both white and mixed. We meet also with alabaster, steatite, asbestos, serpentine, rocks of quartz, yenite, and various other minerals.

There are few oxen or cows on this island; there are asses, and mules and horses, and a considerable number of sheep, goats, and pigs; but the breed of all of these animals is small, and of some of them, particularly the horse, it is miserably bad. Hares, red-legged partridges, quails, wood-pigeons, rabbits, &c. are found in abundance. The fields swarm with noxious reptiles, such as the smaller scorpion, the blind worm, the adder, asps and vipers. There is also the spotted spider, whose bite is said to be mortal. All the insects common to Italy are found here. There are few bees, and no silk-worms, though the situation is remarkably favourable for both. There are two tunny fisheries on the coast of Elba. One of them is carried on at Porto Ferrajo, the other at Marciana. That at Porto Ferrajo was established first, but that at Marciana is more productive by two-thirds. The annual value of both is estimated at L. 2500 sterling. Sword-fish, dog-fish, dolphins, and sea-calfes, are sometimes killed. There are also found the sole, the bearded mullet, and that brilliant fish called by the Italians *dazzelina*. Formerly the coast abounded with oysters, some of them containing pearls of considerable size and fine colour, but the greediness of the people exhausted the beds, and various circumstances have contributed to prevent them from being again replenished. There are numerous marshes in the vicinity of Porto Ferrajo and Lungone, from which a considerable quantity of salt is manufactured. These marshes are accounted more detrimental to the public health, than they are advantageous to the public prosperity. The manufacture itself is conducted with no skill. Sixty thousand sacks, containing about 150 lib. each, are produced annually. The magazines erected for the reception of the article are said to be fine and commodious buildings. There is no machinery in the island, except that of corn mills, and these are ill constructed, and unskilfully managed. The importations of the island consist of grain, cheese, cattle, and other necessary articles; the exportations of iron ore, granite, vinegar, wines, tunny, and salt. The principal places in Elba are Porto Ferrajo, containing about 30,000 inhabitants, and situated in East Long. 10° 19′ 35′′, and North Lat. 42° 49′ 6′′; Rio, about 2000; Port Lungone, about 1500; and Marciana, about 1200.

In 1808, the whole population of the island was estimated at nearly 12,000. It appears from a calculation, that the average of births is one in twelve, and that of deaths, one in twenty three. The character of the Elboise is very superior to that of the Italians in general. They are extremely attached to their country,—industrious as labourers, and brave as soldiers; simple in their attire, and frugal in their mode of living; not very fond of amusements, and rather grave than lively in their disposition; ignorant and credulous; more superstitious than fanatical; somewhat addicted to flattery; not malicious or revengeful, but irritable and impatient of contradiction. The men are of a robust constitution, live to a great age, and enjoy good health. The women are in general not beautiful. Before marriage they are chaste, though possessed of much sensibility; after marriage, they are remarkable for being faithful wives and affectionate mothers.

The political state of Elba has undergone many revolutions. But the most remarkable event that has ever happened to the island, is that of its being assigned to Napoleon Bonaparte as his sole dominion and retreat for life; so that the Elboise are now the only subjects of a man who, but a few years ago, commanded the destinies of Europe; and who might still have maintained that lofty eminence, had not his ambition grown so extravagant as to render his talents useless, and his oppressions so intolerable, as to unite against him all the wisdom and virtue of the world. Perhaps it was impossible to dispose of this extraordinary personage in a better manner; but it is not impertinent to ask, if he be really the remorseless tyrant which he is universally believed to be, of what crime had the inhabitants of Elba been guilty, that they should be doomed to groan beneath his rod? However, since it was agreed that he should retain his life and his liberty, it was merely expedient that his power of doing mischief should be circumscribed within narrow bounds; and probably no place could answer this view so well as that little island, in which the virtue of the people may either teach him to respect while he rules them, or deprive him of his last sceptre, if he shall employ it for their oppression. See *Voyage to the Isle of Elba*, &c. by Arsene Thiebaut de Bernanoud. *Tour through the Island of Elba*, by Sir Richard Colt Hoare, Bart. &c. (c)

**ELBE**, the Albis of the ancients, and the Labe of the Bohemians, is one of the principal rivers in Germany. It takes its rise near the source of the Oder and the Vistula, in that part of the Carpathian mountains, which is called Riesengebirge, or the Mountain of the Giants. In its course through Bohemia, it receives several tributary streams, but particularly the river Moldau, above Melnik. At Leutmeritz, above which it receives the Eger from Saxony, it begins to be navigable for small boats. After leaving Bohemia, at a narrow pass at Winterberg, near Schandau, which Werner conceives to have been the outlet of a great lake, covering the whole of Bohemia, it enters Saxony, passes by Dresden, and receives the Milde, not far from Dessau. After receiving the Saale above Barby, and the Hevel near Hevelberg, which form a communication with the Oder, by means of the Spree, through Berlin, it pursues its way through the confines of the dukedoms of Lauenburg and Mecklenburg Schwerin, where it receives the Ilmenau. It then advances to Hamburg, where its branches form several islands. It receives the Stor below Glückstadt, and at the distance of 100 miles from this it throws itself into the North Sea, not far from Heligoland.

The navigation of the Elbe up to Hamburg is extremely difficult, on account of its numerous sand banks. When a violent wind blows from the west, in autumn, the waters are swelled to such a degree, that all the canals of Hamburg overflow their banks, fill the cellars and magazines with water, and often inundate the streets. An east wind produces an opposite effect. It drives the waters of the Elbe towards the sea, with so much force, that the canals are left dry, and passengers cross them on foot.

The Elbe is navigable for large vessels up to Hamburg, and for small craft for several hundred miles, and form the principal channel of communication with the whole north of Germany.
The free navigation of the river, however, is greatly injured by an excessive number of tolls and restrictions, imposed by the sovereigns of the different territories through which it flows. Merchandise sent from Pisa, in Saxony, was obliged to pay 32 tolls before it reached Hamburg, and at Magdeburg all vessels not under Prussian colours, or carrying Prussian produce, were compelled to unload, and ship their goods in Prussian vessels, of which 500 were employed by Magdeburg alone. Each prince too insists on payment in the coin of his territory, and the officers, when certificates of payment are granted, are often at a great distance from the water side. Were these inconveniences removed, a voyage on the Elbe would be both expeditious and agreeable, as the passage boats are so constructed, that travellers, on taking beds with them, may regularly sleep on board, and escape the risk of bad inns.

In the year 1796, there were no fewer than 460 vessels employed in the navigation of the Elbe, from Hamburg to Magdeburg. See Bohemia for a particular account of the progress of the Elbe through that kingdom; also Hamburg and Magdeburg. See also Oddy's European Commerce, and Cattaneo's Voyage en Allemagne, &c. vol. i. Paris, 1810. (w)

ELBING, a town of Prussia, in the circle of Marienburg, is situated in a fertile district on the river Elbing, near the Frische Haff. This town appears to have been founded by a colony from Lubeck in 1239, and till the end of the 16th century was included in the Hanseatic League. The demolition of the fortifications, at the cession of the town to Prussia by Poland in 1770, has enriched the town with a grand place. Since the year 1772, Elbing has risen in importance as a commercial town on an island formed by the river Elbing and a moat, a custom-house and excellent warehouses have been erected, those for corn holding no less than 30,000 lasts. About the end of the year 1806, the shipping consisted of 7110 tons, besides 50 coasters, and 25 lighters, which are employed in conveying cargoes to Pillau, 50 miles distant; as ships of 100 tons only can come up to Elbing. Cattaneo, in his Tableau de la Mer Baltique, states the number of vessels that arrived annually at Elbing to be between 300 and 400, the same number clearing out annually.

The exports and imports of Elbing are nearly the same as those of Königsberg, and consisted of iron, ironstone, alum, lead, Brazil wood, coffee, oranges and citrons, indigo, vitriol, rice, tobacco, sugar, soda, and French wines. This trade, however, has suffered greatly during the last disastrous wars, but now that peace is established, it may soon be expected to recover its former importance.

A number of vessels are built at Elbing; and there are manufactories of soap, tobacco, wood-ashes, starch, sailcloth and cordage, besides a sugar-house, and a saw-mill.

The library of the college contains some curiosities; and in the environs of the town, viz. at Geiszels, Thumberg, Haff, and Vogelsang, there are some very picturesque lakes. Population in 1802, 18,400. East longitude 1° 22', north latitude 54° 8' 20" by trigonometrical observations. See Oddy's European Commerce; and Cattaneo's Tableau de la Mer Baltique, vol. ii. p. 903. (w)

ELCHE, the Illíci of the Romans, is a town of Spain in the province of Valencia, situated in a plain almost entirely covered with palms. It contains several good streets, several spacious squares, some splendid houses, and six fountains, one of which is of marble in the shape of a tomb, and discharges excellent water by 20 pipes. At the end of a beautiful bridge, without any water under it, is a circular marble fountain which discharges the water by eight pipes; but the water of this and the other four fountains is brackish. There are three parish churches in the town, an hospital with 20 beds, two convents of monks, and one of nuns. The church of St Maria has a marble portal, and, according to Laborde, is a "monstrous assemblage of plain, twisted, and spiral fluted columns." On the road from Orihuela, on the left as we approach the town, there is a large and handsome square building, which is used as barracks for the troops. The Ducal Palace, standing on the bank of a deep ravine, bears marks of a high antiquity.

Elche carries on a great trade in dates and palms, with which the surrounding country is covered. There are several tanneries and a soap manufactory in the town.

The town is the residence of a vicar-general of the Bishop of Orihuela, and is governed by an alcalde major, four regidors, and some deputies of the commons.

The town is remarkably gloomy, and has no kind of amusement, society being very rare. The inhabitants, and particularly the husbandmen, are rich. Don George Juan, one of the most celebrated of the Spanish mathematicians, was born at Elche. Population 2700 houses, 15,000 inhabitants, of whom there are 500 families of labourers, and several noble families. See Laborde's View of Spain, and Townsend's Travels, vol. iii.

ELDEN HOLE. See Derbyshire.

ELECTION LAWS, in Scottish jurisprudence, are those regulations and enactments, which have been made with the view of preserving the purity of parliamentary representation. We shall have occasion to enter into a more general discussion of this subject in a future article; at present we shall merely give a short summary of the rules applicable to elections in Scotland.

Anciently the parliament of Scotland consisted of the clergy and barons; which last title comprehended every man who held immediately of the king, however small his property. The obligation of attendance on parliament was felt as a burden by the lesser barons in those times; and certain exemptions were sanctioned by the act 1427, c. 101, and subsequently by that of 1587, c. 114. But, at a later period, the feelings of proprietors changed with the spirit of the times, and political rights came to be considered as a valuable privilege, rather than as an oppressive hardship. Hence it became necessary to fix, with more precision, the nature and extent of the elector's title. By the acts 1661, c. 35, and 1681, c. 21, it was provided, that an elector should have, in property or superiority, a forty-shilling land of old extent, held of the king or prince; or when the old extent did not appear, that the lands should be liable in public burdens for L. 400 of value rent. By the latter of these enactments, a regular roll of the freetholders is directed to be made up, and annually revised at the Michaelmas head courts in the different counties. By the act 1680, c. 2, the clergy were finally deprived of the privilege of sitting in parliament. By the union of the two kingdoms (1st of May 1707) the Scottish Parliament was absorbed in the Parliament of Great Britain; the Scottish nobility, instead of their hereditary seats, were now to be represented by 15 of their number, and the proportion of the representation in the House of Com-
ELECTION LAWS.

mons, alloted to Scotland, was 45 members, 30 from the counties, and 15 from the royal boroughs. These representatives are chosen in the following manner.

1. Election of the Peers of Scotland.

The 16 peers of Scotland are chosen from among the members of the ancient Scottish Peerage, who are declared to be the body of electors. When a new parliament is summoned, the peers of Scotland are called by proclamation to meet and elect their representatives. This proclamation must be made at Edinburgh, and in the other county towns, 25 days at least before the day of election. The election is held in the palace of Holyroodhouse; and the meeting is attended by the Lord Clerk Register, or two of the principal clerks of session.

After prayers, by one of the king's chaplains, the proclamation and election are read, the roll called, those present marked, and the signed lists and proxies entered in the minutes. The peers present must then take the oaths of allegiance and abjuration, the oath of supremacy, and the test, and those voting by proxy, or by signed lists, must, if in Scotland, have taken these oaths before the Sheriff-depute in court, certified by the subscription and seal of the judge. If in England, the oaths must be taken in the Court of Chancery, King's Bench, Common Pleas, or Exchequer, and certified by writ under the seal of Court. If the Peer be out of the kingdom, it will be sufficient if it be certified that he has formerly taken the oaths in any of these ways; or that he has taken the oaths in Parliament, certified under the great seal. No peer under age, Roman Catholic, or who declines to subscribe the formula, can either vote or be elected. None can be received as a proxy but a peer, who is himself qualified to vote at the election; and the same person cannot act as proxy for more than two peers. The proxies and lists must be signed by the peer, by his Scottish title alone, in the presence of witnesses, who must likewise subscribe.

After the oaths have been administered to those present, and the oaths of the absent examined; the votes are then counted, the lists investigated, and the peers chosen by a majority of votes declared. There is no casting vote allowed in the case of an equality; but the returning officer states the fact, leaving it to the House of Peers to give their directions with regard to the point. A certificate of the names of the 16 peers being made out upon parchment, is signed and read to the meeting by the officiating clerk, and by him returned to Chancery, in a packet addressed to the clerk to the crown, before the period fixed for the meeting of parliament.

The peers have no right to decide upon a disputed title; but any peer may enter a protest against any of the proceedings which he considers objectionable. Such protests must be admitted by the returning officer, and he must give out extracts of them to any of the peers demanding them; but he takes no notice of these protests in the certificate of election.

2. Election of Commissioners for Shires.

The act 1681 provided, that the qualification of a freethearer should be a forty-shilling land of old extent or property rated at £400 Scots of valued rent. The valuation in the cess books is instructed by a certificate under the hands of two of the commissioners of supply for the county, and of the clerk of supply.

The lands, in order to afford a qualification, must be held of the king or prince; and the claimant must have been infert, and his infertment recorded; or his charter expedite, a year before the enrolment; excepting the case of a husband claiming to vote on his wife's titles, and that of an apparent heir in possession under the infertments of his ancestors; in which cases, the requisite of infertment is dispensed with. The claimant must be in possession of the lands, either naturally, by labouring the ground,—or civilly, by drawing the rents or feu-duties, or even by taking steps for enforcing payment of them.

Minors and featurous persons are disqualified from voting, as also aliens, and the eldest sons of peers. Judges of the Court of Session, Justiciary, or Exchequer, are exempted, as are also the clergy. A person who already represents one county, cannot be chosen to represent another. All persons are disqualified from voting at elections, who are concerned in the management of any duties or taxes (the Commissioners of the Treasury excepted), all commissioners of prizes, sick or wounded, transports, wine-licences, navy and Victualling-offices, secretaries or receivers of prizes, comptrollers of the army accounts, agents for regiments, governors of plantations, and their deputies, officers of Minorca and Gibraltar, officers of the excise and customs, clerks and deputies in the several offices of the treasury, exchequer, navy, Victualling, admiralty, pay of the army or navy, secretaries of state, salt, stamps, appeals, wine-licences, hackney-coaches, hawkers and pedlars, and every person who holds any new office under the crown, erected since 1705. All persons holding contracts with government are incapable of being elected; as are likewise all persons holding pensions from the crown; and, even after being elected, any member who accepts of an office of profit under the crown, excepting commissions in the army and navy, must vacate his seat, though he may be re-elected.

A person claiming to be enrolled, must leave a copy of his claim with the sheriff-clerk, two calendar months before the Michaelmas head-court. The sheriff-clerk must indorse on the claim the date of receiving it, and give out copies of it, when required, for the same fee with an ordinary extract. The copy left with the sheriff-clerk, however, need not be signed by the claimant; even the principal claim need not be signed, nor is it necessary for the claimant to appear in person at the meeting; any of the other freethearers may appear for him; and the possession of his titles, which must be produced, will be equivalent to a mandate. An objection to a freethearer's remaining on the roll, must also be left with the sheriff-clerk two calendar months before the meeting, and indorsed, &c. in the same manner as a claim for enrolment. A claim, or objection, must be supported by one freethearer at the meeting, otherwise the sheriff-clerk is under no obligation to bring it forward.

A meeting of freethearers is not entitled to review the proceedings of a former meeting; but a claimant who has been rejected by a former meeting, may be admitted by a subsequent one, on presenting a new claim. When a meeting of freethearers has done wrong, by rejecting a claim, or by striking a person off the roll, a complaint lies to the Court of Session; which must be
The duties incumbent on persons acting at elections in any official capacity, are enforced by heavy fines. The member who presides in the election of presses and clerk must call the roll regularly, under a penalty of £500; the minutes of this nomination must be made up, and delivered under a penalty of £100; the clerk of the election must make his return to the sheriff-clerk, under a penalty of £500; and the clerk of the crown-office must perform his duty under a like penalty.

2. Election of Commissioners for Royal Boroughs.

Of the 55 commoners by whom Scotland is represented in parliament, 15 are chosen by the boroughs, one by Edinburgh, and one by each of the other 14 districts of royal boroughs.

The following is a list of the 14 districts of royal boroughs, in the order of their precedence:

17. Whithorn. Campbell.

When an election is to take place, each royal borough in the district chooses a commissioner, or delegate, who meet and choose the representative for the district. At the meeting of the commissioners for choosing a representative, the commissioners from the several boroughs in the district preside in their respective turns, and have a casting vote in the case of an equality. Any person, whether a burgess or not, may be chosen as a delegate, to whom a commission is drawn up by the clerk of the borough, authenticated with the common seal. The delegates from the different boroughs meet at the presiding borough thirty days after the issue of the writ, and have a casting vote in the case of an equality. Any person, whether a burgess or not, may be chosen as a delegate, to whom a commission is drawn up by the clerk of the borough, authenticated with the common seal. The delegates from the different boroughs meet at the presiding borough thirty days after the issue of the writ, and have a casting vote in the case of an equality. Any person, whether a burgess or not, may be chosen as a delegate, to whom a commission is drawn up by the clerk of the borough, authenticated with the common seal.
ELECTRICITY.

Definition. Electricity, from the Greek word ἀέρας, amber, properly signifies the science which treats of the phenomena of attraction and repulsion, produced by the friction of amber. As similar and analogous appearances, however, were afterwards observed during the friction of sealing-wax, glass, and a vast number of other bodies, and were developed by various other means, and under various circumstances, the term Electricity has been extended to embrace the numerous and diversified phenomena which appear to have the same origin as those of excited amber or glass. As we are not yet entitled to include the Galvanic phenomena as a branch of electricity, we shall reserve for the article Galvanism, the consideration of that interesting subject.

In the present treatise, we propose to give a full and popular view of the various steps by which electricity has advanced to its present importance among the sciences; to describe the numerous phenomena which it comprehends; to explain the various theories which have been brought forward to account for them; and to describe the most improved machines and instruments which have been employed in advancing the progress of the science, in exhibiting its splendid phenomena, or in applying its tremendous energy to the useful purposes of life.

We shall, therefore, divide the article into three parts. I. DESCRIPTIVE ELECTRICITY, or an account of all electrical phenomena, whether they are produced by natural or artificial means; II. PRACTICAL ELECTRICITY, or a description of electrical instruments, and the method of constructing and using them; and III. THEORETICAL ELECTRICITY, or an account of the various theories which have been proposed to explain the phenomena.

HISTORY.

The property exhibited by amber in attracting light bodies seems to have been known in the very infancy of philosophy; and Thales of Miletus, the founder of the Ionian school, endeavoured to explain this remarkable effect, by ascribing to this fossil the functions of an animated being.

The attractive power of amber was afterwards noticed by Theophrastus, who describes amber, and the Lyonsion, (supposed to be the Tournatine,) as possessing the same property of attracting light bodies (ἐνυπερισσότερον ἀκριβείας;) and he remarks, on the authority of Diocles, that they attracted not only straws and small pieces of wood, but also thin pieces of copper and iron. The Geoponic Economies, amber is said to possess the appearance of restraint on the freedom of election, it is enacted, that all soldiers quartered in any city, borough, &c., excepting the royal residence and garrisons, must, when an election is to take place, be removed to the distance of two miles one day at least before the day of election, and shall not approach nearer until the day after the election. See the several treaties of Mr. Wight and Mr. Bell on the election laws; and the article PARLIAMENT in this work. (2)

ELECTION LAWS.

The oaths to government, and against bribery, and proceed to elect the representative. Minutes of the proceedings are prepared and signed by the preses and clerk. The latter must return the person elected to the sheriff, under the penalty of £500, and six months imprisonment; and the sheriff subjoins the return to the writ, and transmits both to the clerk of the crown.

Bribery, when it can be discovered in a candidate, vacates his election. With the view of removing every

Several detached but unsatisfactory notices respecting amber occur in the writings of Pliny; but the ancients seem to have been acquainted with nothing more than the meagre fact which was known in the time of Thales.

Although the electrical property of amber was noticed by several modern writers, such as Cassendi, Kedeligs, and Sir Thomas Brown, yet no experiments seem to have been made upon the subject till the time of Dr. Gilbert of Colchester. This eminent philosopher, whose name will appear with still greater splendour in the History of Magnetism, may be justly regarded as the founder of the science of electricity. He discovered that the power of attracting light substances was possessed by many other bodies besides amber, particularly by

Diamond, Beryl, Mastic,
Sapphire, Crystal, Sealing-wax, made,
Carbuncle, Glass, of gum lac,
Iris, Glass of antimony, Hard rosin,
Amethyst, Sparry substances, Sal Gem,
Opal, Beleninites, Talc,
Vincetina, Sulphur, Alum.
Bristol stone.

These various substances attracted not only light bodies, but also metals, wood, stones, earth, water, oil, thick smoke, and all solids and fluids, with the exception of air, flame, ignited bodies, and matter extremely rare. The substances were in general suspended in long and thin pieces, so as to move freely about their centres, and the electrical bodies, when excited by a light and quick friction was presented to one of their extremities. With a large and smooth piece of amber, he was able to attract substances without any previous excitation. After having thus determined the substances which were capable of affording electrical phenomena, Dr. Gilbert endeavoured to observe what circumstances were most favourable to their production. When the wind was in the north and east, and when the air was dry, the attractive power was exhibited in about ten minutes after the friction commenced; but when the air was charged with moisture, and the wind blew from the south, the electric energy was most materially impaired, and in some cases almost entirely extinguished. When the body was excited, the attractive virtue was greatly encreased by breathing upon the body, or by sprinkling it with brandy or alcohol, and was wholly obstructed by the interposition of several substances.

The virtues of the ancients has been supposed by some authors, to be dead. Beckmann has controverted this opinion, without being able to substitute any thing precise in its place. He supposes it to have been a sweet-smelling plant, called by later writers basilicum. See Hist. of Intellect. vol. ii. p. 240.
ELECTRICITY.

He also remarks, that glass, talle, and crystal, and all other electrical bodies, lost their faculty of attraction after being burned or roasted. Even in this early stage of discovery, Dr Gilbert could not refrain from generalising the few observations which he had made. He conceived that electrical attraction was similar to the attraction of cohesion, and that it was occasioned by the effluvium of the electric body being excited by friction.

Other hypotheses were about this time proposed, to explain the phenomena of electric attraction. The Jesuit Cabeus supposed that the streams which issue from amber, when heated by rubbing, "discuss and expel the neighbouring air;" which, after it has been driven off a little way, makes, as it were, a small whirlwind, because of the resistance it finds from the remoter air, which has not been wrought on by the electrical steams; and that these shrinking back swiftly enough to the amber, do, in their returns, bring along with them such light bodies as they meet with in the way."

According to the hypothesis of Sir Kenelm Digby, embraced by Dr Browne, the amber "being chafed or heated, is made to emit certain rays or files of uncouth steams, which, when they come to be a little cooled by the external air, are somewhat condensed, and having lost their former agitation, shrink back to the body whence they saluted out, and carry with them those light bodies that their farther ends happen to adhere to, at the time of their retraction. As when a drop of oil or syrup hangs from the end of a small stick, if that be dextrously and cautiously struck, the viscous substance will, by that impulse, be stretched out, and presently retracting, will bring along with it the dust of other light bodies that chanced to stick to the remotest parts of it."

The learned Gassendi has adopted the same hypothesis as the preceding, and he supposes that "these electrical rays being emitted several ways, and consequently crossing one another, get into the pores of the straw, or other light body to be attracted, and, by means of their decussation, take the faster hold of it, and have the greater force to carry it along with them, when they shrink back to the amber whence they are emitted."

As the preceding hypotheses were unaplicable to glass, which had not the property of emitting effluvium when heated, Descartes attempted to account for electrical attraction, by supposing certain particles shaped like small pieces of ribbon, to be harboured in the pores or crevices of glass, and to be emitted by friction, like the effluvium of amber.

The ingenious Mr Boyle, to whom some of the other physical sciences owe such lasting obligations, directed much of his attention to the subject of electricity, and has left us an account of his experiments, in a small work, entitled *Experiments and Notes about the Mechanical Origin and Production of Electricity*, Lond. 1675. He found that the hard transparent cake which remained after slowly evaporating the fourth part of good turpentine, was electrical, and that the same property was possessed by the dry mass which remained after distilling a mixture of petroleum, and strong spirit of nitre—by glass of antimony—glass of lead—caput mortuum of amber—the cornelian and the emerald, the two last of which had been supposed incapable of electrical excitation. Mr Boyle also made experiments with the diamond, and remarks that he never found any electric of the same bulk so vigorous as a rough diamond; with which he moved a needle about three minutes after he had ceased to charge it. The superiority of rough to polished diamonds he ascribes to the loss of "effluvial matter," during the operation of cutting and polishing. He found also that the electricity of all bodies is increased by torsion, as he calls it, or by wiping them before they are excited, which he supposes to remove whatever may tend to choke the pores of the amber.

In order to determine if the electrical influence was conveyed by the intervention of the air, he suspended a large piece of amber, well excited, in a small glass receiver, and over a light body, and after rapidly exhausting the receiver, the suspended amber was let down, till it came near the straw or feather, which was always attracted by the amber. In order to determine if an excited electric was acted upon by other bodies, he suspended his large piece of amber by a silken thread, and having excited it by a pin-cushion covered with a black woollen stuff, he allowed the amber to hang freely at the end of the string. As soon as the cushion hold steadily was brought near the suspended amber, it was drawn aside, and when the cushion was removed, it returned to its former position. "This power of approaching the cushion," says Mr Boyle, "was so durable on our vigorous piece of amber, that, by once charging it, I was able to make it follow the cushion no less than ten or twelve times. Whether from such experiments one may argu
t that 'tis but as 'tware by accident that amber attracts another body and not this the amber; and whether these ought to make us question if electrics may, with so much propriety as has been hitherto generally supposed, be said to attract, are doubts that my design does not here oblige me to examine." Like all his predecessors, Mr Boyle could not refrain from speculating on the causes of electrical phenomena. He supports the hypothesis of emitted and retracted effluvium, and replies to the objection of Descartes, by remarking that a "stinking odour" is actually emitted by glass, when two pieces of it are dextrously rubbed together.

While Mr Boyle was engaged in these experiments in England, the celebrated Otto Guericke, Burgomaster of Magdeburg, was successfully occupied with the same subject. Having filled a glass globe with melted sulphur, and afterwards removed the glass, he mounted his sphere of sulphur upon an axis, and performed many electrical experiments, with a new degree of facility. He observed the sound and the light which accompanied the excitation of the globe; he discovered, by means of a feather suspended near his globe, that a body, when once attracted by an excited electric, was afterwards repelled, till it had been touched by some other body; and that bodies, placed on an electric atmosphere, receive an electricity opposite to that of the atmosphere. This interesting result was obtained by suspending threads near the excited globe. He found that these threads were often repelled by his finger, and that a feather, when repelled by the globe, always turned the same side towards it.

The existence of electric light was discovered about the same time, in England, by Dr Wall. Having procured a long and tapering piece of amber, he drew it swiftly through a piece of woollen cloth, and he heard a prodigious number of little cracklings, each of which was accompanied with a small flash of light; but, by holding his finger at a little distance from the amber, he heard a loud snap, and saw it succeeded by a great flash of light. "It strikes the finger," says Dr Wall, "very sensibly, wheresoever applied;
with a push or puff like wind. This light and crackling seems in some degree to represent thunder and lightning.

Sir Isaac Newton is entitled to be mentioned in a history of electricity, more from the splendour of his name than from the contributions which he made to the progress of the science. He found, that when the upper surface of a plate of glass was excited by friction, light bodies were attracted to the opposite side; and in the History of the Royal Society, he has recorded the few experiments which he made upon this subject. In the 8th and 27th queries at the end of his Optics, he has introduced the subject of electricity in such a manner, as to convey some notion of the theoretical views which he had been to form. "A globe of glass," says he, "about 8 or 10 inches in diameter, being put into a frame, where it may be swiftly turned round its axis, will, in turning, shine where it rubs against the palm of one's hand applied to it. And if at the same time a piece of white paper, or a white cloth, or the end of one's finger, be held at the distance of about a quarter of an inch, or half an inch from that part of the glass where it is most in motion, the electric vapour, which is excited by the friction of the glass against the hand, will, by dashing against the white paper, cloth, or finger, be put into such an agitation as to emit light, and make the white paper, cloth, or finger, appear livid like a glow worm; and in rushing out of the glass, will sometimes push against the finger so as to be felt. And the same things have been found, by rubbing along a large cylinder, or glass, or amber, with a paper held in one's hand, and continuing the friction till the glass grew warm." "Let him also tell me," says he in the 27th query, "how an electric body can by friction emit an exhalation so rare and subtle, and yet so potent, as by its emission to cause no sensible diminution of the weight of the electric body, and to be expanded through a sphere whose diameter is above two feet, and yet to be able to agitate and carry up leaf copper, or leaf gold, at the distance of above a foot from the electric body?"

The subject of electricity, as well as other branches of natural philosophy, were about this time cultivated with assiduity by our countryman, Mr. Hawksbee. So early as the year 1705, he ascertained that light was produced by shaking mercury in glass vessels, and that the light became more brilliant when the air was reduced to half its density. He observed a similar light, when amber or glass was rubbed against flannel, glass against oyster shells, woolen against woolen, or glass against glass; but he was not at this time aware, that the phenomenon was electrical. In the course of his experiments, he found that sugar and carnelian when broken produced light; that mercury in a varnished vessel, shaken under an exhausted receiver, also exhibited light; and that an exhausted glass globe rubbed by the hand became luminous, the light being diminished by the admission of the air, but appearing on the point of his finger, or other bodies, when brought near the globe. The experiments of Mr. Hawksbee on electrical attraction and repulsion, were made with a pretty large glass cylinder, turned by a winch, and rubbed by his hand. Seven threads tied round a wire hoop, were attracted towards the axis of the cylinder, and this effect continued about four minutes after excitation. He afterwards found that the threads, when attracted by the cylinder, were repelled by his finger at a certain distance, and attracted by it when the distance was less. He observed also, that threads tied to the axis of the cylinder, diverged in all directions when the cylinder was excited, and were repelled by the finger when held on the opposite side of the glass. When the globe was at rest and unexcited, the threads were moved by the approach of an excited electric, excepting during moist weather.

When an exhausted globe was held within the effluvia of an excited one, he observed a light in the former, which gradually vanished when it was brought to rest, but which reappeared when the exhausted globe was put in motion. Upon presenting an exhausted tube to the effluvia of an excited globe, he perceived what he calls an interrupted flashing light. The experiments of Mr. Hawksbee on the great subtility of electric light, are extremely interesting. He lined more than half of the inside of a glass globe with sealing-wax, which in some places was one-eighth of an inch thick, and where it was thinnest it would just permit a candle to be seen through it in the dark. When this globe was exhausted and excited while in motion by his hand, Mr. Hawksbee saw the shape and figure of all the parts of his hand as distinctly upon the concave superficies of the wax within, as if no wax whatever had intervened between his eye and his hand. The same result was obtained, when pitch was substituted for sealing-wax. Melted flowers of sulphur did not produce the same effect; but common sulphur gave the same result as sealing-wax. When the quantity of common sulphur was large, the light within the globe was sometimes as great, but the shape of his fingers was not so distinctly seen as before. If a small portion of air was admitted into the globe when partially lined with sealing-wax, the light completely disappeared on the part covered with the wax, but not on that which was uncovered. When the globe was full of air, the attractive power of the coated part exceeded that of the uncoated part. Upon again exhausting the globe, the coated parts attracted bodies placed near the outside of the glass, but refused to exercise this force when the wax was removed.

Mr. Hawksbee's attention was next directed to the electricity produced by globes of sealing-wax, resin, and sulphur, having a globe of wood in their centre. The globular wax gave, in general, the same kind of electricity as glass, only differing from it in degree; but he could not make any of the electrical light adhere to his fingers, when it was placed near the excited wax. It was with great difficulty that he could excite the globe of sulphur, whereas a more powerful effect was produced with the globe of resin, (which had a little brick dust mixed with it) than with the sealing-wax. The sulphur exhibited very little light in the dark, and the resin none. Mr. Hawksbee endeavoured in vain to obtain electricity from brass; and from his attempting to explain this, by supposing that a small degree of attrition is not capable of "putting the parts into such a motion as to produce an electrical quality, owing to the firmness with which they adhere," it is evident, that he was unacquainted with the distinction between electrics and non-electrics.

After a considerable interval, during which electricity received no accessions, the subject was taken up by Mr. Stephen Gray, a pensioner at the Charter House, who enriched the science with the most important discoveries. Prior to the year 1728, Mr. Gray had repeatedly observed, that a down feather, tied to the end of a small stick, would cling to the stick after it was withdrawn from an excited tube, as if electricity had been communicated to the stick or to the feather. Hence he was led to the experiment of exciting the feather by drawing it between his fingers, and trying this, with a variety of other bodies, he discovered that feathers
ELECTRICITY.

In February 1729, when Mr Gray was making experiments with a glass tube corked at one end, he was surprised to find that a feather was attracted and repelled by the cork. He then successively fixed to the excited tube a stick of fir, a brass wire, a pack-thread, iron, gold, silver, copper, tin, stones, bricks, wood, animals, and water, and found in every case, that the electric virtue was communicated most powerfully to their further extremity. In this way he tried long cones and reeds above 20 and 30 feet long, and obtained the same results. In attempting to convey the electric virtue to a great distance horizontally, Mr Gray's friend Mr Wheeler, found it necessary to suspend their horizontal line by little vertical lines, to prevent it from bending. When those supporting lines were silk, the electricity was communicated as formerly to the end of lines 124, 147, and 765 feet long; but the silk happening to break, and a piece of brass wire being substituted on account of its greater strength, they were astonished to find that the electric virtue was no longer transmitted, having been all carried off by the brass wire. In this way Mr Gray was led to the important general law, that non-electrics, such as the metals, were conductors of electricity, while electrics, such as glass, silk, hair, and rosin, were non-conductors, and may be employed for the purpose of insulating conductors, in order to convey electricity to any distance. In pursuing these enquiries, Mr Gray next found that he could convey the electric energy from the excited tube to a thread and to a rod without bringing them into contact with the tube, and that a bubble of water, water itself, and all animal bodies, were likewise conductors of electricity.

Mr Gray's attention was next directed to the electrical qualities of rosin, gum lac, shell lac, bees wax, sulphur, and pitch. Having melted in a spherical iron ladle all these substances except the sulphur, either separately, or when two or three of them were compounded, he discovered, that when they were taken out of the ladle, and had their spherical surfaces hardened, they would not attract light bodies until they came down to a certain temperature. The attractive power being then developed, increased during the operation of cooling, and became very considerable when the bodies were cold. Having wrapped the smallest of these bodies in white paper, and the larger ones in white flannel, or in black worsted, he enclosed them in a large fir box, and he found that after 30 days, they were as powerfully attractive as on the first or second day; and that at the end of four months, (the time when he was writing,) they still retained their power. He always melted the sulphur in a glass vessel, and he once obtained a large and curious stone of stone sulphur, which was made in a wine glass, and which he had always kept covered by the wine-glass itself. When the glass was removed, the cone attracted to it bodies as powerfully as the other piece of sulphur which was preserved covered in the box. The glass itself exhibited an attractive power in fair weather, but it was inferior to that of the sulphur, which preserved its efficacy in all weathers. A cake of sulphur which he had kept for months, had only one- tenth of the attractive force of the cone. Mr Gray, in company with Mr Wheeler, discovered, about the end of August 1732, that a thread suspended in a receiver was attracted by the receiver when excited, or by an excited tube, after the air was exhausted; and Mr Wheeler afterwards obtained the same result when the attraction passed through five receivers all exhausted.

Contemporary with Mr Gray in this career of discovery, was M. Dufay, Intendant of the Royal Gardens, and Member of the Academy of Sciences at Paris. His experiments were published in six long memoirs, inserted among those of the Academy of Sciences for 1733 and 1734, and entitle him to be considered as having widely enlarged the boundaries of electrical science. He discovered that all bodies excepting metals, fluids, and sulphur, which are softened by heat or dissolved by water, could be made electric by first heating them, and then rubbing them with any kind of cloth, the softest bodies requiring in general a greater degree of friction; and in repeating Mr Gray's experiments on water, he found that all bodies, whether solid or fluid, were capable of receiving electricity when placed on glass, which was either dry or slightly warmed. He found also that the electric virtue was more easily communicated by pack-thread when it was wetted, and in this way he conveyed it along a string 1256 feet long. M. Dufay had also the good fortune to be the first who observed the electric spark from a living body when suspended on silk lines; and he has described the sensations which he experienced when electrified in an insulated position. The most important discoveries of M. Dufay were two general laws, which enabled him to classify a great number of obscure and inexplicable facts. He discovered, 1. That electric bodies attract all those that are not so, communicate electricity to them, and then repel them as soon as they become electric. And, 2. That there are two distinct kinds of electricity, very different from one another, one of which he calls vitreous, and the other resinous electricity. The vitreous electricity is exhibited by glass, rock crystal, precious stones, hair of animals, wool, and many other bodies, while the resinous electricity is possessed by amber, coal, gum lac, silk, thread, paper, and a great number of other substances. A body possessing vitreous electricity repels all bodies having vitreous electricity, and attracts all that have resinous electricity, and vice versa, or in other words, bodies having the same electricity repel each other, and those which have contrary electricity attract each other. He likewise found, that communicated electricity was always of the same kind as that of the body which communicated it; and that a tube full of condensed air was not capable of being excited.

As soon as Mr Gray was made acquainted with M. Dufay's experiments, he repeated the greater part of them, and was led to some new and interesting results. M. Dufay had observed, that a piece of iron drew sparks from the human body, when insulated by silk cords; from which Mr Gray concluded, that the same effect would be produced if the metal and the human body changed places. He therefore suspended the poker, the tongs, &c., before an excited electric, and found that they gave sparks exactly like the human body. Hence originated metallic conductors, which now form essential parts of an electrifying machine. Mr Gray likewise found, that knobs gave greater sparks than
ELECTRICITY.

points, and that wood was a much less perfect conductor of electricity than the metals; and he very sagaciously conjectured, "that there may be found out a way to collect a greater quantity of the electrical fire, and consequently to increase the force of that power, which, by several of these experiments, si licet magna componere parsis, seems to be of the same nature with that of thunder and lightning." The last labours of Mr Gray in this field of discovery, were not marked with the same genius which he had already exhibited. These experiments related to the resolution of small bodies round great electrics. "This motion," says he, "will constantly be the same way that the planets move about the sun, viz. from the right hand to the left, or from west to east. But these little planets, if I may so call them, move much faster in their apogee then in the perigee parts of their orbit, which is directly contrary to the motion of the planets about the sun." This paragraph was the last that Mr Gray ever wrote. He dictated to Dr Mortimer, on his death-bed, the other experiments which he had made upon this subject; but as they were almost all fallacious, they are not worthy of being recorded in a history of electricity.

Mr Wheeler, whom we have already mentioned as the associate of Mr Gray in several of his researches, made a considerable number of experiments by himself. These experiments related to the repulsive force of electricity, and were made in the autumn of 1732, and repeated before Mr Gray in the summer of 1731. The results of these experiments were: 1. That bodies made electrical by communication with an excited electric, are in a state of repulsion with regard to such excited bodies. 2. That two or more bodies made electrical by communicating with an excited electric, are in a state of repulsion with respect to one another. 3. Excited electrics do themselves repel one another. These results are the very same as those obtained by Mr Dunfay; and there is every reason to believe, that they were obtained before Mr Wheeler had any knowledge of the labours of the French philosopher. The experiment by which he proved the second of his observations, is remarkably beautiful. When a number of silk threads, tied together by a knot at each extremity, were electrified, they were expanded in a fine spherical shape by their mutual repulsion, so that the lower knot was made to ascend. Mr Wheeler conceived this experiment as exhibiting the action of a bundle of muscular fibres, and as suggesting a reason for the dissolution of bodies in menstrum.

Dr Desaguliers, the next philosopher who added to our electrical knowledge, informs us, that he was deterred from pursuing this science, from the peculiar temper of Mr Gray, who would have abandoned the investigation entirely, if he imagined that any thing was done in opposition to him. The death of Mr Gray relieved Dr Desaguliers from this embarrassment; and he accordingly devoted much of his attention to this curious subject. His success, however, was not proportionate to his labour; and he appears to have had a greater talent for giving a clear and succinct account of the discoveries of others, than for original investigation. He found, while endeavouring to electrify a burning tobacco candle, that the thread of trial, but not within two or three inches of the flame; and that, as soon as the candle was blown out, every part of it attracted the thread. The result was the same with a wax candle. He observed, that a glass receiver exhibits marks of electricity merely by being warmed, and that sometimes resin and wax would exert their electricity simply by exposure to the open air. Dr Desaguliers was the first who ranked pure air among electrics; and hence he endeavours to account for the rise of vapours on electrical principles. In 1712 he published an excellent dissertation on electricity, containing a complete account of all that had been done upon that subject; and he had the honour of receiving, for this work, the prize medal of the Academy of Bourdeaux. Dr Desaguliers was the first who distinguished bodies into electrics and conductors; and he gave a list of substances which belong to these two classes.

About this time the subject of electricity began to be assiduously cultivated by the Germans. Professor Boze of Wittenberg revived the use of the globe of glass, and added a prime conductor, which consisted of an iron or tin tube, at first supported by a man standing upon cakes of rosin, and afterwards by silk strings. Professor Winkler invented the cushion for exciting the globe; and Mr Gordon, a Scotch Benedictine monk, and professor of philosophy at Erfurt, had the merit of first introducing the cylinder of glass. The apparatus used in Germany was much more various and powerful than what had been employed either in France or England; and hence the foreign experimenters were led to several interesting results. In 1744, Dr Ludolf, of Berlin, set fire to the ethereal spirits of Frobenius, by the sparks from a glass tube, and also by those from an iron conductor. Professor Winkler performed the same thing by a spark from his finger, and also kindled French brandy, corn spirits, and other still weaker spirits, after they were previously heated. Oil, pitch, and sealing-wax, when heated to a very great degree, were also kindled by the electric spark.

A number of amusing experiments were about this time introduced by the Germans. Mr Winkler constructed a wheel which moved by means of electricity. Mr Boze conveyed electricity from one man to another, 15 feet distant, by a jet of water; and Mr Gordon also kindled spirits by a jet of electrified water. Dr Miller, in 1745, succeeded in kindling phosphorus by the electric spark.

Our countryman, Dr Watson, afterwards Sir William Watson, now began his successful career as an electrical discoverer. His attention seems to have been directed to this subject by the discoveries of the Germans, which he carefully repeated. He fired inflammable air by the electric spark; and, by means of a drop of cold water, and even with ice, he kindled both spirits of wine and inflammable air. He also succeeded in firing gun-powder, and in discharging a musket by electricity, when the gun-powder had been prepared by the admixture of a little camphor. In the experiments of the Germans, the substances which were set on fire were always held by some person who was not electrified; but Dr Watson performed all the experiments by what he has called the repulsive power of electricity, the fluid being held by an electrified person, and then touched by the finger of a person not electrified. He observed, that electricity experienced no deviation from its rectilinear direction, in passing through glass. The electricity transmitted through the glass, was always strongest when the glass was warm. He showed that the fire of electricity was neither affected by the presence nor absence of other fire; that the smoke of original electrics was a conductor of electricity; and that the flame of a candle was a perfect conductor. The attention of Dr Watson was next occupied by the subject of the Leyden phial, which was at
ELECTRICITY.

This time invented at Leyden for the purpose of accumulating considerable quantities of electricity. He endeavoured in vain to give a theory of its operations; but he obtained a number of curious results, which, though of importance at the time when he wrote, could not with propriety be introduced into a short history of electricity. Dr Watson was now at the head of a small party of English philosophers, who associated themselves for the purpose of making a series of experiments on the distance to which the electric shock could be carried, and on the velocity of its motion. On the 14th and 18th of July 1747, they conveyed the shock across the Thames at Westminster, by an iron wire, the water of the river forming part of the chain of communication. One of the party held a wire in one hand, which communicated with the phial, and received the shock by dipping an iron rod in the river. On the 24th of July, at two different places, they forced the electric shock to make a circuit of two miles at the New River at Stoke Newington. At one of these places, the distance by land was 800 feet, and by water 2000; in the other, the distance by land was 8900, and 8900 by water. In other experiments, they found that meadow-ground, covered with grass, conducted the electricity well; and that dry, gravelly ground, was as good a conductor as water. On the 14th of August 1747, in the driest weather, the association assembled on Shooter's Hill, for the purpose of performing a very magnificent experiment. The wire which communicated with the iron rod that made the discharge, was supported by rods of baked wood, and was 6732 feet long. The wire communicating with the phial was supported in a similar manner, and was 3868 feet in length; the distance of the observers being about two miles. Although the circuit was four miles, two of water and two of dry ground, yet no time appeared to elapse during the passage of the shock; so that there was every reason to consider it as instantaneous. In another experiment of the same kind, where the whole length of the wire was 12,276, the same result was obtained. After the completion of these experiments, Dr Watson commenced his individual labours. He discovered that glass tubes and globes did not contain the electrical power in themselves, but were merely movers, or, as he calls it, determiners of that power; and, before any notice of Dr Franklin's celebrated discovery had reached England, Dr Watson had communicated to the Royal Society of London a theory of positive and negative electricity.

While electricity was making such progress in England, Dr Franklin was busily occupied with the same subject in America. The extent and brilliancy of his discoveries gave a form and dignity to the science of electricity which it had never before possessed, and raised their author to a high rank among the distinguished philosophers of the eighteenth century. His earliest discoveries were communicated to his friend Mr Collinson of the Royal Society, on the 26th July 1747, and the letters which contained them were speedily translated into the different languages of Europe. These discoveries related to almost every branch of electricity; but the most important may be reduced to three. 1st, His discovery of plus and minus electricity. 2d, His explanation of the Leyden phial. 3d, His discovery of the identity of lightning and electricity.

Dr Franklin had observed, like Dr Watson, that electricity was not created by the friction of the glass, but was merely collected by that operation from neighbouring non-electrics. He had likewise noticed, that no person could electrify himself, even when standing upon wax or glass, as the tube which he rubbed could communicate to him no more electric matter than it had received from him during excitation; and he had seen, that when two persons stood upon wax, they both seemed to be electrified when one of them rubbed the tube and the other took the fire from it; and that the spark between them was stronger when they touched one another after that operation, than when any other person touched one of them. Hence Franklin was led to conclude, that the electric matter was conveyed from the person who excited the tube to the person who touched it; and he therefore supposed that he who touched the tube received an additional quantity of electricity to what he had naturally, or was electrified plus or positively, while the person that excited the tube was deprived of a part of his natural quantity of the electric fluid, or was electrified minus or negatively. According to this system, therefore, every body has a natural quantity of electricity; and this body may be excited either by increasing or diminishing that natural quantity.

2. This simple theory found a ready and a beautiful application in the explanation of the Leyden phial. This apparatus, which was discovered by Muschenbroek, is nothing more than a glass jar coated both on the outside and inside to within a certain distance of the top with a conducting substance, such as tin-foil. If the internal coating is connected by a wire with an excited tube, or with the electrified conductor of an electrical machine, while the external coating is connected with the ground, or with any conducting substance, a great quantity of electric matter may be accumulated in the jar. If a communication is now made by means of a conductor between the internal and external coating, a loud snap is heard, and a brilliant spark emitted; and if the conductor is a living being, he will receive a severe shock in his arm and heart, proportional to the coated surface of the jar, or rather to the quantity of electricity which has been collected. When the phial is thus discharged, the accumulated electricity has escaped, and the phial is in the same state in which it was before the commencement of the experiment. When the electric shock was first discovered, the philosophers themselves were thrown into such a tumult of wonder and surprise, that they published the most ridiculous and exaggerated accounts of the effects which it produced. Muschenbroek received such a concussion in his arms, shoulder, and heart, that he lost his breath, and required two days to recover from the effects of the blow and the terror, and declared that the kingdom of France would not induce him to take another shock. M. Allamand lost the use of his breath for some moments, and afterwards experienced along his right arm such an acute pain, that he apprehended serious consequences from it. Mr Winkler tells us, that his body was thrown into such convulsions, and his blood into such an agitation, that he employed cooling medicines to keep off fever. At another time, he bled copiously at the nose; and the same effect was produced upon his wife, who was almost deprived of the power of walking. These remarkable effects of the electric fluid excited the attention of all classes of people. The learned and the vulgar were equally desirous to experience the singular sensation; and crowds of half-taught electricians wandered through every part of Europe to gratify the universal curiosity. It was only the curiosity of the unlearned, however, that was satisfied. The electrical philosophers endeavoured in vain to account
for the operation of the Leyden phial; and it was not till the Franklinian theory was discovered, that it received a proper explanation.

This explanation consists in supposing, that when one side of the glass jar was electrified positively, the other was electrified negatively, so that the charging of the phial consisted merely in diminishing the quantity of the electric matter in one side of the glass, and accumulating electric matter in the other. Dr Franklin had observed, that the outside coating was always negative, when the inside coating was positive; and he proved the truth of this, by the attraction and repulsion of a cork ball suspended by silk. When a cork ball was suspended between the wires communicating with each coating, and brought near one another, it was alternately attracted and repelled by each wire, till the phial was discharged.

In order to show, that in the charging of a phial, the one side lost as much as the other gained, he suspended a small linen thread near the coating of a charged phial, and observed that the coating attracted the thread whenever he brought his finger near the wire, the outside coating drawing in by the thread the same quantity that was taken from the inside by touching the wire. Several experiments enabled Dr Franklin to prove, that, in the discharge of the phial, the quantity of electricity which left the one side of the phial, was equal to that which was received by the other. In one of these, he insulated the rubber of his machine, and found, that a phial, suspended from the conductor, could not be charged, even though his hand was constantly applied to it; for, though the electric matter left the outside, there was none to be accumulated on the inside. Upon removing his hand, and connecting the outside coating and the insulated rubber by a conducting substance, the phial was easily charged. Hence it followed, that the very same electric matter which left the external coating, was conveyed by the way of the globe, the conductor, and the wire of the phial, into the inside of the jar.

3. Hitherto, the science of electricity embraced no wider range than the phenomena developed during the excitation of glass and other electrics, and had therefore not yet connected itself with any of the great events of the material world. Astronomy had elevated the mind to the contemplation of the most splendid and magnificent phenomena which the imagination could comprehend; Optics had dared to investigate the properties of that ethereal matter, which constitutes the very soul of the visible world; and Magnetism had connected her facts with the polar attraction of the great globe itself. It had indeed been conjectured, that the shock and spark of the electrical machine, were miniature effects of a more tremendous agent; but it was reserved for Dr Franklin, not only to give a form and character to this infant science, but to raise it to a higher rank among the other great divisions of human knowledge. The discovery of the identity of electricity and lightning was the step by which this great change was effected. The vulgar were astonished at the sight of fire brought down from heaven; and philosophers themselves startled at the recollection, that they had been amusing themselves with a thunderbolt in their hands, and trifling with that terrible agent, which had so often alarmed and convulsed the physical world. Human genius indeed seems on this occasion to have made an impious excursion beyond its mortal range; and one victim was demanded to expiate the audacious attempt.

Suspecting that the electric fluid was similar to that which produced lightning, Dr Franklin drew up a statement of the principal points in which these two agents resembled each other. He found that flashes of lightning, like the electric spark, are generally seen crooked and wavy in the air; that lightning, as well as electricity, strikes pointed objects in preference to all others; that lightning and electricity take the readiest and the best conductor; that they both dissolve metals, and inflame combustible substances; that they rend solid bodies, strike persons blind, reverse the poles of a magnet, and destroy animal life. These points of resemblance appeared to Dr Franklin so very striking, that he resolved to examine, by direct experiment, the truth of his conjecture. For some time he waited for the ejection of a spire in Philadelphia, to assist him in his views; but he afterwards thought of a more simple method of carrying them into effect. Having extended a large silk handkerchief over two cross sticks, he formed a kite, which, unknown to any person but his son, he elevated during the first thunder storm, which happened in the month of June 1752. The kite remained a considerable time in the atmosphere without any appearance of electricity. A cloud, which had the appearance of being charged with lightning, passed over it without producing any result; and Dr Franklin began to despair of success. His attention, however, was roused by the ejection of some loose fibres on the hempen cord, and on holding his knuckles to the key upon the string, he received an electric spark. Before the rain had wetted the string, other sparks were obtained; but when the string was thoroughly wet, Dr Franklin collected the electric fire in great abundance. About a month before Dr Franklin had made these successful trials, the French philosophers had obtained similar results. In order to shew, by direct experiment, that the electricity collected from the atmosphere had the same properties as that which was generated by the friction of an electric, he erected an apparatus in his house at Philadelphia, consisting of an insulated iron rod connected with two bells, which indicated by their ringing that the rod was electrified. After numerous trials, he found that the natural and artificial electrics were in every respect the same; that the clouds were sometimes negatively, and sometimes positively electrified; and that sometimes, in the course of a thunder storm, they changed several times from positive to negative. On one occasion, when there was no thunder at all, he found the air to be strongly electrified during a fall of snow.

The great practical application of the preceding discoveries to the protection of buildings from the destructive effects of lightning, contributed most essentially to extend the fame of Dr Franklin's discovery; and every conductor that has been reared for this purpose, may be regarded as a monument to the genius of the American philosopher. We are disposed to doubt, however, whether this application has been as useful as it at first promised. When a thunder cloud is directly above, and not far distant from, a conductor, the electric fluid will certainly be conveyed into the earth by the conducting power of the iron rod; but there have been numerous instances where one end of a house has been destroyed by lightning, when there was a conductor placed at the other.

A great variety of miscellaneous and important experiments were made about this time by Le Monnier the younger, Mr Smekton, and Dr Miles. Le Monnier made a great number of experiments with a very powe-
ELECTRICITY.

The subject of electricity was cultivated by the Abbé Nollet with great assiduity and success. He was the friend and associate of Dufay, and was worthy of succeeding him in his career of discovery. He observed that electricity of a body placed in the atmosphere of an electrified body, was of the same kind with that of the electrified body, a result, however, which was found to be incorrect; that pointed bodies threw out brushes of electrical light, but did not display other signs of electricity so powerfully as blunt bodies; that the smoke of gum lac, turpentine, karabé, and sulphur, were not so good conductors of electricity as the smoke of linen, wood, the vapour of water, and the effluvia of burning tallow and other fat substances; that a piece of redhot iron throwing off ignited sparks, and placed at the distance of 6 inches from an excited tube, deprived it in two or three seconds of all its electricity, but refused to affect the tube at the same distance before it ceased to be red; that an excited tube lost none of its electricity in the focus of a burning mirror; that glass and other electrics were more strongly excited in the open air than in vacuo; that the electric light in vacuo was more diffuse and unbroken than in the open air; and that oil of turpentine, upon a piece of woollen cloth, was capable of exciting glass very powerfully, but lost this quality by the least intermixture of water. The Abbé Nollet was the first person who made any accurate experiments on animal and organised bodies. This series of experiments he began with several on evaporation, &c. He ascertained that electricity augments the natural evaporation of fluids, and that those evaporate most in this way that are most evaporable in ordinary cases; that electricity has the greatest effect in evaporating fluids, when they are contained in vessels that are non-electric, and that it does not make fluids evaporate through the pores either of metal or glass. Mr Boze having informed the Abbé Nollet that capillary tubes which discharges water only by drops, afforded a constant stream when electrified, he made numerous experiments on that subject. He found that the stream of water was neither sensibly accelerated nor retarded when the bore was above a line in diameter. When it was a line in diameter, the fluid experienced a small acceleration, and when it was capillary, the electrified jet not only became a continued stream, and divided into several streams, but was also considerably accelerated, and this in proportion to the smallness of the bore. The stream of electrified fluid exhibited in these experiments had a very brilliant effect when they were performed in the dark. The Abbé's attention was now directed to the effect of electricity upon vegetables. The first experiments on this subject had been made at Edinburgh, in October 1746, by Mr Maimey, who found that two mealy trees, electrified during the month of October, put forth small branches and blossoms much earlier than other shrubs that had not been electrified. The Abbé repeated this experiment. He sowed seeds in two pots, filled with the same mould, and kept in the same place. One of the pots was electrified during 13 days, two, three, or four hours a day, while the other remained unelec- trified; and it always happened that the electrified pot exhibited sprouts two or three days sooner than the rest, and threw out larger shoots, and a greater number of them in a given time.

In extending his experiments to animals, the Abbé Nollet took several pairs of cats, pigeons, chaffinches, sparrows, &c. and placed them in different cages. After electrifying one of each pair for five or six hours at a time, he weighed them accurately, and always found that the electrified cat was 65 or 70 grains lighter than the other, the pigeon from 32 to 38 grains lighter, and the chaffinch and sparrow six or seven grains. Hence he concluded that electricity increases the insensible perspiration of animals.

Upon these and other results, the Abbé Nollet founded a theory of electricity, which was never received by any other philosopher. He imagined that when an electric is excited, the fluid has two opposite motions, viz. an efflux to the electric and an influx from it. In consequence of the efflux, all light bodies are attracted or carried towards the electric, while, in consequence of the influx, all light bodies are carried from the electric or repelled. Hence he was obliged to suppose, that every electric, as well as every body which receives electricity, has two different kinds of pores; one for receiving, and the other for emitting the electric matter.

About this time a very simple and ingenious theory was brought forward by Mr Ellicott, a fellow of the Royal Society of London, which is remarkable as being almost exactly the same as that which was afterwards so fully illustrated by Espinus and Cavendish. After reciting the principal electrical phenomena, he draws from them the following conclusions: 1. That the phenomena of electricity are produced by means of effluvia, which, in exciting the electrical body, are put into motion and separated from it. 2. That the particles composing those effluvia strongly repel each other; and, 3. That there is a mutual attraction between these particles and those of all other bodies. Mr Ellicott afterwards proceeds to explain, upon these principles, a variety of electrical experiments. See Phil. Trans. 1748, vol. iv. p. 195.

During the years 1747 and 1748, the attention of philosophers was drawn to a series of experiments on the
medical effects of electricity, said to have been performed at Venice, and repeated at Leipsic. J. Francisco Pivati, a gentleman of eminence at Venice, published a pamphlet in Italian, containing an account of these experiments. He inclosed in a glass cylinder a quantity of balsam of Peru, so that none of its effluvia could escape; and with that cylinder he electrified a man who had been afflicted with a severe pain in his side. As soon as the patient returned home, he fell asleep and perspired; and so powerfully had the balsam been transpired through the pores of the glass cylinder into his body, that his clothes, his hair, and his bed, were filled with the effluvia. On the following day Pivati electrified another person who was in good health. In the course of half an hour a warmth was gradually diffused through his whole frame, and he became unusually cheerful. An odour was emitted from his body, and was distinctly perceptible to his companion. Induced by these results, Professor Winkler of Leipsic repeated the same experiments with success. He found that bent sulphur, which, when enclosed in a glass sphere, emitted no odour by being burned over the fire, sent forth a sulphurous vapour, when electrified, to the distance of 10 feet. His friend Professor Haubold, and other visitors, were obliged to leave the room from the intensity of the smell, and the professor’s clothes were impregnated next day with the sulphuric vapour. He afterwards diffused the odour of cinnamon and balsam of Peru in a similar manner, and in both these cases the effects of the odour remained on the day following. The experiment was again tried upon a person ignorant of what was doing, and he distinctly stated that his nose was filled with a sweet smell like some sort of balsam. Encouraged by the success of his first experiments, Pivati drew sparks, for some minutes, from an ulcerated foot, which had resisted every surgical application, by means of a glass cylinder filled with proper materials. In the morning, the patient found a red tumour on his foot. He perspired every night for eight days, and was then perfectly recovered. The Bishop of Sebenico, an old man of 75, who was miserably afflicted with the gout, was attracted to Venice by the fame of Pivati’s cures. His fingers were immovable, and his legs incapable of bending; but as soon as he had been electrified from a glass cylinder filled with discutient medicines, “his Lordship opened and shut both his hands, gave a hearty squeeze with his hand to one of his attendants, rose up, walked, smote his hands together, helped himself to a chair, and sat down, wondering at his strength, and hardly knowing whether or not it was a dream. He walked out of the chamber, and down stairs, without any assistance, and with the agility of a young man. Soon afterwards Pivati electrified a lad, 61 years old, in like manner, from the gout, with which she had been six months tormented. Her fingers were much swollen, and, always trembling, and one of her arms was convulsed. After receiving the electricity for two minutes, the trembling of her fingers ceased, and the next day the swelling was so far abated, that she could draw on her gloves, and make use of her fingers.” See Phil. Trans. 1748, vol. xiv. p. 202.

As soon as these results were known over Europe, every electrician endeavoured in vain to verify them. The Abbé Nollet undertook a journey to Italy, for the purpose of visiting the different experimenters by whom they were published. He repeated the experiments in their own presence; and though he found that in particular cases, such as disorders of the eyes, the ear, and the head, and in some cases of paralysis, the patients had found considerable relief; yet he was convinced, that, in other instances, the effects were greatly exaggerated; and in no one case could he find any transpiration of odours through glass, or any communication of the effects of drugs to persons who were electrified with them in their hands. The British electricians were equally desirous with the Abbé Nollet, either to confirm or refute the experiments of Pivati. They had both tried without success by the members of the Royal Society; and an account of Winkler’s and Pivati’s experiments had appeared among the transactions of that learned body, the secretary was desired to request from Mr. Winkler a circumstantial account of his experiments; and a loan of some of the globes and tubes by which he had obtained such singular results. The German electrician readily complied with this request; and Dr. Watson was appointed to conduct the experiments at his own house, on the 12th of June 1751, before the president and office-bearers of the Royal Society. Notwithstanding every precaution; however, in obeying the instructions of Mr. Winkler, they were unable to force through glass the effluvia of odoriferous bodies.

Mr. Canton, one of the most eminent of the English electricians, had early distinguished himself by a successful repetition of Dr. Franklin’s method of drawing electricity from the atmosphere during a thunderstorm. He was the first who discovered that air was capable of receiving electricity by communication, and of retaining it for a considerable time; and, by a delicate apparatus, he even measured the quantity of electricity which it had received. He found also a method of electrifying, to a considerable degree, the whole air of a room, either positively or negatively. In the year 1753, he even succeeded in electrifying a room to such a pitch that it retained its electricity for some time. In very dry weather, the electricity thus communicated sometimes continued above an hour.

Hitherto the same electricity had always been produced by the same electric; a result which had been introduced into the very terms of vitreous and resinous electricity. It was reserved, however, for Mr. Canton to dispel this long established result, and to shew that every electric was capable of affording both kinds of electricity, according to the state of the surface of the body, and according to the nature of the rubber by which that surface was excited. Mr. Canton had found before he completed this great discovery, that he could communicate positive electricity to sealing-wax. The stick was two feet and a half long, and one inch in diameter; and when an excited glass tube was drawn several times over one part of it without touching the other, the half thus excited was positively, while the other was negatively electrified. In December 1758, Mr. Canton removed the polish from a glass tube by grinding it with emery and sheet-lead; and, upon exciting it with new flannel, he found that it possessed negative electricity, but when it was excited by a piece of dry oiled silk, it exhibited signs of positive electricity. If the rough tube be all greased over with tallow, and as much of the tallow as possible wiped off with a napkin, the oiled silk will receive a polish by rubbing it, and after a few strokes, the tube will exhibit signs of negative electricity. When the oiled silk is covered with chalk or whitening, the greased rough tube will give positive electricity; but by continuing the friction till the rub-
ELECTRICITY.

Having observed that the friction of mercury, included in a glass tube, not only produced electrical light, but also electrified the glass on the outside, Mr Canton plunged a piece of dry glass in a basin of mercury, and found that by taking it out, the mercury was electrified negatively and the glass positively, and to a considerable degree. He likewise found that amber, sealing-wax, and Iceland crystal, were all electrified positively when taken out of mercury. From these experiments, Mr Canton was led to the discovery of an amalgam of mercury and tin, which he always found highly efficacious in the excitation of glass. The subject of electric atmospheres was also illustrated by some fine experiments of Mr Canton. These experiments exhibit a curious variety of attractions and repulsions of electrified bodies under different circumstances, and led to the establishment of the general fact, that bodies immersed in electric atmospheres always become possessed of the electricity contrary to that of the body into whose atmosphere they are plunged.

Contemporary with Mr Canton, was Giambattista Beccaria, who has laid the science of electricity under great obligations, and has published his discoveries in a work entitled, Dell' elettricismo artificiale e naturale, which appeared at Turin in 1753, and was translated into English in 1776. Having no knowledge of the experiments of Mr Canton, Beccaria made the same discovery respecting the communication of electricity to the air. He demonstrates that the air which is adjacent to an electrified body acquires gradually the same electricity; that the electricity of the body is counteracted and diminished by this electricity of the air; and that the air parts with its electricity very slowly. He also found that there was a mutual repulsion between the particles of the air and electric matter, and that a temporary vacuum is formed by the electric fluid in passing through any portion of air. His experiments on water are equally interesting and important. He has shown that water is a very imperfect conductor of the electric fluid; that it conducts electricity according to its quantity; and that a small quantity of water makes a great resistance to the electric fluid. Small tubes of water, for example, when forming part of the electric circuit, refused to transmit a shock, while it was readily conveyed by tubes of a larger bore. He even made the electric spark visible in water, by inserting wires nearly meeting in tubes filled with water, and discharging shocks through them. The electric spark appeared as if no water had been present; but the tubes, though often 8 or 10 lines thick, were generally broken to pieces with tremendous force. The same philosopher discovered also that metals were not perfect conductors; and by suspending a wire of 500 Paris feet in length, and using a pendulum vibrating half seconds, he thought that he could determine the rate at which the electric fluid advanced. Light bodies, for example, placed at one end of the wire, did not move till one vibration after a charged phial had been applied at the other extremity. When a hemp cord was used, five or six vibrations elapsed, and only three or four when the cord was wetted.

These experiments of Signor Beccaria, valuable as they are, were greatly surpassed by those which he made on the electrical phenomena of the atmosphere. An account of these experiments, however, would require us to enter into a minutness of detail which is inconsistent with a general history of electricity. They will be given with more propriety in another part of the article.

About this time, the death of Professor Richman of St Petersburg, while employed in bringing electricity from the heavens, created a great sensation in the scientific world, and is well entitled to be particularly mentioned in a history of electricity. This eminent individual was engaged in a work on the electricity of the atmosphere; and was therefore extremely desirous of observing the electrical state of the air during thunder storms. On the 6th of August 1753, he had prepared his apparatus for observation. From a metallic rod passing through a perforated bottle, and fixed upon the roof of his house, there passed a chain surrounded with electrics. The other end of this chain was fixed to another metallic rod placed in a glass vessel, and to this second rod was attached a linen thread, which marked, by its elevation on a quadrant, the intensity of the electricity of the rod.

While Professor Richman was attending an ordinary meeting of the Academy of Sciences in the forenoon, his attention was excited by the sound of distant thunder. He immediately set off for his own house to observe the electrical state of the air, and took with him his engraver Sokolow, that he might be enabled to give a better representation of any phenomena that should present themselves. Richman remarked, that the thread pointed to four degrees on his quadrant; and while he was describing to his friend the dangerous consequences that might ensue if the thread rose to 45°, a dreadful clap of thunder alarmed all the inhabitants of St Petersburg. Richman inclined his head to the gnomon to see the degree of electricity which was indicated, and when he was in that bent posture, with his head about a foot distant from the rod, a large globe of white and bluish fire, about the size of Mr Sokolow’s fist, flashed from the rod to his head, with a report as loud as that of a pistol. The Professor fell back upon a chest behind him, and instantly expired. Sokolow was stupified and benumbed by a sort of steam or vapour, and was struck by several fragments of the red-hot wires; and the moment he recovered, he ran out of the house, acquainting every person whom he saw with the accident. In the mean time, Mrs Richman, who heard the stroke of thunder, hastened to the chamber, and found her husband without any appearance of life, in the attitude of sitting upon the chest, and leaning against the wall. The house was filled with a sulphurous vapour; an English clock was stopped in an adjoining room, the ashes were thrown from the fire-place, and the door-posts of the house were rent asunder. As soon as medical assistance was obtained, a vein of the Professor’s body was opened, but no blood flowed, and every attempt to restore life by violent shaking, and other means, were wholly fruitless. When the body was turned upside down, a small quantity of blood fell from the mouth during the rubbing, and on the forehead appeared a

ELECTRICITY.

red spot, from the pores of which some drops of blood oozed, without wounding the skin. The shoe on the left foot was burst open, and below the aperture there was a blue mark on the foot, from which it is probable that the electricity had issued. Several red and blue spots resembling leather shrunk by being burnt, appeared on the left side, on the back, and on other parts of the body. The stocking was entire at the place where the shoe was burst, and the coat had received no damage. The back of the engraver's coat, however, was marked with several long and narrow burnt stripes. Upon opening the body 24 hours after the accident, the cranium and brain were uninjured; some extravasated blood appeared in the cavities below the lungs, and in the lungs towards the back, which were of a brownish-black colour. The throat, glands, and the thin intestines, were all inflamed, but none of the entrails were touched. The singed leather-coloured spots merely penetrated the skin; and 48 hours after death, the body was completely corrupted. It is a curious circumstance, that Professor Richman had in his left coat pocket 70 rubles of silver, which were not in the least degree affected.

Our countryman, Mr Delaval, a member of the Royal Society, contributed considerably to the progress of electricity. He found that the calces of metals, such as ceruse, lead ashes, minium, cals of antimony, &c. are all non-conductors, although metals themselves are the most perfect conductors. Animal and vegetable solids also, when reduced to ashes, were likewise non-conductors. A piece of Portland stone, which conducted perfectly well, became a non-conductor when powdered, exactly like the oxides of metals; and after making similar experiments with pounded alum, and gum arabic, Mr Delaval believed that all bodies that can be pulvissed in the mortar will have the same property. Having formed some of the Portland stone, (granular limestone) into plates nearly as thin as window-glass, he heated them to a proper degree, and coated them on both sides with metal, in order to perform the Leyden experiment. When the heat was great enough to singe paper, the stone conducts as perfectly as when cold. Upon cooling, it begins to lose its conducting power and afford small shocks, which increase in intensity for ten minutes, and then continue the same for fifteen minutes. The shocks then became weaker as the stone cooled, and completely ceased a little while before the stone was cold. The same result was obtained with tobacco pipes. These results were attributed, by Mr Canton, with great reason, to the moisture contained in the Portland stone and the tobacco pipe. When they are heated, the moisture is expelled, and the conducting power destroyed; and when they begin to cool, the moisture is absorbed, and the conducting power restored. Mr Delaval made some curious experiments on calcareous spar. After being rubbed, when the heat of the air is moderate, it shows weak signs of electricity. When the heat is a little greater than that of the hand, it destroys completely its electric power, and by cooling, the electric power is again revived. He plunged the same crystal into a vessel of quicksilver surrounded by ice. After remaining two hours in cold water, he took it out with a pair of tongs, and upon again rubbing it, it showed more electricity than it had done formerly. He also found some pieces of calcareous spar that did not possess this property. This circumstance will account for the failure of Mr Bergman in trying to repeat these experiments of Delaval.

Mr Benjamin Wilson made a number of experiments on electricity, which he published in 1750, in a treatise on that subject, and in several papers in the Philosophical Transactions. He was unfortunately one of those individuals who opposed, with such obstinacy, the use of pointed conductors for thunder-rods, and was the means of introducing into the Royal Society those animosities and dissensions so fatal to the character and interests of science. The electrical properties of the tourmalin had been lately announced in the Memoirs of the Academy of Berlin, by M. Epinus, who found that when this mineral was moderately warmed, it exhibited a plus electricity on one side, and a negative electricity on the other. The Duke de Noys, who wrote upon this subject, maintains, that the two sides are electrified plus, and one of them more strongly than the other. In this state of the subject, it was taken up by Mr Wilson, who made his experiments on a specimen belonging to Dr Heberden, which weighed about 120 grains. The general result of these experiments was, that the tourmalin suffers the electric fluid to pass through it only in one direction, having, as it were, two electrical poles; that there are three different methods of heating the tourmalin, which produce different electric appearances; that different degrees of heat give different phenomena; and that friction has the same effect upon it as upon glass. Mr Wilson found that a number of other crystallised minerals of a red and orange colour, and having the hardness of topaz, possessed the same electrical quality as the tourmalin. Dr Thomson, however, has remarked, that these must have been varieties of tourmalin, which the imperfect state of mineralogy did not enable Mr Wilson to recognize. Mr Wilson also found, that when two electrices are rubbed together, the one is always electrified positively and the other negatively, the harder of the two having generally acquired the positive electricity.

About this time a number of curious experiments were made by Mr Symmer, on the electricity of stockings of different kinds. His papers were published in the Philosophical Transactions for 1759, and relate to four subjects: 1. On the electricity of the human body; and the animal substances silk and wool. 2. On the electricity of black and white silk. 3. On electrical cohesion. 4. On two distinct powers in electricity. Mr Symmer had frequently observed, that, on pulling off his stockings in the evening, they emitted a cracking noise, and even gave sparks of fire in the dark. He immediately conjectured that these phenomena were electrical, and commenced a series of experiments on the subject. He found the electricity very powerful when a silk and worsted stocking were on one leg, and it was of no consequence which of them was uppermost. When the stockings are thus excited, they appear more or less inflated, discharge an electrical wind felt by the bare leg, attract or repel another stocking visibly, and by being touched, emit or receive electrical fire. The best way of taking off the stockings is to pull the hand between the leg and the stockings, and to push them off together. They must then be pulled asunder, and will exhibit signs of electricity. When two stockings were both of the same material, they produced no electricity, so that it was always necessary to have one of them black and the other white. Having worn a pair of black silk stockings on his leg for ten minutes, he found them so highly inflated when taken off, that each of them exhibited the entire shape of the leg, and rushed together at the distance of one foot and a half. All these effects are most powerful when the stockings are either new, or newly washed.
In order to perform these experiments with less trouble, Mr Symmer made his subsequent experiments by drawing the stockings through the hand. The following are the leading results: Black silk is highly susceptible of electricity, being excited almost instantaneously, and with very little friction. White silk is greatly inferior to it, exhibiting neither sparks, nor emitting a crackling noise, but affecting the electrometer very slightly. A black and a white silk stocking drawn through the hand together, exhibit no electricity till they are separated. Mr Symmer went so far as to charge the Leyden phial by means of excited stockings; and with four silk stockings he even kindled spirits of wine. The electrical cohesion between white and black silk stockings attracted Mr Symmer's particular notice. A weight of from one to twelve ounces was required to separate them. At another time they required 17 ounces, including the scale and the black stocking, which was 20 times the weight of the white stocking that supported them; the weight acting in a direction parallel to the cohering surfaces. When one of the stockings was turned inside out, and put within the other, the separation required six ounces, whereas 10 was sufficient when they were applied to one another externally. With stockings of a more substantial make, one of them being put within the other, without being turned inside out, the separating weight was nine pounds, wanting a few penny-weights, which is 55 times the weight of the supporting stocking. When the white was turned inside out, and put within the black, so that their interior or rough sides were together, the separating weight was no less than 15 lbs. 1¼ dwt. which is 92 times the weight of the supporting stocking. When the application of the stockings was merely external, as before, they lifted only 1¼ of a pound, or 10 or 11 times the weight of the whole stocking. Mr Symmer found likewise, that excited stockings adhered also to unelcrtificd bodies, with broad and polished surfaces. Having thrown a stocking accidentally out of his hands, he was astonished to find it, some time afterwards, sticking to the paper hangings of the apartment. They adhered also to the painted boards of the room, and to the looking glass, and often remained suspended for a whole hour upon the hangings.

Mr Symmer concludes, from his experiments, that there are two distinct electri aide: that electricity is in the possession of a larger portion of one or the other power, as is necessary to maintain an even balance with the body; and that the electricity is negative or positive, according as the one or other power prevails.

Signior Alessandro Amadeo Vanudonia, who constantly wore a beaver shirt between two others, in cold weather, found that the upper shirt always adhered to the beaver shirt when it was taken off, and emitted electric sparks. This experiment was repeated by his friend Beccaria.

The experiments of Mr Symmer attracted the notice of M. Cigna, who published an account of several interesting results, in the Memoirs of the Academy of Turin for 1765. Having extended two dry white or black silk ribbons above each other, upon any smooth plain surface, he drew over them the sharp edge of an ivory ruler. Both the ribbons adhered to the plain, and when taken from it together they attracted each other, the upper one having been electrified positively, and the lower one negatively. When they were lifted separately, they repelled one another, having both acquired the negative electricity. In removing both the ribbons from the plain, and in their subsequent separation, electric sparks were always visible between them. If the ribbons, after having acquired, by the preceding operation, the same electricity, were placed upon any rough conducting body, such as cotton or hemp, not very dry, they exhibited, on separation, two contrary electrifications, which disappeared upon joining them together. When the two ribbons were rubbed upon that rough surface, they always were electrified in an opposite manner, the upper one having the negative electricity. The effect of a rough surface was produced by a pointed conductor. When the two ribbons, hanging parallel, and repelling each other, had the point of a needle drawn opposite to one of them, along its whole length, they instantly rushed together, the ribbon nearest the needle having its electricity changed. An unelcrtificd ribbon acquired electricity by placing it upon a rough surface, and having an electrified ribbon above it, or by holding it parallel to an electrified ribbon, and drawing a pointed conductor opposite to it, as before. If the ribs were rubbed with any skin, or a piece of smooth glass, in place of the ivory ruler, the same results were obtained; but when a stick of sulphur was employed, the electrivities were always the reverse of what they were before, the rubbed ribbon being always negative. If one of the ribbons was black and the other white, the excitation of the two was the uppermost, and in whatever way they were rubbed, the white one was generally positive, and the black one negative. Whenever the upper piece of silk, however, was loose, yielding, and like a net, or of the same structure as a stocking, so that it could be rubbed against the lower one, and whenever the rubber was of such a nature as to impart but little electricity to glass; under these circumstances, the electricity imparted to the upper piece of silk did not depend upon the rubber, but upon the surface which supported it, the black being always negative, and the white positive. When the structure of the silk was hard, stiff, and close, and when the rubber had the character of communicating much electricity to glass, then the upper piece of silk derived the character of its electricity from the rubber, and not from the supporting surface.

In another set of experiments, he brought an electrified ribbon near an insulated plate of lead, and observed a feeble attraction. When his finger was brought to the lead, a spark was emitted, after which the ribbon was vigorously attracted, and both together exhibited no marks of being electrified. Upon taking away the ribbon, appearances of electricity were exhibited in both, and a spark was seen between the plate and the finger. When two glass plates were placed upon a smooth conducting body, communicating with the ground, and excited in the same manner as the ribbons, they likewise acquired electricity, and stuck firmly both to the conductor and to one another. When the conductor was a plate of lead, not very thick, it was supported by the attraction. No signs of electricity were exhibited when they were all together. Upon removing from the conductor the two plates of glass together, their electricity was positive on both sides, while the conductor, if it had been insulated, seemed to be negatively electrified. When the two plates of glass were separated, the upper one was positively electrified, and the lower one negatively. With a rough conductor they scarcely contracted any electricity, though,
upon separation, they were electrified as before. Hence he endeavours to explain the nonexcitation of a globe or tube, from which the air is exhausted.

The celebrated chemist, Torbern Bergman, of Upsal, made a few experiments on electricity. He found, what had already been discovered by Boccara, that a small quantity of water was not capable of conducting the electric fluid, but that more was transmitted as the quantity of water was increased. He obtained a similar result from ice, and concluded that ice is a worse conductor than water. It was ascertained by later experiments, that ice became a non-conductor when cooled down to 13° of Fahrenheit.

To Mr Kinnesley, the friend and associate of Dr Franklin, electricity owes considerable obligations. Mr Kinnesley first distinguished himself by discovering the two opposite electricities of glass and sulphur, in which, however, he had been anticipated by Dufay; but he immediately saw that Dufay did not imagine that these two electricities were the same as the positive and negative electricities of Dr Franklin. He found that a coated flask, containing boiling water, could not be charged, as the electricity passed off with the steam; but as soon as the water was cold, the flask was readily charged. He found, that if a person insulated, and negatively electrified, should hold out in the dark a long sharp needle, pointing upwards, a light would be observed on the point of it, the electricity being in this case drawn from the air. Upon sending the charge of a case of 35 bottles through a piece of brass wire about 24 inches long, with a pound weight at the lower end, the whole wire became red hot, and was an inch longer than before. By means of a second charge, the wire was melted. It was drawn asunder near the middle, and when the two ends were put together, it measured four inches longer than before. *

M. Jalla-ber.

One of the most successful cultivators of the science of electricity was Mr Wilke of B-stock, in Lower Saxony, who has published an account of his labours in his celebrated work, entitled Disputatio Physica experimentalis de Electricitatis, Rostock, 1757, 4to. His researches respecting spontaneous electricity, a name which he gives to the electricity produced by the melting of electric substances, have contributed most essentially to the progress of the science. He found, that sulphur melted in an earthen vessel, which he placed upon conductors, was strongly electrical when taken out after it was cold, but it exhibited no indications of electricity when it was cooled upon electric substances. When melted in vessels of glass, the sulphur acquired a strong electricity, whether the vessels were placed upon glass vessels or not; but it was always stronger when they were not placed on electrics, and strongest of all when the glass vessel had a metallic coating. The electricity of the glass was, in these cases, constantly positive, and that of the sulphur negative; and, what was very singular, the electricity of the sulphur did not develop itself till it began to cool and contract, and reached its maximum at the point of greatest contraction. The electricity of the glass was then the least, and was strongest of all when the sulphur was shaken out of it, before its contraction commenced. Melted sealing-wax he also found to acquire negative electricity when poured into glass, and positive electricity when poured into sulphur. Sealing-wax poured into baked wood was negative, and the wood positive. Sulphur poured into wood became negative, but when poured into sulphur, or rough glass, it acquired no electricity. Mr Wilke's experiments on the friction of bodies are also interesting. When sulphur and glass were rubbed together, the glass was strongly positive, and the sulphur strongly negative. Wood excited with cloth was always negative. Wood rubbed against smooth glass is negative, but positive when rubbed against rough glass. Sulphur exhibited positive electricity only in the case when it was rubbed against metals. Lead, however, formed an exception; for sulphur became negative when rubbed against it, and the metal itself positive; from which Wilke concludes, that lead is not such a good conductor as the other metals. In the following catalogue given by Mr Wilke, the substances are arranged in the order in which they are disposed to acquire positive or negative electricity, any one of the bodies acquiring positive electricity when rubbed by any that follow it in the catalogue, and a negative electricity when rubbed with any that go before it:

|--------------|--------|-------|--------------|-------------|----------|--------|------------|--------|-------|-------------|

Mr Wilke believed, that smooth glass gives in all cases a positive electricity; but Mr Canton had discovered that the smoothest glass may be negatively electrified when drawn over the back of a cat.

The experiments of Dr Franklin and Mr Canton on electric atmospheres, were verified and extended by Mr Wilke, who concluded, that parts of non-electrics immersed in electric atmospheres acquire an opposite electricity to that of the atmosphere itself. The subject of electric light received also considerable illustration from the labours of this ingenious electrician. When two pieces of glass were rubbed together, he noticed a vivid phosphoreal light, which threw out rays, but adhered to the place where it was produced, and emitted a strong phosphoreal smell. As it was accompanied with no attraction or repulsion, he concluded that friction was not able of itself to produce electricity, but that it was necessary to have the bodies of different kinds; and he

* See Franklin's Letters, and Phil. Trans. 1763, vol. III. p. 84.
considered the production of phosphoreal light without attraction, as the excitation of electricity without the accumulation of it. When a tube was excited with a woolen cloth, with white wax or oil upon it, it ejected flames, each of which seemed to issue from a little fiery protuberance. He found, that when sparks were produced between two balls, (except when both the balls were metallic,) the light formed a cone, the base of which was always on the body positively electrified, and the vertex on the one negatively electrified,—a criterion which he considers as sufficient for discriminating the two elec-
tricities. When a point not electrified is opposed to a positively electrified point, the luminous cones, which in other circumstances would have been seen upon both of them, are not in this case visible; but if a positive cone be opposed to a negative cone, they both retain their characteristic properties.

We come now to lay before our readers an account of the labours of Epinus, who may be considered as the first person who employed geometry and analysis in extending the science of electricity. He performed a series of experiments similar to those of Mr. Wilke, on melted sulphur. When the sulphur was poured into metallic cups and cooled, the cup and the sulphur together showed no signs of electricity till they were separated, when the electricity was very strong; the electrical effects always disappearing when the sulphur was put back into the cup, and re-appearing when the separation was repeated. The electricity of the cup was always negative, and that of the sulphur positive; but if either of the two had been deprived of its electricity when they were separate, they both exhibited, when united, the electricity which had not been taken away, and which was always on the surface of the sulphur. Upon pressing together two plates of looking-glass, one of them exhibited after separation a strong negative, and the other a strong positive electricity. When they were again joined, the electricity of both disappeared; but if one of them had its electricity taken off when separate, then the two, when reunited, had the electricity of the other plate. He made the same experiments with glass and sulphur, with several other electrics, and with an electric and a piece of metal. Epinus and Wilke happening to be resident at the same time at Berlin, pursued in company their experiments on electric atmospheres, and were led to the discovery of a beautiful method of charging a plate of air, in the same manner as the charge had been communicated to plates of glass. Having found that the negative state of one of the bodies depended on the opposite state of the other, which was precisely the case with a charged pane of glass, they therefore tried to give an electric shock by means of air, which they effected, by suspending large wooden boards coated with tin, having their flat surfaces parallel, and some inches distant. When one of the boards was electrified positively, the other possessed a negative electricity, and when a person touched one of the plates with one hand, and the other plate with his other hand, he received a shock exactly as in the Leyden jar. The opposite electrics of the two boards occasioned a strong attraction, which it was necessary to counteract by means of strings, which prevented the approach of the boards. Sometimes the electricity of both the boards was discharged by a strong spark between them, in the same manner as when a pane of glass bursts with an overcharge. A shock was experienced when the discharge was effected by the intervention of the finger, and when there was any eminence on either of the plates, the spontaneous discharge always passed through it, and a pointed body fixed at this place, prevented the boards from being charged. Wilke and Epinus considered the two boards as representing the earth and the clouds electrified in an opposite manner, and the phenomenon of lightning as the bursting of the plate of air by a spontaneous discharge, which is always made through eminences. M. Epinus performed also some interesting experiments on the tourmalin, which he published in the Memoirs of the Academy of Berlin for 1756.

Notwithstanding the value of these experiments, the greatest service which Epinus did to electricity, was in connecting together all the scattered phenomena by an ingenious and plausible theory, of which he has given a full account in his Tentamen Theseei Electriatitus et Magnetismi; published at St Petersburg in 1759. This theory is founded on the following simple principles: 1. That the molecules of the electric fluid mutually repel each other, even at considerable distances, and with a force decreasing as the distance increases. 2. The particles of the electric fluid attract the particles of all known bodies, and are attracted by them in their turn, with a force following the same law. 3. The electric fluid exists in the pores of bodies, moving without any perceptible obstruction in non-electrics, such as the metals, water, &c. but with extreme difficulty in the pores of electrics, such as glass, rosin, &c. 4. The phenomena of electricity arise from two causes, 1st, From the transference of the fluid from a body containing more, to another containing less of it; and, 2d, From its attraction and repulsion, where no transference takes place. These simple principles are managed with great address, in explaining even the most singular phenomena of electricity, and enable us to predict, with the utmost exactness, the result of any proposed experiment.

The work of Epinus is, perhaps, too mathematical for ordinary readers, but it has been rendered accessible to those who have no mathematical knowledge, by the labours of the Abbé Hauy, in his work entitled Exposition raisonnée de la Theorie de l’Electricité et du Magnétisme après les Principes de M. Epinus. Paris, 1787, 8vo.

The labours of our countryman, Dr Priestley, were not confined to the composition of his labours on the history of electricity, which appeared in the year 1767, and which contains a full and instructive account of all the discoveries in electricity which had been made either in Europe or America. At the end of this work, he has given us an account of a number of original experiments, and he afterwards published several papers on electricity in the Transactions of the Royal Society. In attempting to ascertain the electrical qualities of mephitic air, Dr Priestley was led to make experiments on charcoal, as it was from that substance that he procured the gas in the greatest quantity. He found that charcoal, whatever was its state with regard to heat or cold, was nearly as good a conductor of electricity as the metals; a result which overturned the established notion, that all other bodies but water and the metals are non-conductors. Different pieces of wood charcoal had different degrees of conducting power; but the most per-
ELECTRICITY.

Dr. Priestley observed a great variety in the electrical properties of different pieces of pit charcoal; but he had not ascertained the circumstances in the mode of preparing it, from which this variety was produced. Dr. Priestley likewise found that common coal cinders from an open fire were little inferior to charcoal in their conducting power. This discovery, says a celebrated chemist, "is a curious and unexpected analogy between the metals and charcoal; and chemistry furnishes us with several other no less striking and important. When the conducting power of charcoal was tried by succeeding electricians, it was found to vary in the most unaccustomed manner, sometimes scarcely conducting at all, sometimes imperfectly, and sometimes remarkably well. This diversity indicates a difference in the nature of different specimens of charcoal. Hence we may be assured that charcoal is a compound, and that it often varies in the proportion of some one or other of its ingredients." Dr. Priestley also found that there was a current of air from the points of bodies electrified plus or minus; that hot glass is a conductor; that electricity is easily diffused over the surfaces of new glass tubes, and therefore that the first coat of new glass is in some measure a conductor of electricity, but that after six or seven months these tubes lose this faculty, and are as easily excited as older tubes; and that the metallic tinge was much better communicated to the new than to the old glass, twice the quantity of metal being in all cases struck into it, a result which Dr. Priestley ascribes to the greater magnitude of its pores. Dr. Priestley found also that coloured circular spots are produced upon metallic plates, which receive an electrical shock from a strong battery. The most beautiful appearance of this kind, was one which he made upon a gold watchcase. The central spot was generally formed of shining dots, and the external circle consisted of cavities resembling those of the moon as they appear through a telescope; but in the spot upon the gold case there appeared, in several places of it, hollow bubbles of the metal. The cavities were deeper in some metals than in others, and he thought that the following was the order, beginning with those in which they were deepest, tin, lead, brass, gold, steel, iron, bismuth, zinc, copper, silver. Dr. Priestley likewise observed, that when an electrical battery is discharged, light bodies placed near the electrical circuit are put in motion, an effect which he ascribes to the sudden elasticity given to the air. He found that a long circuit conducts worse than a short circuit, even when the conductors are the same; and that when the circuit contains an imperfect conductor, a shock passes to bodies near, and yet no electricity is communicated.

The late Mr. Cavendish, whose genius has extended so many branches of physics, was likewise a successful cultivator of electricity. He conceived and executed the design of explaining all the phenomena of electricity by a simple theory, and his paper was actually drawn up and ready for the Royal Society, when he was made acquainted with the theory of Aepinus, of which, though published ten years before, he had never received the slightest notice. The theory of Cavendish may be considered as absolutely the same with that of Aepinus, though it is more accurate and more extended. "Since I wrote the following paper," says Mr. Cavendish, "I found that this way of accounting for the phenomena of electricity is not new. Aepinus, in his Tentamen Theoriae, &c. has made use of the same, or nearly of the same, hypothesis that I have; and the conclusions he draws from it agree nearly with mine, as far as he goes. However, as I have carried the theory much farther than he has done, and have considered the subject in a different, and, I flatter myself, in a more accurate manner, I hope the Society will not think this paper unworthy of their acceptance." In this paper, Mr. Cavendish lays down the hypothesis, and examines by as strict mathematical reasoning as the subject will admit, the various consequences that flow from the hypothesis, and then he compares it with the various experiments that have been made on the subject. Mr. Cavendish informs us, that he proposed soon to publish the results of some experiments in which he had been engaged for the purpose of trying the truth of his hypothesis, and of discovering the law of electric attraction and repulsion.

Notwithstanding the immense interval which elapsed between the publication of Aepinus' theory and the appearance of Mr. Cavendish's paper, yet no person can doubt that the latter is entitled to the credit of a second discoverer. Among his countrymen, at least, he is fully entitled to this honour; and if foreigners, who were less acquainted with the integrity of his character, should hesitate in conferring this secondary honour, we should at least have expected some acknowledgment of his labour, and some portion of praise for having improved and extended the theory of the Russian philosopher. We were therefore not a little surprised to find, that the name of Cavendish never once appears in the exposition of Aepinus' theory by the Abbe Hany, published sixteen years after the appearance of Cavendish's paper, nor in the extract from the Register of the Academy of Sciences, in which Laplace, Cousin, and Legendre, have given an account of the Abbe's work.

The extraordinary shocks given by the torpedo having been found by Mr. Walsh to be purely electrical, Mr. Cavendish began a series of experiments, with the view of obtaining an explanation of these singular effects. As the shock of the fish was given under water, and was incapable of being transmitted through water, of producing electric light, or of affecting an electrometer, the difficulty of obtaining a proper explanation seemed to be very great. He constructed an artificial torpedo made of wood, connected with glass tubes and wires, and covered with a piece of sheep's skin leather, and found in numerous experiments, that the effects of this apparatus agreed very well with those of the natural torpedo. See p. 476.

Mr. Cavendish likewise discovered, that iron wire conducts about 400,000,000 times better than rain or distilled water, or in other words, the electric fluid experiences no more resistance in passing through a piece of iron wire 400,000,000 inches long than through a column of water of the same diameter only one inch long. He also found that sea-water, or a solution of one part of salt in one of water, conducts 100 times better than fresh water, and a saturated solution of seawater 720 times better than fresh water. The former

* Dr. Thomson's History of the Royal Society, p. 44.
† See Phil. Trans. 1775, vol. 131: p. 461.
The science of electricity was now destined to receive the most brilliant accessions from the genius of M. Coulomb, to whom many of the physical sciences owe the deepest obligations. By means of an ingenious instrument invented by himself, called a torsion balance, Coulomb was enabled to measure small forces with a degree of accuracy hitherto unknown in physics. In order to avail himself of this contrivance, he investigated, both theoretically and experimentally, the laws of the force of torsion, (or the force with which a body untwists itself,) relative to the length, the thickness, and the nature of the metallic wires which he employed, and he has applied these laws with the utmost address, and in the most successful manner, to the most delicate researches in electricity, magnetism, and hydrodynamics. In the theories of Epicurus and Cavendish, the action of the electric fluid, in producing attraction or repulsion, was considered merely as diminishing with the distance; and in consequence of the law being undetermined, several problems received only an approximate solution. By the contrivance however already mentioned, of which we shall give a minute account in another part of this article, M. Coulomb discovered that the electrical force was, like that of gravity, in the inverse ratio of the squares of the distances; a conclusion the more interesting, as Newton and other natural philosophers had believed that the electrical and magnetic forces followed the inverse ratio of the cube, or even some higher power of the distance. The experiments from which this result was obtained, he varied in different ways, and always found them conformable to the preceding law; and in another memoir, he has explained different means by which he had obtained a similar result. The labours of Coulomb, however, were not confined to the determination of the law of electrical action; he found that the momentary dissipation into the air of moderate degrees of electricity, is proportional to the degree of electricity at the time; that the dissipation is not sensibly changed by any variation in the temperature or weight of the air; and that when the electricity was very weak, there was no perceptible difference in bodies of different kinds, or differing in shape or magnitude. The dissipation, however, was greatly affected by the hygrometrical state of the atmosphere, and was very nearly as the cube of the moisture of the air. M. Coulomb likewise examined the dissipation which took place along imperfect insulators, in which case the electricity seems to be conveyed along the surface of the insulator chiefly by the moisture which adheres to it, and obtained the following results: 1. The densities in different points of an imperfect insulator are in the subduplicate ratio of their distance from the point of complete insulation. 2. The lengths of canal requisite to insulate electricity of different densities, is in the duplicate ratio of the densities. And, 3. The length of canal necessary for insulation, is in the inverse ratio of the coercive or insulating force of the canal. M. Coulomb likewise found, that the most perfect of all insulators is a thread of gum lac, which, measuring its excellence by its shortness, insulates ten times better than a silk thread as dry as possible. When the silk thread was covered with fine sealing-wax, it had the same power of insulation as gum lac, when it was four times as long. The dissipation along these insulating bodies is not wholly owing to moisture, but to a small degree of conducting power.

The next object of M. Coulomb was to ascertain the distribution of the electric fluid in an overcharged body. He found, that if we bring an electrified conducting body into contact with another in its natural state, the electricity conveyed to the latter will depend solely on the shape of the two bodies, and in no respect upon the nature of the body itself; and that the fluid diffuses itself along the surface without penetrating the body. This result Coulomb at first obtained for bodies similar in form, and equal in surface; but he afterwards extended his enquiries to spherical bodies having surfaces of different magnitudes; and the general result was, that when the surfaces of the unequal spheres were as the numbers 1, 4, 16, 64, \(^{\infty}\), the density on the small globe was as the numbers 1, 1.08, 1.3, 1.65, 2, but never obtained the magnitude 2. The density of the fluid on different parts of the surface of two equal spheres in contact, he found to be as the numbers 0.1, 4, 5, 6, at the angles 6°, 90°, 60°, 90°, 180°, being almost uniform from 90° to 180°. M. Coulomb has likewise determined the mode in which the electric fluid is distributed among globes placed in a row, and between different points of the surface of a cylinder. In all his calculations, he has employed the hypothesis of the electric fluid being composed of two fluids, which are neutralized in the ordinary state of bodies, and disengaged when the body exhibits signs of electricity. The particles of each fluid mutually repel each other, and attract those of the other fluid. These two fluids have been called the fluid of \(\text{vitreus}\), and the fluid of \(\text{resinous}\) electricity.

There are few philosophers of the present day to discover whose electricity owes so much as M. Volta, professor of natural philosophy, at Como, in Italy. He invented an elegant instrument for collecting electricity, called an electrophorus, \(\dagger\) the first hint of which is said to have been given by Epicurus; and another instrument, called a condenser, the object of which is to accumulate and render visible the smallest quantities of natural or artificial electricity. The Galvanic discoveries of Volta have raised him to a high rank among the discoverers of the present day; and under the article \text{Galvanism} we shall have frequent occasion to follow him in his career of discovery.

In the year 1781, MM. La Place, Lavoisier, and Experiments of La Place and Lavoisier.

\(\dagger\) The name of electrophorus was given to this instrument from its retaining or carrying its electric virtue for a long time. See p. 515.

\(\dagger\) See Part 1, Chap. 1, Sect. 29, pp. 441, 480, 481.
ELECTRICITY.

The general result of these experiments was, that the mutual repulsion of two spheres, electrified either positively or negatively, varied in \( \frac{1}{d^2} \), or was nearly as the inverse ratio of the square of the distance. When the experiment was made on the attractive force of balls oppositely electrified, the irregularities were greater than in the preceding case, amounting, in some instances, to \( \frac{1}{4} \)th of the whole force. The results, however, deviated rather less than the former, from the inverse duplicate ratio of the distances; but the deviation was in defect, as the other was in excess. From these results, Dr. Robison concluded, that the action between two spheres was like that of gravity, in the inverse ratio of the squares of the distances of their centres. It is much to be regretted, that Dr. Robison did not publish some account of these conclusions at the time when he obtained them. He would then have been entitled to a considerable share of that honour which has been bestowed on Coulomb. See page 440.

Towards the end of the 17th century, electricity was assiduously cultivated by a great number of eminent individuals, who extended the boundaries of the science by numerous experiments, and by the invention of ingenious and useful instruments.

By the aid of an admirable electrifying machine, and powerful batteries, M. Van Marum performed a series of interesting experiments on the fusion and the oxidation of metals by the electric shock. He obtained some curious results respecting the magnetic effects of electricity; and he made numerous experiments to ascertain the influence of the electric fluid upon animal and vegetable bodies.

The late Mr. Cavallo made many important additions to the science. His experiments with electrical kites, and thunder rods, added greatly to our knowledge of atmospheric electricity; and his instruments for measuring, doubling, condensing, and multiplying electricity, bespeak a mind full of ingenuity, and intimately acquainted with the science which he cultivated.

Mr. Nicholson made several curious experiments on the form of the electric spark, and on the excitation of electrical machines; and he enriched the science with two elegant instruments, which he called the spinning condenser, and the revolving doubler.

Electricity has derived new light from the labours of Hauy. That venerable philosopher M. Hauy, who has discovered, that the property of becoming electrical by heat, resides in mesityle, boracite, calamite, and prehnite, as well as in the tourmaline and the topaz. He found, that the boracite possessed eight electrical poles; and we owe to him the fine discovery, that the polarity which those minerals acquire from heat, is related to the secondary form of their crystals, those which have this property, deviating from that symmetry of form which is conspicuous in other minerals.

Mr. Cuthbertson had the great merit of giving a new degree of elegance and power to the electrical apparatus. His improvements on the plate glass machine; his mode of constructing and improving batteries; his new condenser, and his compound electrometer; entitle him to be considered as one of the most ingenious practical electricians of the present day. Along with Van Troschlywijk, he was the first that decomposed water by the electric shock; and he made many interesting experiments on the fusion and oxidation of metals by electricity.

Mr. Brooke was the first person who proposed the Brooke balance electrometer, and from numerous experiments
History.

on the fusion of metals by batteries, he was enabled to determine the law which was followed in the melting of metallic wires.

Bennet, Mr. Bennet, by his experiments, as well as by his invention of the gold leaf electrometer, and the doubler; Mr Read, by his experiments on atmospheric electricity; Mr Morgan, by his various researches; and Mr Henley, by his inventions and experiments, contributed greatly to the advancement of the science.

The conclusion of the 18th century was marked by an electrical discovery, which excited the most general attention. In 1790, M. Galvani, professor of anatomy at Bologna, discovered that muscular contraction could be excited in a frog recently killed, either by transmitting through the nerve a small quantity of artificial or atmospheric electricity, or by the mere contact of two different metals. This singular experiment was every where repeated and varied, and, during the discussions to which it gave rise, professor Volta of Como was led to the invention of the Voltaic or Galvanic battery; an instrument of enormous electrical power, which has led to the creation of a new science, and given rise to the most brilliant discoveries in chemistry. In our article Galvanism, we shall have occasion to give a full account of these splendid discoveries, and to review the labours of Volta, Sir H. Davy, Dr Wollaston, Biot, Thenard, Humboldt, Dr Robison, Dr Monro, Dr Henry, Dr Bostock, Messrs Nicholson and Carlisle, Mr Cruikshanks, Mr Sylvester, Mr Children, Mr Ritter, De Lue, Paafi, Van Marum, Simon, Wilkinson, Hisengen, Berzelius, Oersted, Erman and Brande.

The science of electricity seemed for a while to be completely abandoned, and the attention of philosophers wholly engrossed by the new science which had been established. The 19th century, however, commenced under circumstances very favourable to the science.

La Place.

The celebrated Count La Place, the Newton of the present age, investigated the manner in which electricity was distributed on the surface of ellipsoids of revolution. Coulomb had considered only the case of a conductor perfectly spherical; but La Place has shown, from an elegant application of the formulæ which he used in his researches on the figure of the earth, that the electricity will be distributed over the surfaces of all ellipsoids of revolution, and that the thickness of the coat of fluid at the pole will be to its thickness at the equator, as the equatorial to the polar diameter.

In this investigation, La Place was followed by M. Biot, a mathematician and natural philosopher of distinguished eminence, whose labours and discoveries we shall have frequent opportunities of reviewing in other parts of our work. He extended the results obtained by La Place to spheroids, differing but little from a sphere, whatever be the irregularity of their figure; and he found that the quantities of fluid carried off by discharging a glass plate by successive contacts, form a geometrical progression.

Our countryman Dr Wollaston had the merit of being the first who decomposed water by a simple current of sparks from an electrified conductor; and the arrangement by which this was effected, is marked by that ingenuity and beautiful simplicity which is characteristic of the labours of that eminent philosopher.

The science of electricity was now destined to receive the most brilliant ascensions from the application of the higher analysis. M. Poisson, a young mathematician of rare talents, and well known by his discoveries in the higher branches of astronomy, adopting the hypothesis of two fluids, has determined analytically the manner in which electricity is distributed on the surface of two spheres of different diameters placed in contact, and the results which he has obtained coincide wonderfully with the experiments of Coulomb. He then applies the analysis to the case where the two fluids occur at the same time upon the surface of the same body; and in the case of two spheres whose radii are as 1 to 3, and the distance of whose nearest surfaces is equal to the radius of the smaller sphere, he has computed tables, showing the distribution of electricity at the different points of the two spheres, and the kinds of electricity which they possess. These results also agree with the experiments of Coulomb, so far as he has carried them, and appear to furnish a confirmation of the theory of two fluids. The case of two spheres leads to equations with variable differences, and with two independent variables, which, M. Poisson observes, is the first time that an equation of this kind has presented itself in the solution of a physical problem.

In another part of the present article, we have given as full an account as we were able of the researches of this eminent mathematician; but we trust, that in some other part of our work we shall find an opportunity of again calling the attention of our readers to this interesting subject.

ELECTRICITY.

Part I. Descriptive Electricity.

Descriptive Electricity, is that branch of the science which describes all the various phenomena which are either produced, or supposed to be produced, by the same cause as the phenomena of excited amber. It naturally divides itself into three heads: I. The phenomena of electricity produced by friction; II. The phenomena of electricity produced without friction; and III. The effects of electricity, comprehending its mechanical, chemical, and magnetic effects, and its influence upon animal and vegetable bodies.

CHAP. I.

On the Phenomena of Electricity produced by Friction.

As friction is the mean which has almost always been employed for the production of electrical phenomena, and as the various discoveries which have been made respecting the communication, the distribution, and the dissipation of the electric matter, have been made by electricity excited in this manner, we shall introduce into the present Chapter an account of these important results, although they are equally deducible when the electricity has been either excited by heat, or obtained from any other source.

Sect. I. On the Production of Electricity by Friction.

If we rub a piece of amber with dry fur, or woollen cloth, and then hold the amber over any light substances, such as small pieces of paper, or the down of a feather, the light body will be attracted by the amber. The same effect will be produced, by rubbing the glass of a watch against the sleeve of the coat; and still more powerfully, by rubbing a glass tube with a piece of dry silk. In this latter case, when the tube is rubbed in the dark, sparks of brilliant light, accompanied with a crackling sound, will be emitted as long as the friction is continued. In like manner, if a dry black silk ribbon, about two feet long, be laid upon a white one of the same length, and be drawn over woollen cloth, or silk velvet, or even between the finger and the thumb, they will be found to adhere strongly to each other. When separated, they will attract one another, and rush together with considerable velocity. In a dark room, the separation of the ribbons will be accompanied with a flash of light; and any one of the ribbons, when separated from the other, will attract light substances like the amber and the glass already mentioned.

Now in these three simple experiments, the amber, the glass, and the silk ribbons have obviously received new properties, which they did not possess before they were rubbed, viz. the property of attracting light bodies, and the property of emitting light in the dark. These properties are called electrical. The amber, the glass, and the ribbons, are said to be excited by friction. The power of drawing to themselves light bodies, is called electrical attraction, to distinguish it from the attractions of cohesion, of gravity, and of magnetism. The light emitted in the dark, is named the electric spark, or electric light; and the body which is capable of acquiring these properties, is called an electric.

By rubbing a great number of other bodies with woollen cloth, fur, silk, &c. they are found to exhibit the same properties as amber and glass; while another class of bodies exhibit no such properties, with whatever substances, and in whatever manner, they are rubbed. Hence bodies are divided into two great classes, viz. electrics, or those which acquire by friction the faculty of exhibiting electrical properties; and non-electrics, or those which are incapable of acquiring electrical properties by friction. The following is a list of electrics arranged in the order of their perfection, those being regarded as the most perfect which produce the most powerful electricity by the least friction.

Table of Electrics.

Glass, and all vitrifications, even those of metallic substances.

The precious stones, such as diamonds, garnets, rubies, topazes, emeralds, sapphires, the most transparent of which are generally the most perfect.

Amber.

Sulphur.

Shell lac, and all resinous bodies, and resinous compounds.

Bituminous substances.

Silk.

Wax.

Cotton.

Dry animal substances, as feathers, wool, hair.

Dry paper, parchment, and leather.

White sugar.

Sugar candy.

The vapour of quicksilver.

Perfect Toricellian vacuum.

Ice of distilled water, at the temperature of — 13° of Fahrenheit.

Oil.

 Metallic oxides.

 Ashes of animal and vegetable substances.

 Dry vegetable substances.

 Hard stones, the hardest of which are the best electrics.
The substances in the above list which are marked in italics are evidently such as cannot be excited by friction; but they are inserted in the table, from their possessing, like the other electrics, another property, which we shall soon have occasion to notice. All bodies not contained in the preceding enumeration, cannot be considered as non-electrics. Those only are properly entitled to that name, which have been found incapable of electrical excitation. A list of them will be introduced with more propriety under another head.

**SECT. II. On Positive and Negative Electricity.**

In whatever manner, and by whatever bodies, electricity is produced, its general effects are always the same. Electric attraction, and electric light, are both produced, whether we make the experiment with excited glass, or excited amber. The electrics, however, generated from these two substances, have different characters, which manifest themselves by an attentive examination of their effects. If two small balls, turned from the pitch of elder, are suspended by silver wires, or fine threads, as is represented in Plate CCXLIII. Fig. 1, they will remain in contact. But as soon as a tube of glass, excited by friction, is presented to them, the balls diverge, and separate from each other, as in the figure. The same divergence is produced, by presenting excited amber or wax to the pith balls. But if, when the pith balls are in a state of divergence by the application of excited glass, we present also a stick of excited wax, the electricity will disappear, and the balls will collapse. If, on the contrary, when the divergence of the balls has been produced by the application of excited wax, we present to them a tube of excited glass, the balls will collapse as before. If the excited wax, and the excited glass tube, are presented together to the pith balls, no divergence will take place. Here then we have an unequivocal indication of two different kinds of electricity, viz. that of the glass and of the sealing-wax, the one always counteracting the effect of the other. These two kinds of electricity were denominated the _vitreous_ and the _resinous_ electrics, from the bodies by which they were produced; but as it has since been found, that resinous electricity can be obtained by the excitation of glass, and vitreous electricity from the excitation of resinous bodies, the terms vitreous and resinous can no longer be admitted. The terms _positive_ and _negative_, or _plus_ and _minus_, have therefore been universally employed to denote the vitreous and resinous electrics.

The substitution of these new terms will appear still more appropriate, when we consider that, in every case, where a body is excited, both positive and negative electricity are simultaneously produced, and in almost every case can be rendered visible by the application of the pith balls. This truth admits of a very simple proof, by exciting sealing-wax with dry flannel, and applying them together and separately to the pith balls. When they are applied separately, the flannel will indicate a positive electricity, like a tube of glass excited with silk, while the wax will indicate negative electricity. When they are presented together to the pith balls, no effect whatever will take place, so that the positive electricity of the flannel is in equilibrium with, or equal in effect to, the negative electricity of the wax. In the same manner, when the black ribbon is separated from the white ribbon, after being excited in the manner already described, the black will be found negatively, and the white ribbon positively electrified.

But the positive and negative electrics are not only simultaneous phenomena;—any electric can be made to exhibit either of the electrics, according to the nature of the substance with which it is excited, or the state of the surface of the electric itself. This important discovery we owe to Mr Canton, who established it by numerous experiments. Polished glass, for example, is positively electrified when rubbed with flannel, but negatively electrified when rubbed with the back of a cat; while rough glass acquires positive electricity by the friction of dry oiled silk, and negative electricity by the friction of flannel.

The results of the numerous experiments which have been made on this subject, are contained in the following Table, altered and greatly enlarged from the Table drawn up by the late Mr Cavallo, from the experiments of various electricians.

---

* De Luc found, that when glass and caoutchouc were rubbed together, the electricity was on some days positive, and on other days negative. See *Nicholson's Journal*, vol. xxviii. p. 11.

† The effect of wax and resinous bodies is here given on the authority of Libes. Cavallo states, that they communicate negative electricity to rough glass.
ELECTRICITY

In the repetition of some of the preceding experiments, the minutest attention must be paid to the state of the bodies which are rubbed together, and to the manner in which the friction is applied. When a stick of sealing wax is rubbed with an iron chain, the electricity of the wax will be positive when its own surface is scratched, and negative when it is smooth. When a silk ribbon is drawn lengthwise over a part of another ribbon of the same length, the ribbon which has been rubbed along its whole length becomes positively and the other negatively electrified. In like manner, when the whole length of the bow of a violin is drawn over a limited part of the string, the hairs of the bow exhibit a positive, and the string a negative electricity, the body whose excited portion is of the least extent being generally negatively electrified. Some other examples of a similar kind have been given in our historical account of the experiments of Cigna.

In exciting metals with woollen cloth, similar anomalies have been observed by Haüy: the same piece of metal, even when placed in similar circumstances, sometimes acquiring positive and sometimes negative electricity. M. De Luc has observed a similar irregularity in the friction of glass and caoutchouc. This anomaly, however, is seen in a most beautiful manner in the mineral commonly called cyanite, which was first described by the younger Saussure, under the name of apparc. Some of the crystals of this mineral acquire positive electricity by friction, while others acquire negative electricity; and in some of them the one species of electricity is found on one face, and the opposite species on the other face, although neither the eye nor the touch could discover any difference either in the lustre or the polish of the two faces. From this property Haüy has called the mineral diathene, which signifies having two virtues.

The effect of minute circumstances in the simultaneous production of positive and negative electricity, is excellently illustrated by the experiments of Mr Cavallo, on the electricity of glass tubes containing mercury, and hermetically sealed. These tubes were about 31 inches long, less than half an inch in diameter, and half an inch thick. Having put about three-fourths of an ounce of mercury into the tube, he boiled it, and, when the air was rarefied, the tube was hermetically sealed. After cleaning and warming the tube, he brought it into a horizontal position, and excited it by the friction of the mercury, which took place in elevating and depressing either end alternately. When the tube after this kind of excitation was brought into a vertical position, the end containing the mercury was electrified positively, and all the rest of the tube negatively. When the positive end was raised, the mercury flowed to the negative end, but the end where the mercury now stood acquired a positive electricity, and the rest of the tube a negative one. When the positive end where the mercury first stood, was elevated without touching it with the hand, it exhibited only a very slight degree of negative electricity; and if the mercury was made to flow back to it, and again retire from it, its electricity was positive, while by elevating it with the finger it always became strongly negative.

Sect. III. On the Communication of Electricity.

In the few simple experiments of which we have given an account, the reader must already have seen, munition that electricity is capable of being communicated to other bodies. The pith balls obviously diverge, in consequence of the electricity which they receive from the excited glass or resin, and retain it for a considerable time. If we touch any of the pith balls, when in a state of divergence, with a piece of glass free from moisture, or with a dry stick of sealing-wax or sulphur, the di-
Electricity.

The emergency will still continue. The electricity, therefore, possessed by the balls, is not capable of being carried off by passing through these bodies. Glass, sealing-wax, and sulphur, are hence called non-conductors of electricity, as they do not possess the power of transmitting the electric matter. If, on the contrary, we touch any of the pith balls with a piece of any metal, with the finger, or with any body containing moisture, the pith balls will instantly lose their electricity, and collapse. The electricity, consequently, which occasioned their divergence, has escaped, or been carried off by those bodies, and hence they have received the name of conductors. Between these two classes of substances, there are others which do transmit the electric fluid, but with less facility than those which are called conductors, and therefore they have been distinguished by the name of imperfect conductors. Substances called non-conductors, have also received the name of electrics, and sometimes insulators, from their having the property of insulating bodies, or forming a barrier, which prevents the communication of the electricity of the insulated body to those which surround it. The following Table contains all the substances which have the property of conducting electricity, arranged in the order of their conducting power. We have followed the order assigned to them by Mr Singer.

**List of Conductors.**

- All the metals.
- Charcoal well burnt.
- Plumbago.
- Concentrated acids.
- Charcoal in powder.
- Diluted acids.
- Saline fluids.
- Metallic ores.
- Animal fluids.
- Sea water.
- Spring water.
- River water.
- Ice above —13° of Fahrenheit.
- Snow.
- Living vegetables.
- Living animals.
- Flame.
- Smoke.
- Steam.
- Most saline substances.
- Rarefied air.
- Vapour of alcohol.
- Vapour of ether.
- Most earths.
- Most stones.

To these, we may add powdered glass and powdered sulphur, which have been found to be conductors by the experiments of Van Swinden.

**Remarks on the table.**

Several of the bodies in the preceding table lose their power of conducting electricity when they are made very dry, and therefore they owe their conducting power solely to the moisture, or the fluids which they contain: hence vegetables and living animals, for example, conduct electricity solely in virtue of the juices and fluids which they contain. The conducting power varies also with the temperature. Hot charcoal and hot water transmit electricity with more facility than when they are cold; and glass, which is a perfect non-conductor when cold and dry, becomes a tolerably good conductor when heated to redness; and the same change takes place upon resinous bodies when melted, and upon baked wood when heated. Air, however, does not conduct electricity, whatever be its temperature.

Although flame is here enumerated in the list of conductors, yet it has been shown by M. Erman, that the insulated flames of wax, oil, alcohol, and hydrogenc gas, only conduct positive electricity; while other substances, such as phosphorus, conduct only negative electricity. Mr Cuthbertson had observed, (Practical Electricity, p. 48.) that when the flame of a common candle was placed midway between two equal balls, one positively and the other negatively electrified, the flame was attracted to the negative ball, which became very hot, while the positive ball remained cold.

Mr Brande* has endeavoured to explain these phenomena in another manner. As some chemical bodies are naturally negative, and others positive, he supposes Mr Brande that the positive will be attracted by the negative ball, and the negative by the positive ball; and in order to ascertain the probability of this conjecture, he placed the flames of various bodies between two insulated brass balls, one of which was electrified positively, and the other negatively. By this apparatus he obtained the following very interesting results:

**Substances attracted to the Positive Ball.**

- Sulphurous acid vapour.
- A small flame of phosphuretted hydrogen slightly.†
- Fumes of white arsenic slightly.
- Large flame of carbonic oxide.
- Vapour of burnt sulphur.‡
- Flame of phosphorus.
- Vapour of phosphorus.
- Stream of muriatic acid.
- Stream of nitrous gas.
- Vapour of benzoic acid.

**Substances attracted to the Negative Ball.**

- Olefiant gas.
- Sulphuretted hydrogen slightly.
- Arsenicated hydrogen.
- Flame of hydrogen weakly.
- Sulphuret of carbon.
- Potassium in combustion, and its fumes.
- Flame of benzoin.
- Smoke of benzoin.
- Charcoal emitted by camphor in combustion.
- Resinous bodies exhibit the same phenomena as camphor.
- Amber exhibits the same phenomena as benzoin.

Dr Priestley found the conducting power of charcoal to vary very much in different pieces of that substance; and it has since been found, that this variation arises from, and is proportional to, the different degrees of heat that have been employed in making it.

The conducting property of ice was first discovered by M. Jallabert, and confirmed by Dr Priestley. M. Achard of Berlin, however, observed, in January 1776, that ice, at the temperature of 13° of Fahrenheit, lost

---

*See Philosophical Transactions, 1814, Part I.
† A large flame of this substance was equally attracted by both balls.
‡ The direction of the flame could not be determined.
its conducting power, and became an electric. Above this temperature, the ice begins to conduct. This faculty increases with the temperature, and becomes very great near the boiling point. M. Achard employed, in his experiments, ice perfectly transparent, and free from air-bubbles. To obtain this, he poured distilled water into a vessel, and placed it, in frosty weather; on the window of a room tolerably warm, when compared with the external air. Hence the water froze on one side when it was fluid on the other; and the air, as it was extricated, passed into the fluid part, and thus left the ice perfectly transparent, and free from air-bubbles. He then formed the ice into a spheroid, and, by rubbing it when in motion about its axis, he was able to produce electricity in large quantities. The following Table contains a list of bodies that are non-conductors, arranged in the order of the resistance which they oppose to the passage of the electric fluid.

**List of Non-conductors.**

**Shell lac.**
**Amber.**
**Resins.**
**Sulphur.**
**Wax.**
**Jet.**
**Glass.**
**Vitrifications of all kinds.**
**Talc.**
**Diamond.**
**Transparent gems.**
**Raw silk.**
**Bleached silk.**
**Dyed silk.**
**Wool.**
**Hair.**
**Feathers.**
**Dry paper.**
**Parchment.**
**Leather.**
**Air.**
**All dry gases.**
**Baked wood.**
**Dry vegetable bodies.**
**Porcelain.**
**Dry marble.**
**Some siliceous stones.**
**Some argillaceous stones.**
**Camphor.**
**Caoutchouc.**
**Lyceopodium.**
**Native carbonate of barytes.**
**Dry chalk.**
**Lime.**
**Phosphorus.**
**Ice at 
\[\text{\degree} \text{Fahrenheit}.\]**
**Many transparent crystals when perfectly dry.**
**Ashes of animal bodies.**
**Ashes of vegetable bodies.**
**Oils, the heaviest being the best.**
**Dry metallic oxides.**

The remarkable property possessed by shell lac of transmitting the electric fluid with more difficulty than any other body, was discovered by M. Coulomb, and has already been noticed in our History of Electricity. When any of the substances in the preceding Table receive the least accession of moisture, their non-conducting power is diminished in proportion to the quantity of moisture which they have absorbed.

The slightest examination of the Table is sufficient to convince us, that there is no relation between any of the chemical and physical properties of the bodies which it contains, and their power of resisting the passage of the electric fluid. The early electricians imagined that metals and waters were the great conducting principles; but this property is obviously possessed by bodies which, so far as we know, contain neither of these ingredients.

In our History of Electricity, p. 416, we have already given some details respecting the length to which electricity has been conducted along metallic wires, and the rapidity of its motion. These details are sufficient to show, that no measurable interval of time elapses during the passage of the electric fluid along a space of four miles.

Mr. Singers, however, has expressed a doubt respecting the accuracy of these experiments. "They were made," says he, "at a very early period, and have not, I believe, been repeated since the improved state of the science has afforded the means of effecting such experiments with precision. Metals, although the most perfect conductors we have, oppose some resistance to the motion of electricity, and a charge will even prefer a short passage through air to a circuit of 20 or 30 feet through thin wire. It is therefore rather uncertain that the charge of a small phial has ever passed through an interval of four miles." Elements of Electricity, p. 142.

The subject of electric atmospheres belongs properly to the present Section. The term atmosphere is here employed to denote the space round any electrical body through which its electrical influence extends. Mr. Canton was the first electrician who examined this curious subject, and he found that all bodies immersed in the electric atmosphere of a positively electrified body, were negatively electrified; while those which were placed in the atmosphere of a negatively electrified body attained positive electricity. This may be proved by the very simple experiment of holding a pair of pith balls at some distance from an excited glass tube, and they will be found to diverge with negative electricity. In like manner, they will diverge with positive electricity when placed within the sphere of action of a stick of excited sealing-wax negatively electrified.

**Sect. IV. On Electrical Attraction and Repulsion.**

The attraction exhibited by electrified bodies was one of the first phenomena that was observed by philosophers; and we have already had occasion to notice an example of repulsion, in the divergency of two pith balls. These simple phenomena may be perceived with sufficient distinctness, by employing merely a tube of glass excited by a piece of silk; but, in order to exhibit the more interesting phenomena, of the approach and recession of light substances to an electrified body, we must be able to produce a higher degree of electricity than can be effected by a simple tube.

In order to obtain this, a cylinder of glass is mounted in a frame, so that it can be turned rapidly round its axis by means of a winch or handle. On one side of it is placed a small cushion covered with silk, against which the glass cylinder is rubbed during its rotary motion; and on the other side a brass or metal tube, resting upon a stand of glass, for the purpose of collect-
ELECTRICITY.

The electricity generated during the excitation of the cylinder. This apparatus is called an Electrical Machine, and the metallic tube is called the Prime Conductor. Several of these machines, fitted up in various ways, are represented in one of our Plates, of which we shall afterwards give a very particular description; but it is enough for our present purpose to know, that a very high degree of electricity can be excited by the simple apparatus which has been mentioned.

Exp. 1. If, upon a tube of glass highly excited by a piece of silk, or by the human hand, we let fall any light substance, such as a piece of gold leaf or thin paper, the substance will be attracted to the tube, and then quickly repelled from it. If the tube is made to follow the body, it will still escape from it, till it meets with some other substance which is a conductor, and is not electrified. To this conductor it will impart all its electricity, and being again attracted by the tube, will experience another repulsion as before. This experiment was first made by Otto Guericke.

Exp. 2. Having electrified the prime conductor of the electrical machine by exciting the glass cylinder, bring near to the conductor a pitch ball, or a small feather suspended by a slender wire, the ball will be attracted by the conductor, and will continue to adhere to it till the electricity of the conductor is dissipated.

Exp. 3. If the ball or feather used in the preceding experiment is suspended by a silk thread instead of the metallic wire, it will at first be attracted by the conductor, and then immediately repelled, and will not return to it again till it has imparted its electricity to some conducting body.

Exp. 4. Take a number of threads, from 10 to 18, and about a foot long, and, having tied them together at both ends, suspend them by the upper knot to the conductor of the machine. As soon as the threads are electrified, the lower knot will rise, and they will swell out in the middle, and assume a spherical form. This experiment was first made by Mr. Wheeler.

Exp. 5. Suspend a metallic plate, or a wooden plate covered with tinfoil, either from the conductor of the machine, or from a separate stand connected by a chain with the conductor; and at the distance of three or four inches below a similar plate on a stand connected with the ground. Put some pieces of gold leaf or thin paper between these plates, and when the conductor is electrified, they will be attracted and repelled alternately by the two plates, and will continue their motion as long as the electricity remains in the conductor.

This experiment is rendered doubly interesting, by using small painted figures cut out of paper. These figures will dance upon the lower plate as if they were really animated, and will exhibit a number of attitudes of the most singular kind.

This experiment is excellently represented in Plate CCXLIII. Fig. 2, where every part of the apparatus is distinctly seen as to require no description.

Exp. 6. Place two small balls on separate glass pillars, three-fourths of an inch distant, so that the balls are insulated. Suspend by a silk thread a clapper, or small brass ball, so as to hang in the middle between the balls. One of the balls being made to communicate by a conducting substance with the conductor of the machine, and the other with the ground, the small ball of brass will oscillate between the two balls, striking them alternately, and producing an electrical chime.

This experiment is still more interesting, if we hang three balls upon a horizontal rod of brass communicating with the prime conductor. The two outermost balls must be suspended by metallic wires or strings, and the middle one by a silk thread, so as not to communicate with the rod, but to have a communication with the ground or table, by means of a chain going from the inside of the bell. A clapper or brass ball is suspended by silk strings upon the same horizontal rod, and between each of the two balls. As soon as the conductor is electrified, the brass balls will alternately be attracted and repelled by the adjacent balls, and by striking against them, they will produce a chime by no means disagreeable.

This experiment is distinctly represented in Fig. 3. Plate CCXLIII. A still more interesting variation of CCXLIII. The experiment is represented in Fig. 4, where a b is a rod of solid glass, supported upon a wooden stand, and passing through a perforated ball, No. 5. The other end of the glass rod supports two metallic arms crossing each other at right angles, having suspended at their extremities, by means of wires, four balls, 1, 2, 3, 4. From a point of each of these arms, equidistant from the extremity and the point of intersection, is suspended a brass ball by silk threads. Upon electrifying the conductor, all the five balls will set a ringing at the same time.

Exp. 7. Place upon the prime conductor a pointed wire, and by means of it electrify the inside of a very dry glass tumblers or jar. Place several pitch balls on the table, and cover them by the glass thus electrified. They will immediately begin to leap up and down against the sides of the vessel, and will thus be alternately attracted by it and the table for a considerable time.

Exp. 8. Suspend from the prime conductor a circular ring of brass or any other metal, about a foot in diameter, so that the ring is in a horizontal position. Place below the ring a circular plate of metal of a larger diameter than the ring, upon a stand like that represented in Fig. 2, so that it can be placed at different distances from the ring. Take a very small hollow ball of glass, blown extremely thin, and about two inches in diameter, and having brought the surface of the metallic plate to a distance from the ring less than its diameter, place the ball within the ring, and upon the plate, and as soon as the ring is electrified it will attract the ball, which will be animated at the same time with a rotary motion, and a circular motion of translation. If the experiment be made in the dark, the ball will appear luminous at all the points where it successively touches the ring.

Exp. 9. If the circular ring, in the preceding experiment, is insulated, and stands about an inch and a half from the flat surface of a table, and if a ball of glass, about two inches in diameter, is placed upon the table, and within the ring, it will first be attracted towards the ring, and after touching the ring and becoming electrified at the point of contact, this point will recede and be attracted by the table, while the ring attracts another part of the ball. Hence the ball will revolve about its axis, and move round the circumference of the ring.

Exp. 10. Fix a piece of sealing-wax at the end of a wire, and insert it into one of the holes of the prime conductor. When the sealing wax is softened by heat, turn the cylinder, and fine waxen fibres will be separated from the wax, and if received on a sheet of paper, will cover it with threads like red wool. By receiving it upon paper, and afterwards gently heating it, the result of the experiment will be rendered permanent.
The electrical effects which we have hitherto been considering, are of the most transitory kind, and exist only during the excitation of the electric. Although the electricity developed by the friction of a glass tube, or of a glass cylinder, was sufficiently strong for exhibiting many interesting experiments, and for the purpose of investigating the nature and properties of the electric fluid, yet it was not till the method of accumulating electricity was discovered, that philosophers became acquainted with the overpowering energy of this extraordinary agent.

This great step in the progress of the science was made by the celebrated Muschenbroek, in his invention of the Leyden phial or jar. This instrument is represented in Plate CCXLI. Fig. 5, where a b is a cylindrical glass vessel, having the lower part of its circumference covered with tinfoil all around, the inside being coated in a similar manner, and to nearly the same height. Through a perforation in the piece of wood or cork which forms the mouth of the jar, is inserted a brass rod d e, having a small ball of brass d at one end, and two or three inches above the top, and communicating by its other end with the inside coating, by means of a chain or wire. If the jar thus constructed is held to the conductor of an electrifying machine, so that the knob d may be about half an inch from it, a number of sparks will pass from the conductor to the knob d, and after growing weaker and weaker, they will at last cease. The electricity from the conductor has now been accumulated in the jar, and the jar is said to be charged. If any person now holds the jar in one hand by the outside coating, while with the other he touches the knob d, he will hear a sharp sound, accompanied with a brilliant flash of light, and will experience a severe and most disagreeable concussion in his wrists, elbows, and breast, the accumulated electricity of the jar having passed through his body. This sensation is called the electric shock, and the jar is said to be discharged.

The electric shock may also be experienced by any number of individuals, provided they take one another by the hand, and form the line of communication between the inside and outside coatings of the phial. If the person at one end of the line touches the outside coating, then the shock will be felt by every individual that composes it, the instant that the person at the other extremity touches the knob of the phial. In this manner the Abbé Nollet electrified 180 of the French guards in the king's presence; and, at the Carthusian convent in Paris, the whole of the religious persons formed a line of 5400 feet by means of iron wires between every two persons, and were all simultaneously electrified upon the discharge of the phial.

In order to discharge the jar without receiving a discharging shock, it is necessary to have two circular wires f m, g n; rod. (Fig. 6), having knobs f, g, at each end, and connected by a joint at m, where a glass handle, mn, is inserted. The experimenter takes hold of the glass part, and placing the lower knob g on the external coating, the discharge is effected as soon as the other knob f comes in contact with a. This instrument is called a discharging rod, and is represented in Fig. 5, in the act of discharging the jar.

The cylindrical form of the jar is by no means necessary to the accumulation of the electric fluid. The same effect is obtained when a plate of glass is coated on both sides with tinfoil, the glass extending about two inches beyond the metal all around, as is represented in Fig. 7. With this plate of glass, the same quantity of electricity will be accumulated as in a cylindrical jar, having the same area of coated surface.

When it is required to accumulate great quantities of electrical electricity, several of the cylindrical jars are placed in a battery with a box containing as many compartments as there are jars. The bottom of this box, upon which the jars must rest, is either covered with tinfoil or a treillis of wire, so that the outside coatings of the jars will communicate with one another by means of this metallic surface. The inside coatings are made to communicate with each other by horizontal bars of metal passing through the knobs of each jar; a construction which is represented in Fig. 8, which is a battery composed of 16 jars. Sometimes the wires from the inside coating, instead of terminating in a knob, are bent at top, and inserted in one common central knob. This form is shown in Fig. 9, which represents a battery of nine jars.

A battery may also be constructed by a combination of panes of glass coated as in Fig. 7. Dr Franklin formed a battery of this kind with 11 panes of common window-glass, and with it he made the greater part of his experiments.

Batteries of great size have been constructed by different electricians, so as to accumulate an enormous quantity of electricity, capable of melting the hardest metals, and of putting an instantaneous termination to the functions of animal life. Dr Priestley constructed a battery consisting of 64 jars, and containing 32 square feet of coated surface. Mr Cuthbertson completed, in 1784, for the Teylerian Museum at Haarlem, a battery of 135 jars and 132 feet of coated surface; and in 1789 he completed another battery for the same Institution, consisting of 100 jars, and containing 550 feet of coated surface.

Batteries are charged and discharged exactly in the same manner as a single jar. If one of the knobs of the battery communicates with the prime conductor of the machine in a state of action, it will soon be filled with the electric fluid; and the discharge may be effected by making a communication between the external and internal coating, by means of a discharging rod, or any other conductor.
The mode of constructing batteries, and the precautions which are necessary in using them, will be fully detailed in the practical part of this article. It is enough to know, at present, that, by such combinations, electricity is capable of any degree of accumulation.

**Sect. VI. Phenomena of the Leyden Phial.**

In the preceding Section we have already had occasion to mention the general construction and use of the Leyden phial as a means of accumulating the electric fluid. It presents, however, many phenomena of a very curious and instructive kind.

It is obvious, that the external coating of the Leyden phial has no communication whatever either with the internal coating or with the conductor of the electrostatic machine, and yet there is a manifest accumulation of electricity on the outside of the glass, or in the metallic coating which covers it. It becomes, therefore, an interesting inquiry, to discover in what way the electricity is communicated to the outside of the jar, whether the electricity is one side of the glass or in the coating, —what is the character of the internal and external electricities,—and in what manner they stand related to each other.

Dr Franklin, to whom we are indebted for almost every thing that has been done respecting the Leyden phial, began his experiments by examining the internal and external electricities of the jar. Having suspended a cork ball by a silken thread, he found that it was attracted by the outside coating while it was repelled by the inside coating; and that it was repelled by the outside when it was attracted by the inside coating. Hence it followed, that the inside of the phial always possessed an opposite electricity to the outside, the one being electrified positively when the other was electrified negatively. This important conclusion was still better established, when Dr Franklin observed that he could charge a Leyden phial by holding it by the brass knob, and presenting the external coating to the prime conductor. When the phial was charged in this way, the electricity of the external coating was positive, and that of the internal coating negative; and when the phial was charged in the usual way by the knobs, the internal coating was positive, and the external coating negative.

When two phials were both charged through their knobs, a cork ball suspended between them by a silken thread, was first attracted and then repelled by both the knobs as they were positively electrified. When both the phials were charged through their outside coatings, the ball was also repelled by them both; but when one of the phials was charged by its knob, and the other by its outside coating, the suspended cork ball played vigorously between them both, till the jars were nearly discharged. Hence it follows, that the one side of the phial possesses always the opposite electricity to the other, and that the two sides are simultaneously electrified, whether the electricity is drawn from the prime conductor by the one side or the other.

As glass is impenetrable to the electric fluid, it necessarily followed that the electricity was not communicated from the one side of the glass to the other; and this was easily ascertained by observing, that when the jar was insulated it was not capable of being charged but in a very trifling degree. Hence it followed, that the electricity of the outside of the jar was supplied from the earth by the conducting bodies which surrounded it, and that whenever one side of an electric receives one kind of electricity, the opposite side is simultaneously supplied with the opposite electricity, either from the earth or other conducting bodies which are near it.

The next object of Dr Franklin was, to ascertain if the positive electricity of one side of the phial was equal to the negative electricity of the other. For this purpose he hung a small linen thread near the outside coating of a charged phial, and every time that he presented his finger to the wire, the thread was attracted by the coating; the electricity taken from the inside by touching the wire being exactly equal to what was drawn in on the outside by the thread. Professor Richman obtained the same result by a very elegant experiment. Having coated both surfaces of a pane of glass within two inches of its edge, he fixed linen threads to the upper part of the coating on both sides. When the plate was not charged, the linen threads hung down in contact with the coating; but when the plate was placed in a vertical position and then charged, the threads were repelled from the coating, and formed equal angles with it on both sides. When his finger was conducted near the thread on the same side formed a less angle with the coating, while the thread on the opposite side formed an angle as much greater. Upon bringing his finger in contact with one of the sides, the corresponding thread fell down upon the coating, while the opposite thread formed twice the angle with the coating which it had done before. The angle formed by the two threads with each other was therefore always a constant quantity.

Dr Franklin at first imagined that the electricity accumulated in the jar existed in the coatings in contact with the glass, but he soon found upon further examination, that the electricity was contained in the glass itself, and that the sole use of the coating was, in the act of charging the jar, to conduct the electricity to all the parts of the glass which was in contact, and in the act of discharging it, to facilitate the communication between the two sides of the glass. In order to ascertain these points, he charged a jar, and placed it upon glass, or any insulating stand. He then took out the cork and the wire, and ascertained that they did not contain any electricity, by touching the outside coating with one hand, and putting the finger of the other hand into the mouth of the bottle, when he received a shock as powerful as if the wire and cork had been in their place. Having put water into the phial, which being a conductor, has always the same effect as a tinfoil coating, he charged the jar, and then pouring the water into an insulated bottle, found that it also would not give the shock. It then struck him, that the electricity must either have gone off in the act of pouring out the water, or must still be resident in the bottle. He therefore filled the phial with fresh water, and without any new charge he received the shock as before, which completely proved that the electricity resided in the glass. Dr Franklin made similar experiments with coated panes of glass, and obtained the same result, by changing the coating as he had charged the water. The same truth may perhaps be more satisfactorily established by the following experiment. Fix the outside coating of an uncoated jar with a little grease; and, instead of the inside coating, substitute a quantity of mercury, or of small shot, or gold leaf, or brass filings. As soon as it is charged, turn it upside down, so as to allow the mercury or shot to fall out along with the wire and knob, and remove also the outside coating. By this operation, the jar will not have
lost its charge; for if new mercury or shot be put into the inside, and a new piece of tinfoil on the outside, the shock will be felt as strongly as if no charge had taken place.

Dr Franklin likewise found, that when the glass was gilt, a part of the gilding was torn off, as if the electricity had passed from the glass through the gilding; and when a thin bottle was broken by the powerful attraction of the negative and positive electrics on each side, the glass was always broken inwards, while the gilding was broken outwards. The theory by which Dr Franklin explained these various phenomena, will be fully explained in the third Part of the article.

Other electric substances are capable of being charged in the manner as before; Boccelli indeed, on a charge being divided to a smooth plate of sealing-wax, made by pouring it in a fluid state upon an oiled marble table. He charged also a mixture of pitch and colophony, sulphur, and pitch, the magnitude of the charge being in the order in which these substances are named.

In our history of electricity, we have already given a sufficient account of the beautiful experiment in which Wilke and Epimius succeeded in charging a plate of air, and taking shocks from it as if it were a plate of glass.

We have already seen, that when a jar is discharged by the discharging rod, no effect is transmitted along the glass handle. When the handle, however, is made of brass, or any other metal, a small shock is transmitted to the person that holds it, when the quantity of electricity accumulated in the jar is considerable. In like manner, if a small chain is connected with the outside coating of a charged jar, it will appear luminous when the jar is discharged in the dark by any conducting circuit, of which this chain does not form a part. This effect has been named the lateral explosion, and may be shown most conspicuously by the following method, which was pointed out by Dr Priestley. Insulate a thick metallic rod, and place it with one of its ends contiguous to the external coating of a charged jar, and at the distance of half an inch from its other extremity place a large body about 6 or 7 feet long, and a few inches broad. Let a chain be now placed upon the table, at the distance of 14 inch from the outside coating, and apply one end of the discharging rod to the other extremity of the chain. As soon as the opposite extremity of the discharging rod is made to communicate with the knob of the jar, the discharge will take place, and a brilliant spark will be seen between the insulated metallic rod and the large body adjacent to it. This spark does not change the electrical state of the body; and it is therefore imagined, that this lateral spark flies from the coating of the jar, and returns to it before an electrometer can be affected. This lateral spark has the same length and brilliancy, whether it is received on flat or smooth surfaces, or on sharp points. In opposition to the result of the preceding experiment, Dr Robison informs us, that he has perceived a delicate electrometer affected by the lateral explosion.

**SECT. VII. On the Electrical Spark, and Electrical Light.**

The light which always accompanies the excitation of an electric, was observed about the same time by Otto Guericke of Magdeburg, and our countryman Dr Wall, and attracted the particular attention of every subsequent electrician.

During the excitation of a glass tube in the dark, small flashes of light, accompanied with a crackling noise, are always observed; and in working an electrically charged machine, streams of blue light are constantly flashing over the surface of the glass cylinder. The electric light, however, is more distinctly observed when any round body is brought near the prime conductor of the machine. A brilliant light, called the electric spark, is seen between the body and the conductor, and exhibits a vast variety of appearances under different circumstances.

**Exp. 1.** If we hold a brass ball, about three inches in diameter, near the prime conductor of an electrical machine, sparks of bright white light will appear between them, attended with a loud snapping noise. When the ball is very near the conductor, the sparks appear in quick succession, and are quite straight.

**Exp. 2.** Having screwed a brass ball, about 2 inches in diameter, into the prime conductor positively electrified, so as to stand about three inches from it, hold another ball near the first, and long ramified or zigzag sparks will be obtained. This positive spark is represented in Fig. 10, where nat denotes the ball held in the hand, and in a natural state of electricity, while pos is the positive ball connected with the conductor. When the ball on the conductor is made very small, the spark becomes a faint divided brush of light.

**Exp. 3.** If the first ball in the preceding experiment is electrified negatively instead of positively, the spark becomes dense, straight, and more luminous than before. This is represented in Fig. 11.

**Exp. 4.** If one of the balls is positively and the other negatively electrified, the spark combines the appearance both of Figs. 10 and 11, as in Fig. 12. When the distance between the balls is not too great, the positive zigzag spark strikes the negative straight spark generally at the distance of one-third of the length of the latter from its point, the other two-thirds being rendered very bright. On some occasions, the positive spark strikes the negative ball at a distance from the negative spark.

**Exp. 5.** Take two conductors P, M, about three quarters of an inch in diameter, with spherical ends of the same diameter, and place them parallel to each other, so that their distance is about two inches, and their ends pointing in opposite directions, and six or eight inches asunder. These conductors are to be successively electrified. When P is positively electrified, it exhibits the ramified zigzag spark, and strikes the side of the other conductor M, as in Fig. 13. When M is negatively electrified, P being now connected with the earth, the sparks cease to strike as formerly; but the end of the electrified conductor M will exhibit the negative spark, and strike the side of P, as in Fig. 14. When one of the conductors is electrified positively, and the other negatively, the ramified or positive spark appears at one end, and the negative spark at the other, streams of electricity constantly passing between the ends of the conductors, as is shown in Fig. 15.

**Exp. 6.** Fix a fine point upon the extremity b of a stem b c, and upon this stem place a brass ball a, about six inches in diameter, in such a manner, that, by turning round the ball A, the point may be made either to withdraw itself within the surface of the ball, or protrude itself beyond it. The point will not act when it is beneath the surface of the ball, and the ramified spark will be seen between the two balls, as in Fig. 16; but in proportion as the point is protruded beyond the surface, it increases the transmitting power, and may be made to have the same effect as any ball whatever, from the smallest size to six inches in diameter. When it projects to a sufficient distance from the ball, it acts as
ELECTRICITY.

If no ball were present. Mr Nicholson, to whom we are indebted for the preceding experiments, remarks, "that the effect of a positive surface appears to extend further than those of a negative one, for the point acts like a ball when considerably more prominent, if it be positive, than it will if negative."

Mr Nicholson has applied the preceding principle to the construction of a simple instrument for distinguishing positive from negative electricity, when they are sufficiently strong to afford sparks. Two metallic balls A, B, Fig. 17, may be placed at different distances, by means of a joint C. The arms CA, CB, are made of glass, and covered with varnish, and a short point p projects from the ball B towards the ball A. This simple apparatus is now to be placed near any electrified body, so that the electric power may pass through the balls; then if the electricity passes from A to B, there will be a certain distance of the balls, at which a spark will pass between them, and this distance will be much shorter when the electricity is passing from B to A.

Exp. 7. Hold an uninsulated sheet of paper near a positively electrified conductor, and the electrical light will form a beautiful star, about four inches in diameter, consisting of distinct radii, but not ramified. Perform the same experiment with a negatively electrified conductor, and instead of forming a star, it will throw out many pointed brushes of light to the paper.

Exp. 8. Present the point of a needle to a body positively electrified, in the dark, and the point will be illuminated with a star; but when the body is negatively electrified, it will exhibit a pencil or brush of light.

From the two preceding experiments, it becomes very easy to distinguish positive from negative electricity, by means of the different characters of the electric light.

Exp. 9. It appeared from experiment 6, that the effect of a point was destroyed, when it was withdrawn into a large brass ball, and sparks were produced as if the point had been wholly removed. The same effect will be obtained if the point is inclosed in a glass tube, or if it is placed between two balls.

Exp. 10. When sparks are passing between the conductors and a brass ball 14 inches distant, present a sharp point at double that distance, and the sparks will no longer appear.

The brilliancy of the electrical spark is proportional to the conducting power of the bodies between which it passes. Hence metals are used for the production of the electric spark. When an imperfect conductor, such as wood, is employed, the electric light appears in the form of faint red streams. The length of the spark depends upon the power of the electrical machine, and the state of the weather when the experiment is made. With a very powerful electrical machine sparks may sometimes be procured from 10 to 20 inches long, and these sparks always pass from the positive to the negative ball.

The electric spark always varies its character with the nature and density of the medium through which it is transmitted. The earliest experiment upon this subject was made by Dr Watson, on a large scale, and is one of the most beautiful which can be exhibited.

Exp. 1. Take a glass cylinder, three feet long and three inches in diameter, and fit it up at one end so as to be able to let down a brass plate from the top, in order to approach another brass plate fixed at the bottom of the cylinder. Let the cylinder be now exhausted and insulated. When the upper plate is electrified, the electric matter will pass from one plate to another, at the greatest distance at which the plates can be placed, and the lower plate will be electrified as if it had been connected with the prime conductor. When the room is dark, the electric matter, which in the open air passes in small brushes or pencils of light about an inch or two long, will now be transmitted in vivid coruscations of a bright silver hue along the whole length of the tube. These coruscations do not divide as in the open air, but from a base apparently flat, they frequently divide themselves into smaller and smaller ramifications, like the coruscations of the northern lights. When the vacuum is very perfect, the electric matter will pass between the plates in a continued stream of the same size throughout its whole length.

Exp. 2. Having placed the brass plates at the distance of 10 inches, make this vacuum a part of the circuit through which a jar is discharged, and at the instant of the discharge, a mass of bright embodied fire will be seen to leap from one of the brass plates in the tube to the other. When the distance of the plates is greater than 10 inches, the light begins to diverge and lose its force, and this diversity is nearly proportional to the distance of the plates.

Exp. 3. Form a Toricellian vacuum in the angular part of a long bent tube of glass filled with mercury and inverted, and place the legs of the bent tube in separate basins of mercury. If this vacuum is insulated, and one of the basons of mercury made to communicate with the conductor, while some non-electric substance touches the other, the electric light will pervade the vacuum in a continued arch of lambent flame, without the least diversification. If one of the basons be connected with the machine, which should be insulated, the light will pervade the vacuum in a contrary direction.

These three experiments were made by Dr Watson.

Exp. 3. Through the top of the receiver of an air-pump, a foot high and half a foot broad, insert a pointed wire, so as to project two inches into the inside, place the receiver on the plate of the air-pump, and connect the wire with the prime conductor of the electrifying machine. A brush of light will appear at the point of the wire; but as soon as the exhaustion of the receiver commences, this brush will enlarge itself, and vary its shape; and when the rarefaction is considerable, the whole of the receiver will be filled with a beautiful blush of light, the colour of which changes with the strength of the electricity.

Exp. 9. Into the extremity of a glass tube 30 inches, insert an iron wire projecting into the tube, and having a ball on the outer end of it. Fill the tube with mercury, and at the open end place a drop of ether, and secure it by the finger, while the tube is inverted so as to form a Toricellian vacuum in the upper part. The ether will rise to the top, and upon the removal of the finger, and the descent of the mercury, it will expand into vapour. If electricity is now transmitted through this vapour it will become luminous, and assume various hues according to its strength. If a strong spark passes through some inches of the vapour, the light is generally of a blue colour.

In condensed air and in carbonic acid gas, the light of the spark is white and brilliant, but in hydrogen gas it is red and faint.

Exp. 10. Charge a Leyden phial by its knob, and take away the knob by a stick of sealing wax. Place
the charged jar under the receiver of an air pump, and exhaust the receiver. The electric light will then flow out copiously from the neck of the bottle, and will divide itself into several jets, which will bend round in order to reach the internal surface of the jar. If the jar is charged by its external coating, and placed under the receiver as before, the electric light will throw itself in jets, from the external coating to the neck of the jar.

Exp. 11. Into a piece of soft deal, about three inches long, and 1½ inch square, insert obliquely two pointed wires, having their points 1½ inch distant, and penetrating to different depths below the surface, so that the line joining them is in the direction of the fibres. While the spark passes from the one wire to the other, it will exhibit different colours at different depths. If the one point is deeper than the other, all the colours will appear at once, as the electric light is transmitted at various depths.

When the sparks pass through balls of wood or ivory, they are of a crimson colour. They are green when taken from the surface of silvered leather, yellow when taken over powdered charcoal, and of a purple colour when taken from imperfect conductors. In the vapour of ether, the green sparks appear while the eye is placed close to the tube, and reddish when seen at a considerable distance.* The colour of the spark in very rare air is green, and in denser air it becomes blue, and then violet and purple, till the medium has become so dense as to be unable to conduct electricity.†

Upon rarefying the air 500 times within a glass jar, about one foot long and eight inches in diameter, Mr Smeaton placed the jar upon a lathe, and turned it round rapidly, whilst at the same time he rubbed it with his hand. A considerable quantity of lambent flame appeared under his hand, variegated with all the colours of the rainbow. The light was steady, but every part of it was constantly changing colours.

When metallic substances are completely continuous, and of sufficient size, they do not become luminous by the transmission of the electric light. The difficulty therefore of making bodies luminous by electricity, must increase with their conducting power. When there is any breach of continuity in the body, a spark will always appear at every separation; hence at each link of an electrified chain, a spark is distinctly visible, and, from a similar cause, perhaps, gold leaf may be rendered luminous. The appearance of light at the separation of the parts of a metallic body, is the foundation of several curious experiments, which we shall lay before our readers.

Exp. 12. Having connected one end of a chain with the outside coating of a charged phial; place the end of another piece of chain, coming from the knob of the jar, at the distance of a quarter of an inch from the former, and set a glass vessel full of water upon both these ends. When the jar is discharged, the water will appear completely luminous.

Exp. 13. A strip of gold leaf, about the eighth of an inch broad, and three feet long, will be rendered luminous throughout its whole extent, by the explosion of a jar containing two gallons. If the gold leaf is laid on glass, and below water, it will be still more brilliantly illuminated when the charge of a battery is passed through it.

Exp. 14. Attach one wire to the outside coating of a charged jar, and another to one of the branches of the discharging rod, and having placed their other ends at the distance of 1-10th of an inch, press the thumb upon the two ends. Bring the other branch of the discharging rod in contact with the knob of the jar, which being thus discharged, the spark will pass under the thumb, and illuminate it in such a manner that the bone and the principal blood vessels may be readily observed.

Exp. 15. Place a lump of sugar on the table, and in contact with the outer coating of a charged jar. Place one of the knobs of the discharging rod on the outside of the sugar, and bring the other to the knob of the jar. As the spark passes through the sugar it is rendered luminous, and retains the light for a considerable time.

Exp. 16. Paste upon a tube of glass a number of small round pieces of tinfoil, as in Fig. 18. The distance between each being about the 30th of an inch. When this tube is held near the prime conductor, a brilliant line of light will appear to surround it, a spark being visible between each of the small circles of tinfoil.

Exp. 17. Let several of those spiral tubes be placed on a board, as in Fig. 19, and round a central glass pillar supporting a wire ab, having a ball a and b at each extremity, and capable of turning round an axis. Communicate several sparks from a conductor to the ball C, and pushing the wire ab gently round, each tube will receive a spark from the balls, and will be illuminated as in the preceding experiment.

In like manner, luminous words may be made, as in Fig. 20, and a similar effect may be produced, by discharging a jar coated in the manner represented in Fig. 21, where there are on the outside five rows of square pieces of tinfoil, with eleven in each row, and the same number on the inside of the jar, making in all 110 square pieces. The diagonals of the square pieces are in a horizontal and a vertical position, and there is a round hole in the centre of each. Every adjacent pair on the outside, nine, have two of their square points meeting in the centre of the round hole in the intervening pieces of tinfoil on the inside, so that 110 sparks will be seen at once in a horizontal direction upon the discharge of the jar, and 110 sparks in a vertical direction.

It was imagined by some of the early electricians, that the electric light contained no prismatic colours. Light has the same optical properties as any other light.

Sect. VIII. On the Influence of Points in receiving and discharging Electricity.

In the section upon electric light, we have already seen the effect of obtuse bodies, such as balls, in carrying off the electricity of a conductor by a succession of brilliant sparks; and we had occasion to observe, that when a ball was thus receiving sparks, any pointed body placed...
ELECTRICITY.

Exp. 1. Bring a metallic point near the prime conductor after it has been charged with electricity, and it will draw off the whole of its electricity without any noise, so that no spark will be received either by presenting the knuckle, or any metallic body. In the dark, there will be seen at the point a plume of light if the conductor be negatively electrified, and a simple point of light if it be positively electrified.

Exp. 2. Fix a metallic point in the prime conductor, and when it is electrified by the action of the machine, a hissing noise will be heard arising from the rapid discharge of the electricity from the pointed wire. By holding the hand near it, a strong blast of air will be felt as proceeding from the point, and in the dark it will emit a beautiful plume of light if the conductor is positively electrified, but will exhibit a luminous point if the conductor is negatively electrified. This current of air is so strong, as to be able to give a rotatory motion to pointed bodies balanced upon a pivot.

Exp. 3. If when the electricity is drawing rapidly off by means of a point, we present several points together, a spark will pass from the conductor to the points, so that the effect of one point is diminished by the presence of another, and when the points are numerous, they produce the same effects as a round body.

Exp. 4. If a man, insulated by standing upon a stool with glass feet, holds in his hand a rod, with a ball at one end and a point at the other, he will be able to electrify himself, so as to give sparks when he holds the point at a short distance from the prime conductor; but when he holds the round end at the same distance from the conductor, he will not be able to draw any electricity from the conductor.

Exp. 5. If a man, insulated as before, is electrified, the electricity will be rapidly discharged when he holds out any pointed body, and in the dark the light will be seen streaming from the point.

Exp. 6. If two cross wires ab, cd, Fig. 1, with a cap c at the point of intersection, and having 4 sharp points as a, b, c, d, turned in the same direction, be nicely balanced upon a point at the top of the insulated rod or stand ef, and if they are connected with an electrified conductor by the chain gh, they will immediately receive a rotatory motion. In the dark, a stream of light will issue from each point, and, from the velocity of rotation, these four streams will form a beautiful circle of light.

Exp. 7. Upon the preceding principle, an apparatus called the electrical orrery is constructed. If a globe S (Fig. 2) representing the sun, has a projecting arm SB, and if upon the pointed extremity of this arm is balanced another ball E, representing the earth carrying a wire M a, with a point a at one end, and at the other a ball representing the moon; then, if a point b is fixed in the middle of the arm SF, and if the whole is balanced on an insulated stand, by loading one side of the globe S, let the apparatus be connected by a chain gh, with the prime conductor of an electrical machine, and a rotatory motion will be given to both the arms, so that the moon M will move round the earth E, while the earth performs its revolution round the sun S.

Exp. 8. Insert five arms of wire, having their extremities pointed and turned in the same direction, into a piece of wood supported upon a point at the top of a glass pillar, as shown in Fig. 3. To one of these arms, which is longer than the rest, suspend a glass clapper by a silk thread, and behind it a rod cd. Let 8 bells be now placed upon the stand, and if a chain passes from the upper point a to the prime conductor, the points will move round, and the glass clapper will strike against the bells during its successive revolutions.

Exp. 9. Let an inclined plane be formed of two straight parallel wires, AB, CD, and insulated by four glass pillars, A, B, C, D fixed in a stand; and let a small wire, mn, with two little balls at its extremities, be made so as to slide down the parallel wires by the force of gravity. On a pivot in its centre, balance a wire ap with two points turned in the same direction. When the wire mn is near the lower end of the inclined plane, connect the parallel wire with an electrified conductor by means of a chain. The wire ap will immediately turn round the pivot upon mn, and will ascend the inclined plane.

The great utility of points as conductors or thunder rods for carrying off the electricity of the atmosphere, and the theory of their mode of action, will be fully explained in other parts of the present article. See Sect. XI. On the Distribution of Electricity, Art. 3, p. 455.

Sect. IX. On the Law of Electrical Attraction and Repulsion.

Sir Isaac Newton, and some other philosophers, had long ago imagined, that electrical and magnetic attraction followed the inverse ratio of the cube, or some higher power of the distance. Ampère and Cavendish, in their theories of electricity, have assumed no particular law, but merely that the action decreases as the distance increases, although the former had suspected that the law was the same as that of gravity.

Lord Stanhope had endeavoured to show, that electrical actions followed the inverse ratio of the square of the distance, and his reasons were by no means conclusive, and the law was still considered undetermined.

Our countryman Dr Robison, more than 40 years ago, made a variety of experiments on this important subject, and determined that the law of electric attraction and repulsion was nearly in the inverse duplicate ratio of the distance. An account of his experiments was read before a public society so early as 1760, but unfortunately he did not then regard them as of sufficient importance to be laid before the public. As we conceive that Dr Robison is entitled to a share of that honour, which is now given to Coulomb, we shall lay before our readers an account of the method by which he ascertained the law of electrical action.

The instrument with which Dr Robison’s experiments were made, is represented in Figs. 5 and 6. Fig. 6, being a perspective view of the whole instrument. A polished black ball A, ⅔ of an inch in diameter, is fixed on the point of a very slender needle three inches in length; the other extremity of the needle passes through a ball of amber or glass F, about three-fourths of an inch in diameter, but though the ball is completely perforated, the end of the needle must not extend quite to the surface. At right angles to the needle, a slender glass rod is fixed into the ball F; it is bent at right angles at
E, and is continued to L, exactly above the centre of the ball A. The length of this rod is six inches from F to L. At the extremity L is fixed a piece of amber C, with an opening in the middle to admit the rod DCB. The rod DB is formed of a silk thread coated with sealing-wax; the silk thread must be very strong and very dry, and, when completely penetrated by the melted wax, it must be made straight and smooth, so as to be sufficiently stiff and free of all asperities. This rod passes through a small cube of amber, which has fine holes drilled in two of its opposite sides; and by means of two round pins passing through the piece of amber C, the rod DB has a free motion round these pins as an axis. The branch CB of this rod is about three inches long, and carries at its extremity a ball B a quarter of an inch in diameter, which may be either made of metal, or of cork gilt and burnished. The other branch CD, which is of the same length, passes through a small cork ball. When the instrument is thus constructed, the lower ball B must just touch the ball A, when the arm FE is in a vertical position. The ball F, Fig. 5, must now be fixed at the extremity of a glass rod FI, which passes through a right angle through the centre of a divided circle GHO, and has a handle of boxwood at its other extremity I. This rod, which is perpendicular to AF, is supported by the head of a pillar IK, in which it turns with some difficulty. An index NH, fastened to the rod FI, is always set parallel to the line LA, drawn through the centre of the fixed ball. This index will point out the angle which LA forms with the vertical line. It will also be convenient to have another index, which turns stiffly on FI as an axis, and stretches a considerable way beyond the graduated circle. The graduated circle is divided into 360 degrees; the zero of the division is placed uppermost, and 90 on the right hand.

In order to use this instrument, take hold of the handle I, and set the index to 90. The lines LA and CB will now have a horizontal position, and the ball B will rest on A. Let the balls be now electrified, and let the index be brought back to 0 on the scale, by the handle I, during this motion the balls will be seen to separate in some particular position of the index; repeat this operation till the exact position is ascertained at which the separation takes place. This will shew the repulsive force when in contact, or at a distance equal to the sum of the radii. Let the instrument be now turned still more towards the vertical position, and the balls will be observed to separate more and more. An assistant must turn the long index, so as to make it parallel, by making the one appear to coincide with the other. In order to show that this instrument will give an absolute measure of the repulsive force of the two balls, we have only to balance the rod BD in a horizontal position by loading the ball D with some greater weight; then, by computing for the proportional lengths of BC and DC, we shall find the exact number of grains with which the balls must repel each other, in order merely to separate, when the rod BD has a horizontal position. When this rod has any oblique position, a very simple computation will give us the number of grains of repulsion, with which they will then separate; and a third computation, founded on the resolution of forces, will give us the repulsive force in grains, when A I has an oblique position, and when the rod BD forms any angle.

In order to make this instrument measure the attractions of two balls, one of which is positively and the other negatively electrified, we must incline the instrument to the left, and by electrifying the balls A, B, in an opposite manner, when at a great distance from each other, they will approach by their mutual attraction; and by means of the deviation of BC from a vertical line towards A, we shall be able to determine the magnitude of the attractive force. In making experiments with this instrument, the greatest care should be taken to provide as much as can be done against any dissipation or waste of the electric matter, by having all angles and asperities removed, by varnishing all its parts, and by making the experiments in a warm room, and when the atmosphere is particularly dry. Dr. Robison recommends, that the dissipation per minute, under various circumstances, should be determined by a previous set of experiments.

By means of different instruments of this kind, of different sizes, and of some of them of balls of an inch in diameter, and radii of 18 inches, Dr. Robison performed more than an hundred experiments, from which he concluded that the mutual repulsion of two spheres, electrified in the same manner, varied as \( \frac{1}{d^2} \), \( d \) representing the distance of their centres.

Several years after these experiments of Dr. Robison's were made, and read before a public society, the attention of Coulomb was drawn to the same topic, by the prize on the subject of the magnetic needle, which he had the good fortune to share with Van Swinden. His first object was to contrive an apparatus for measuring very small quantities of electricity. This apparatus, which he employed in all his experiments, and which he calls a torsion balance, is represented in Plate CCXLIV. Fig. 7, where ABCD is a glass cylinder, 12 inches high and 12 inches broad, on which is placed a plate of glass AC, 13 inches in diameter. This plate, which covers the whole of the cylinder, is pierced with two holes \( f, m \), both of which are 20 lines in diameter. Into the hole \( f \) is cemented a tube of glass \( fh \) two feet high, and at the upper end of the tube at \( h \) is placed a torsion micrometer, which is seen on an enlarged scale in Fig. 8.

The upper part of this micrometer consists of a button \( m \), an index \( i, o \), and a pair of pinsers \( g \). This upper part is let down into the hole \( G \), in the centre of the circle \( a, b \), which is divided upon its edge into 360 degrees. This plate is soldered upon a tube of copper \( N \), which enters into the tube \( H \), Fig. 9; and this tube is cemented into the upper extremity of the long glass tube \( f h \). The pinsers \( g \) have nearly the shape of the extremity of a solid port-crayon, which can be opened and shut by means of a ring \( r \). These pinsers lay hold of the extremity of a very slender silver wire, the other end of which is held at \( P \), Fig. 10, by the pinsers of an iron or copper cylinder \( P \), about a line in diameter. These pinsers, like the former, are opened and shut by a ring \( Q \).

This cylinder is perforated at \( C \), to receive the needle \( q \). The weight of this part of the apparatus must be sufficiently great to stretch the silver wire without breaking it. The needle \( a, g \), which must be suspended horizontally about six inches from the bottom of the glass cylinder ABCD, is formed of a silk thread, or a straw covered with sealing-wax, and has the part \( qa \), about 18 lines in length, formed of a cylinder of gum lac. At this extremity is a small ball \( a \) of the pith of elder, about two or three lines in diameter; and at the other extremity \( g \), is a small vertical plane of paper, covered with turpentine, which serves as a counterpoise to the ball \( a \).
ELECTRICITY.

Into the hole $m$, is introduced a small cylinder $m x t$, the lower part of which, $x t$, is formed of gum lac, and carries a pith ball $t$. At six inches from the bottom of the glass cylinder there is pasted round its circumference a band of paper $z q$, divided into 360 degrees, so as to be on a level with the needle $a g$.

In order to adjust this instrument for use, the hole $m$ is made to correspond to the zero of the scale $z q$. The index $o f$ of the micrometer is then placed upon the zero of its graduated circle $o p$, and the whole micrometer is turned in the tube $f h$, till, in looking past the vertical silver wire $P$, and the centre of the ball, the needle $a g$ shall correspond with the zero of the scale $z q$.

The other ball $t$ is then introduced, so that it may touch the ball $a$, and so that a line joining the centre of the silver wire, and the ball $t$, may also point to the zero of the scale $z q$.

**Coulomb's Method of determining the Law of the Repulsive Force.**

When the instrument was thus adjusted, Coulomb applied it in the following manner to determine the law of the repulsions of the two balls $t$, $a$. Having provided a brass pin $A B$, Fig. 11, with a large head, he stuck it into a handle AC of sealing-wax, and having electrified it he introduced it through the hole $m$, Fig 7, and touched the ball $t$ in contact with $a$. The electricity of the pin was thus communicated to the two balls, which of course possessed the same kind of electricity; and as soon as the pin was withdrawn, the balls mutually repelled each other to a distance which is measured by observing the degree on the circle $z o q$, which is pointed out by a line joining the silver wire and the ball $a$. If then the index $o$ of the micrometer is now turned in the direction $p o n$, the silver wire $P$ will be twisted, and we shall produce a force proportional to the angle of torsion, which is requisite to make the ball $a$ return to the ball $t$. By this means he observed the distance at which different angles of torsion bring back the ball $a$ to the ball $t$, and in comparing the forces of torsion with the corresponding distances of the balls, he obtained a measure of their repulsive force.

**Exp. 1.** The two balls being electrified with the head of the pin, and the index of the micrometer being set to zero, the ball $a$ was repelled by the ball $t$ to the distance of 36 degrees.

**Exp. 2.** The silver wire being twisted by turning the index of the micrometer 126 degrees, the ball $a$ approached to $t$, and stopped at the distance of 18 degrees from it, having moved backwards through an arc of 18°.

**Exp. 3.** Having again twisted the silver wire through an arc of 567°, the two balls approached, and stopped at the distance of 8½.

Now, as the force of torsion, or the force which is capable of keeping a thread twisted to a certain degree, so as to hinder it from turning round its axis, and recovering its natural state, has been shewn by Coulomb to be proportional to the angle of torsion, or the arch through which it has been twisted, we have in these experiments a force of torsion equal to 567°; and in the second experiment, when the distance of the balls was 18°, the angle, and consequently the force of torsion, was $126° + 18° = 144°$; so that the repulsive force, at the distance of 36°, was 36°; and the repulsive force, at the distance of 18°, was 144°, or quadruple at half the distance. In the third experiment, when the distance of the balls was 8½°, the force of torsion was 567°; so that, at a quarter of the distance, the repulsive force was nearly eight times as great. Hence it follows, that the repulsive force of two small globes electrified either positively or negatively, is in the inverse ratio of the squares of the distance of the centres of the two globes.

In the preceding experiments, the wire $P$ was 28 inches long, and $\frac{1}{4}$th of a grain in weight, and the force necessary to twist it through an angle of 360°, when at the distance $a P$, or four inches from the wire, is $\frac{1}{4}$th of a grain, as calculated from the formula given by Coulomb in his Memoir on the force of Torsion. Hence the real forces in the preceding experiments were,

**Distances of the Balls.** | **Angles and Forces of Torsion.** | **Absolute Forces in grains.**
---|---|---
36° | 36 | $\frac{1}{4}$th of a grain.
18 | 144 | $\frac{1}{4}$th
5½ | 567 | $\frac{1}{4}$th

M. Coulomb has remarked, that with a silver wire, so fine as that which he used, and which requires only a force of $\frac{1}{4}$th part of a grain to twist it through an angle of 90°, it is impossible, with every precaution, to ascertain the position of the needle to within 2° or 3° when the force of torsion is nothing. He recommends therefore, after electrifying the balls, to twist the wire 30° or 40°, which, joined to the observed distance of the two balls, will give a force of torsion so great as to remove any sensible error arising from the uncertainty of 2° or 3° already mentioned. He recommends also the use of a wire nearly double in diameter to that which he used, as it was liable to break with the least agitation. A wire of this thickness should also be stretched for two or three days by a weight equal to half of that which is necessary to break it, and should never be twisted through an arch of more than 300°.

It must have already occurred to the reader, that while these experiments are making, the balls were losing their electricity. Coulomb found, that when they repelled one another through an arch of 30°, they reapproached one another about one degree in three minutes; but as he was able to make the experiments in two minutes, he did not consider it necessary to make any correction for the loss of electricity. By observing, however, the rate at which the electric matter is dissipated during every minute, a correction may be applied when the air is very moist, or when the dissipation happens to be considerable.

In the preceding experiments, the distance of the balls was measured by the angular distance to which they were separated, which is greater than the chord, or the correct distance; but this is in a great degree compensated by an opposite error, arising from making the lever, by which the force acts, equal to the radius, or half the length of the needle, whereas it is equal only to the cosine of half the angular distance of the balls. This compensation is sufficiently corrected when the distance of the balls does not exceed 25 or 30 degrees; but, at greater angles, the distance between the balls and the length of the lever must be accurately computed.

**Coulomb's Methods of determining the Law of the Attractive Force.**

The next object of M. Coulomb was to determine the law which regulated the action of two oppositely electrified bodies; but in employing his apparatus for this purpose, he encountered a practical difficulty which he
ELECTRICITY.

Distance of the centre of \( i \) from the centre of \( G \) | Number of oscillations performed by the needle \( lg \) | Number of seconds in which these oscillations were performed
---|---|---
9 | 15 | 20°
18 | 15 | 40°
24 | 15 | 60°

From these experiments we may now deduce the attractive force of the globe \( G \) at the distances 9, 18, and 24; for the oscillations of the needle (abstracting the effect of the force of torsion) are produced solely by the action of that globe, in the same manner as the oscillations of a pendulum are produced by the action of gravity. As the circle \( d \) is only 7 lines in diameter, we may safely suppose all the lines drawn from the centre of \( G \) to every part of the plate as equal and parallel, and the whole of its action united in its centre \( l \). If we now call \( F \) the attractive force, and \( T \) the time in which a given number of oscillations are performed, we shall have \( T \) proportional to \( \frac{1}{\sqrt{F}} \); but if we make \( d = Gl \), the distance of the centres of the circle and globe, and suppose the attractive force to be inversely as the squares of the distances, or as \( \frac{1}{d^2} \), then it will follow that \( T \) is proportional to the distances \( d \); so that if this law is correct, the time of any number of oscillations should be as the corresponding distances between the centres of the globe and the circle. Now,

The distances are as the numbers \( 3\ 6\ 8 \),
The times in which 15 oscillations are performed by experiment \( 20\ 41\ 60 \),
The times in which they are performed by theory \( 20\ 40\ 54 \).

The difference between the theory and the experiment is almost 0 at the distance of 18 inches, but at the distance of 24 it is nearly \( \frac{1}{\sqrt{2}} \). A correction, however, remains to be applied to the experimental result; for as four minutes were spent in the experiments, the globe and the plate had lost a portion of their electricity. Coulomb found that the action was diminished \( \frac{1}{\sqrt{r}} \) of the whole per minute, and therefore \( \frac{1}{\sqrt{r}} \) in 4 minutes. Consequently, in order to obtain the correct number instead of 60°, we have \( \frac{1}{\sqrt{10}} : \frac{1}{\sqrt{9}} = 60° \) : 57°, which differs only \( \frac{1}{\sqrt{10}} \) from the number 60° determined experimentally. Hence it follows, that the law of the inverse ratio of the squares of the distances is correct also, for the attractive forces of oppositely electrified bodies.

We have already stated, and the reader must himself have made the remark, that the oscillations of the needle \( lg \) are partly due to the force of torsion, and are not produced solely by the mutual attraction of the globe and the gilt circle. Coulomb, however, has shewn, that the force necessary to twist through a whole arch of 360° a silken fibre 6 inches long, and acting at the
on the Disseption of Electricity.

When any electrified body is insulated in the most perfect manner, the quantity of electricity which it possesses is found to suffer a gradual, and sometimes a rapid diminution, till the whole of its electricity is completely dissipated. It becomes a matter of the greatest importance, therefore, to determine the law according to which this dissipation takes place, and we are fortunately able to lay before our readers a series of beautiful experiments which have been made by Coulomb, by means of the very delicate apparatus which we have already described.

When any insulated electrified body dissipates its electricity, the effect is produced by three causes; 1. By the conducting power of the air which surrounds the electrified body; 2. By the deposition of humidity on the surfaces of the electrics, which are employed to insulate the electric body; and, 3. By the imperfect insulation produced by the best non-conductors. The last of these causes has probably the smallest share in the dissipation of the electric fluid, and cannot easily be estimated separately from the rest.

In measuring the dissipation produced by the two first causes, the reader must see, that there is some difficulty in separating the effects of the one cause from those of the other; for as the electrified body must always be insulated by imperfect conductors, the real quantity of electricity dissipated during a given time must be owing to both causes. Coulomb, whose inductive genius overcame every difficulty, has succeeded completely in separating the two effects. He saw, that if the portion of the surface of the electrified body, which communicated with the insulating support, was made extremely small, the loss of electricity along this support must be immeasurably minute, in comparison with the loss which was due to the humidity of the ambient air. He therefore put this idea to the test of experiment, and found, that when the electrified body did not possess much electricity, such as a pith ball 5 or 6 lines in diameter, he could insulate it completely by a cylinder of sealing-wax, or gun lac, about half a line in diameter, and 18 or 20 lines long; that a very fine silk thread, penetrated with melted wax, and covered with wax, so as to form a cylinder of a line in diameter, had the same insulating power when it was 5 or 6 inches long; and that an equal degree of insulation could not be procured by a fine thread of glass 5 or 6 inches long, or by a hair, or by a fibre of silk, unless when the air was uncommonly dry, or the electric density of the ball was weak.

1. On the Disseption of Electricity by the Contact of Air.

Having suspended a pith ball similar to that upon the needle ag, to a very fine silk fibre, covered with sealing-wax, and terminated with a cylinder of gun lac 18 or 20 lines in diameter, Coulomb introduced it through the opening m in his torsion balance, so as to touch the pith ball a, as in the former experiments. By means of the conductor, Fig. 11, he communicated the same kind of electricity to the two balls, which immediately repelled one another to such a distance, that the repulsive force was equal to the force of torsion. Let us suppose that the angular distance of the balls was 40°, then twisting the thread of suspension through 140°, Coulomb brought the ball back to 20°. He next observed the instant when this ball pointed exactly to 20°. As the electricity was dissipated, the balls approached one another some minutes after the operation; so that, after the distance of 20°, he twisted the thread of suspension 30° by means of the index, and as the force of torsion was diminished by these 30°, the balls repelled a little more than 20°. He then waited the instant when the ball of the needle arrived at 20°, and counted, with great exactness, the time which elapsed between the two operations. Suppose that this time was three minutes, then it will follow, that at the first observation the distance of the balls was 20°, and the repulsive force 140° - 20° = 160°; that three minutes after, the repulsive force at the same distance of 20°, was only 110° - 20° = 130°, or was diminished 30°, or 10° per minute. Hence as the mean force between the two observations was 160° - 130° = 145°, and diminished 10° per minute, it follows that the electric force of the two balls diminished 10° per minute.

In this way Coulomb constructed the following Table, which contains the observations made on the 28th May, the 29th May, the 22d June, and the 2d July, which he selected from a multitude of others, as on these four days the variation of the humidity of the air was very great, while its temperature was very nearly the same.

In this Table, the first column represents the instant of observation; the second, the distance of the balls; the third, the degree of torsion given by the micrometer; the fourth, the time which elapsed between two consecutive observations; the fifth, the loss of the electric force during that time; the sixth, the mean force of repulsion between the two observations, as measured by the mean torsion indicated by the micrometer added to the distance of the two balls; and the seventh, the ratio of the electric force lost in one minute to the total force.

</table>
It will appear by examining the seventh column, that the ratio of the electric force lost to the total force is a constant quantity during the same day, or while the air has the same degree of humidity; from which it follows, that the loss of electricity is always proportional in the same state of the air to the electrical density.

From these experiments, Coulomb has shown how to determine the electricity of the two balls after any given time. Thus from the first set of experiments in the Table, when the dissipation is $\frac{1}{4}$, every minute, he has shown, that if we make $t$ the interval of time, $d$ the electrical density of each ball, and $D$ the primitive density of the electric fluid in each ball, and $\mu$ the modulus of the logarithmic system, then we shall have

$$t = \log \left( \frac{D}{d} \right)$$

but as the distance is constant, $D$ is proportional to the primitive action, and $d$ to the action while the time is $\frac{1}{4}$. Hence in using the ordinary table, where the modulus $\mu = 0.4343$, we shall have

$$0.4343 t = \log \left( \frac{D}{d} \right)$$

If we now seek from this formula the value of $d$ in the 1st experiment, it will be found that at the first experiment $D = 150$, and that at the 6th experiment $d = 50$. Hence

$$0.4343 \log 3 = 0.4343 = 3$$

and consequently $t = \log 3 = 0.4343$ by the experiment.

Now the first experiment commenced at 6 h 32' 30" and the sixth at 6 h 17', the difference of which is 44' 30'' instead of 45', as found by the experiment.

Coulomb has also shown, that the ratio of the force lost in a minute to the total force, is double of the ratio of the loss of the density of each body to the total density. For calling $d$ their electrical density, and $a$ their distance, then since the two balls are equal, and receive at first the same quantity of electricity, their reciprocal action will be represented by $\frac{d}{a^2}$, and consequently its momentary diminution will be proportional to $\frac{2dd}{a^2} + \frac{dd}{a^2}$. Hence the ratio of this variation of repulsion to repulsion itself, will be, neglecting $d_d$, equal to $\frac{2d}{d}$. But $\frac{d}{d}$ is the relation of the loss of density of each ball to its own density, and consequently the dissipation is only one-half of the diminution of repulsion. Thus in the experiment of the 28th of June, the diminution of repulsion was $\frac{1}{4}$, from which it follows that the dissipation was $\frac{1}{4}$ per minute.

Our author made a great number of experiments of a similar kind with balls of different magnitudes, and when the quantity of electricity, as well as the electrical density of each ball, were very different, he always found, that the ratio of the dissipation of the electric force during a minute, to the total force, was uniformly a constant quantity. On the 28th June, for example, though he presented to the ball $a$ a ball double the size, and though he communicated to this ball a degree of electricity greater or less than that of the ball $a$, yet the loss of the electrical force was constantly $\frac{1}{4}$ per minute.

The most important result, however, which he obtained, was, that when the air was dry, and the degree of electricity not great, the ratio of the decrease of the electrical density to the density itself, was always a constant quantity, whatever was the form, and whatever the magnitude of the electrified body. This experiment was made with a globe a foot in diameter, and with cylinders of all lengths and magnitudes; he even substituted, in the place of the balls, circles of paper and of metal; and, on a dry particularly dry, he armed one of the balls with a small copper wire 4th of a line in diameter, and 10 lines long; and in measuring the dissipation of its electricity, he found that every body which he used on that day lost the 8th part of its electricity in a minute. It must be carefully observed, however, that this equality of dissipation exists only when the electric density has been reduced to a certain point; for, when the electricity is very strong, all angular bodies dissipate their electricity according to a law which will afterwards be determined.

The nature of the body, too, has no influence on the law of the dissipation. On the 28th June, the electricity decreased $\frac{1}{4}$ per minute when pitch balls were used; and the same result was obtained when the balls were made of copper or of sealing-wax.

The next object of Coulomb was to discover the relation which subsisted between the humidity of the air and the dissipation of electricity. He therefore drew up the following Table, in which the first column marks the day when the observations were made; the second the state of Saussure's hygrometer; the third the quantity of water dissolved in a cubic foot of air, when the thermometer is between 10$^1$ and 10$^2$ of Nélaton, according to the experiments of Saussure; and the fourth, the dissipation of electricity per minute.

</tbody>
</table>

If we now wish to determine the law between the dissipation of the electricity and the quantity of water in the atmosphere when the thermometer is between 10$^1$ and 10$^2$, the temperature when the four experiments were made, let us call $m$ the power which expresses that relation; then comparing the experiment with the three others, we shall obtain,

Experiments compared

1st and 2d, $m = (7.197) \div (6.180)$, whence $m = 2.76$

1st and 3d, $m = (8.045) \div (6.180)$, whence $m = 2.76$

1st and 4th, $m = (9.281) \div (6.180)$, whence $m = 3.61$

Mean $m = 3.05$

Hence it follows, that the diminution of the repulsive force, or, what is the same, of the electric density,
ELECTRICITY.

Descriptive

Electricity.

is proportional to the cube of the weight of the quantity of water dissolved in a given volume of air.

The preceding conclusion, however, cannot be considered as certain, since it depends upon several circumstances which have not been determined with sufficient exactness. Coulomb proposed to enclose the balls in different kinds of air, to communicate to the air different degrees of humidity, and then to determine the law of the dissipation of the electricity of the balls; but he found this investigation too arduous, for want of proper instruments for measuring the purity and the humidity of the different gases which he employed.

Although the quantity of water dissolved in a given quantity of air increases with the temperature, yet this is not indicated by the hygrometer of Saussure. As the conducting power of the air, therefore, must increase with the temperature, the dissipation of electricity ought to be greater in warm weather than in cold weather, even when Saussure's hygrometer indicates the same degree of humidity. This conclusion Coulomb confirmed by experiment; but the law of the increase depending on the augmentation of temperature, he has not been able to ascertain. Saussure* has published a Table, shewing the correspondence between the degrees of his hygrometer, and the quantity of water which a cubic foot of air holds in solution at every degree of the thermometer. But this Table is not given by its author as correct; and therefore Coulomb merely concludes, in general, that, in proportion as the temperature increases, the dissipation of electricity is not so great as it ought to be, by calculating from Saussure's Table.

The dissipation of electricity seems also to be affected by some other causes, which it is not easy to discover. On different days, when the barometer, the thermometer, and the hygrometer, indicated that the air was in the same state, the dissipation underwent considerable changes. The only general observation which Coulomb was enabled to make, was, that when there was a sudden change of weather, and when the hygrometer varied sensibly in a few hours from moist to dry, the loss of electricity, relative to its density, remained, during some time, greater than it ought to be, according to the degree of dryness indicated by the hygrometer, and vice versa when the hygrometer changes suddenly from dry to moist. If, in 12 or 15 hours, for example, the hygrometer passes from moist to dry eight or ten degrees, and that it afterwards remains stationary at that degree of dryness for several days, it will often happen that the electrical density will decrease the first day after this rise of the hygrometer, at the rate of \( \frac{1}{7} \) per minute. Some days afterwards, though the hygrometer is stationary, the electricity density will decrease more than \( \frac{1}{7} \) per minute. Coulomb ascribes this variation to the aqueous vapours contracting an adhesion to the air, after having conti-

</table>

Conclusions deduced from the preceding Table.

It appears from the preceding Table, that the diminution of electricity is at first much more rapid when the electrical density is considerable, than it ought to be if it were produced solely by the contact of the air; and when this density is reduced to a certain degree, the diminution of electricity becomes precisely the same as it is when the insulation is perfect, or as it is when the dissipation is entirely due to the contact of the air.

It follows, therefore, from this observation, that the silken fibre 15 inches long is a perfect insulator when the reciprocal action of the two balls is measured in the first set of experiments in the preceding Table by a force of torsion of 40° or under, since the loss of electricity is then only 2½ per minute, the very same dissipation that took place on the same day, and that was due solely to the contact of the air.

It results likewise, that in the second set of experiments in the above Table, the silk fibre 15 inches long insulated perfectly when the repulsive action of the two balls was 70° or under, for then the dissipation was 2½, or, the very same that was obtained on the same day, and that was due solely to the conducting power of the air.

Since the repulsive forces are measured at a constant distance, by the product of the densities of the two equal balls, the next object of Coulomb was to ascertain the relation between the primitive density, and the different degrees of density of the ball supported by the silken fibre, when the silk fibre begins to insulate the ball in a perfect manner.

In the first set of experiments in the preceding Table, the two balls were equally electrified. The ball a upon the needle insulated by means of gum lac lost 2 × 71° = 40° of its electricity per minute, solely by the conducting power of the ambient air. The other ball supported by the silken fibre, dissipated its electricity not only by the contact of the air, but also by its imperfectly-insulating support; and it was not till 10° 40' that the silk fibre began to insulate completely the second ball, at which time the repulsive force of the two balls was 40°. But at 10°, the beginning of the experiment, the repulsive force of the two balls equally electrified was 180°. Since the action at a constant distance is always proportional to the product of the densities, and since the densities at the first experiment were equal, the electric density of each ball is proportional to √180 at 10° 0'. But we have already seen, (p. 446. col. 1.) that the dissipation of electricity from the contact of air was \( \frac{d}{2} = mi \), where \( d \) is the density at the end of any time \( t \), and \( m = 2 \times 71° = 40° \) in col. 7. of the first set of experiments in the preceding Table.

Now the fluent of the above formula is \( \frac{D}{d} = \frac{0.4343}{82} \), \( D \) being the primitive density of the ball, and 0.4343
ELECTRICITY.

449

DESCRIPTION OF THE ELECTRICITY.

4. The modulus of the common logarithms. Hence we shall have

\[ \log d = \log D - \frac{0.4343}{82}. \]

Now if we wish to know the density \( D \) after 40 minutes, when the silk fibre begins to insulate perfectly, we shall find for the ball \( a \) supported by gum lac, and perfectly insulated during the whole of the experiment, \( D \) being equal to

\[ \sqrt{180 = 13.416}. \]

\[ \log d = 1.0176 - 0.2848. \]

Hence the electrical density of the ball of the needle at \( 10^\circ 40' \), which at \( 10^\circ 00' \) was equal to \( \sqrt{180 = 13.416} \), is now equal to 7.291. But as the action of two balls is always proportional to the product of the density, if we call \( \Delta \) the density of the ball supported by the silk fibre when it insulates perfectly, or when the action of the two balls is measured by \( 40' \), then 7.291 \( \Delta = 40' \), and \( \Delta = \frac{7.291}{40} = 52.9 \). Hence it follows, that the electrical density of the ball supported by the silk fibre is 52.9, when the fibre begins to insulate perfectly, the distance of the two balls being 30'.

Making use of the preceding formula, Coulomb found, from a comparison of several experiments, that a small cylinder of gum lac 18 lines long, did not cease to insulate perfectly till the ball was charged with a degree of electricity nearly triple that of the silk fibre, that is, assuming 52.9 for the electrical density of the ball when supported by the silk fibre 15 inches long, when it begins to insulate perfectly, we must triple this density to have the density at which the gum lac cylinder 18 lines long commences its perfect insulation.

Our author next endeavoured to find the relation between the electrical density and the length of the supports at which they begin to insulate perfectly; and he found from experiment, that the electric density, when a silk thread, or hair, or any fine cylindrical electrical commenced its perfect insulation, was proportional to the square root of the length of the support; that is, if a silk fibre, whose density is \( D \), and whose length is one foot, begins to insulate perfectly, a fibre 4 feet long will be necessary to insulate perfectly when the density is double or \( 2D \). This experimental result Coulomb has shown to be quite conformable to theory, but we cannot venture to follow this ingenious author into the field of speculation. We shall merely lay before the reader the principle upon which he proceeds.

He supposes that the imperfect insulating power of electric depends on the distance of the conducting molecules which compose the imperfectly insulating support, or which are spread over its surface, and therefore, in order that the electric matter may pass from one conducting molecule to another, it must traverse a small non-conducting space of a greater or less magnitude, according to the nature of the body. He supposes likewise, that this non-conducting space opposes a resistance constant for the same body, because the conducting molecules are uniformly distributed, or at the same distance from one another. These suppositions being admitted, Coulomb demonstrates the two following propositions. 1. That in a very delicate conducting fibre, the electric fluid is uniformly distributed throughout all its length. And, 2. That if the fibre has a certain degree of non-conducting power, the action which each point experiences will depend solely on the electrical density of the molecule in contact with this point, and that the action of the rest of the fibre may be regarded as nothing.

SECT. XI. On the Distribution of Electricity.

When any conductor receives electricity from an excited elec
tric, this electricity is instantly distributed over the body; for every part of the conductor exhibits electrical properties. It is therefore a most interesting enquiry to discover the cause by which this distribution is effected, to determine in what parts of the conductor the electricity resides, and in what manner the distribution takes place, between two or more bodies in contact, and in bodies of various forms.

The apparatus employed by Coulomb to determine these important points, is nearly the same as what we have already described. The only change which he made upon it, was to remove the divided band of paper \( z \), and to substitute in its place a wooden circle, like the horizon of a globe, resting on four pillars, and having a diameter nearly double that of the cylinder. This circle is placed in such a manner, that its centre may coincide with the axis of the wire or fibre which suspends the needle, and that the first division on the wooden circle may be in the same line with the fibre of suspension, and the centre of the ball \( a \) when the needle \( g \) is at rest.

1. On the Cause of the Distribution of Electricity.

In order to determine whether electricity was distributed over conductors by an affinity or electric attraction for one body in preference to another, or merely in virtue of a repulsive force, Coulomb instituted the following experiments.

**Exp. 1.** Having suspended in the hole \( m \) of the balance, by means of a cylinder of gum lac, a small ball of copper, so as to touch the ball \( a \) of the needle as before, he placed the centre of this ball in a straight line with the suspending fibre and the zero of the scale on the wooden circle. The ball \( a \) of the needle which touched the copper ball was then distant from the position where the torsion was nothing by the sum of the semidiameters of the two touching balls. The two balls were then electrified by the insulated pin \( CAB \), as in the former experiments, and the ball \( a \) was repelled to the 48th degree upon the scale. The suspending fibre was then twisted 120° by the head of the micrometer, in order to bring back the ball of the needle into contact with the copper ball as before, and as soon as the oscillations of the needle ceased, it stopped at 28°. At this instant Coulomb quickly brought another pith ball of the same size as the copper ball, and insulated with gum lac, into contact with the copper ball, and upon removing the pith ball, the ball \( a \) approached the ball of copper. In order to bring it back to its first distance of 28°, it was necessary to untwist the fibre, so that the micrometer marked 120° before contact, and only 44° after it.

**Exp. 2.** In place of the ball of copper, Coulomb now substituted a circle of iron, 10 lines in diameter, suspended by a cylinder of gum lac, and having its vertical plane passing through the zero on the wooden scale. He then electrified the ball \( a \) and the iron disc, as in the preceding experiment, and the ball \( a \) was repelled. In order to bring back the ball \( a \) into contact...
with the iron disc, it was necessary to twist the fibre 110°, and the ball a was now stopped at 30° from the iron disc. He then instantly touched the iron disc with a small circle of paper of the same diameter, and having withdrawn it, he found that, in order to make the ball a stop at 30°, it was necessary to untwist the fibre, or reduce the torsion to 40°.

Now, in the first of these experiments, the copper ball having, before its contact with the pith ball, repelled the ball a to 28°, while the micrometer marked 120°, the force of torsion was then 120° + 28° = 148°. But after its contact with the pith ball, it repelled the ball a only to 28°, while the micrometer indicated only 46°, so that the total force of torsion, equal to the repulsive force of the two balls, was only 46° + 28° = 72°. A minute, however, had elapsed between the two observations, and as the dissipation was then 4° a minute, the total force of torsion must be corrected by +4° of 72° or 48° nearly, so that the corrected force of torsion will be 73°, which differs only 4° from 76°, the half of 148° the former total force of torsion which measured the electric repulsion before the electricity of the copper ball was communicated to the ball of elder. Since the distance of the balls, therefore, was in both cases the same, and since the action is directly as the densities of the fluid, and inversely as the square of the distance, it follows, that the pith ball has received exactly one half of the electricity of the ball of copper, and that the ball of copper has no more affinity or elective attraction for the electric matter than the pith ball.

In the second experiment, the electricity was distributed equally between the iron disc and the disc of paper, and by trying various other substances, and repeating the experiments by means of a large torsion balance with globes of five or six inches in diameter, Coulomb always obtained the same result.

In repeating the preceding experiments, we must take care, to avoid the pith of the copper balls to remain a short time in contact, for when one of the substances is an imperfect conductor, several seconds elapse before it is able to deprive the other of half of its electricity. The time in which this distribution takes place, depends not only on the conducting power of the two bodies, but on their relative extent, and on the manner in which the contact is effected. In bringing into contact two circular discs, as in the second experiment, we must take care, that they touch one another symmetrically, or that the surface of the one is in the same plane as the surface of the other. When this precaution is not taken, the electric matter will be distributed unequally between the two discs.

On the superficial distribution of electricity.

We have hitherto seen, that in the communication and distribution of the electric matter, every part of the surface of an electrified body is charged with electricity; we have now to inquire whether this electricity pervades the whole mass of the body, or is merely distributed over its surface. The determination of this point is owing likewise to Coulomb. As a more delicate instrument was necessary for these experiments, he made the following change in his apparatus: Having formed a fibre of gum lac, about 10 or 12 lines long, and nearly as thick as a strong hair, one of its extremities was attached to the top of a small pin without a head, suspended to a silk fibre, such as comes from the silk worm; the other extremity of the gum lac fibre being fixed to a small circle of tinsel about two lines in diameter. When this electrometer is suspended in a cylinder of glass, its sensibility is so great that a force equal to a sixty thousandth part of a grain is sufficient to repel the ball and the needle to a distance of more than 90 degrees. Having communicated a small degree of electricity to the circle of tinsel, Coulomb suspended it in a glass cylinder, so as not to be affected by currents of air. He then took a solid cylinder of wood, four inches in diameter, and pierced with several holes, four lines broad and four lines deep, and having placed this cylinder upon an insulating stand, he gave it several electric sparks, either by means of a Leyden jar, or the metallic plate of an electrophorus. He next insulated, at the extremity of a small cylinder of gum lac a line in diameter, a circle of gilt paper a line and a half in diameter, and with this apparatus he made the following experiments:

Exp. 1. The tinsel of the electrometer being electrified, as we have already stated, he touched the surface of the electrified wooden cylinder by the circle of gilt paper, and upon presenting it to the electrometer, the tinsel was repelled with force.

Exp. 2. He then introduced the circle of gilt paper into one of the holes of the cylinder, so as to make it touch the bottom of the hole, and upon presenting it to the electrometer no signs of electricity were exhibited.

Exp. 3. When it was made to touch it, and consequently received a quantity of electricity equal to that which was contained in a part of the surface equal to that of the small circle. The small circle was not only charged with a quantity of electricity perceptible to the small electrometer, but capable of being exactly measured by it.

In the second experiment, on the contrary, when the small circle was placed at the bottom of one of the holes, four lines below the surface, and twenty lines from the axis of the cylinder, and when it was taken out of the hole, so as not to touch its sides, it exhibited no marks of electricity; and hence it follows that there was no electric matter in the interior of the cylinder, even at the small depth of four lines. On some occasions, the circle of gilt paper exhibited signs of a weak electricity, opposite to that of the cylinder, an effect which Coulomb ascribes to a small degree of electricity received by the gum lac, from its being within the atmosphere of the electrified cylinder. In order to prove that this opposite electricity existed in the gum lac, and not in the circle of gilt paper, he touched the gilt circle, and was not able to destroy its electricity. The opposite electricity of the gilt circle is, however, always very feeble when the gum lac is pure, and when the weather is not very damp.

On the distribution of electricity between two conducting bodies in contact.

In the experiments of Coulomb on this subject, he found it necessary to employ a torsion balance of a larger size than that which is represented in Plate CCXLV. and of a different form. The two balances which he used, are represented in Plate CCXLV. Fig. 1 and 2. In Fig. 1, AB is a square box, formed by four plates of glass, 2 feet long and 15 or 16 inches high, which must be placed upon a table, very dry, and coated with a non-conducting varnish. This square box is covered
with glass, so as to leave an opening for introducing the globe $a$, placed at the end of a small cylinder $ac$ of gum lac, which is terminated upwards in a small cylinder of baked wood, coated with gum lac, and passing perpendicularly through a hole in the piece of wood $cd$, in which it is stopped by a screw $e$. The vertical tube $mn$ from 12 to 15 inches high, is made of glass, and is supported by a frame $pqrs$, carrying a semicircle $t, 0, w$, about four feet in diameter, having its centre coincident with the vertical line $mn$, and divided into two quadrants of 90° each, beginning at 0. The suspending fibre $mn$ carries the piece $uv, w$, to which is attached a thread of gum lac $ub$, terminated in $b$ by a small disk of gilt paper.

Fig. 2. Represents another balance of the same kind, but still more simple. The four vertical and square plates of glass, rise from a groove in a piece of well baked wood. Instead of the semicircle $t, 0, w$, a band of paper $mn$ is pasted on one of the glass plates, and on both sides from 0 is divided into degrees, according to the tangents of a circle, whose centre is the suspending fibre.

The micrometer $m$, at the top of both these balances, does not differ materially from that which has been represented in a former Figure. The head of it consists of two circles, the lowest of which has a space of five degrees divided into single degrees, while the other circle is divided into spaces of five degrees each. These two circles are intended to adjust the needle to the zero of the scale. The suspending fibre in both these balances was a copper wire of the diameter No. 12. in commerce.

In using the preceding apparatus, Coulomb employed two methods for determining the manner in which the electric matter distributed itself between two bodies in contact. In the first, he placed the electrified body in the balance, after having electrified in the same manner the small circle of gilt paper at the end of the needle. The needle being repelled through a certain distance, was then brought back by means of the micrometer to any distance from the electrified body; and the angle of torsion given by the micrometer, added to the distance of the needle from the zero of the scale, measured the repulsive force which the bodies exercised at that distance. The electrified body placed in the balance, was then touched by the body with which it was to divide its electricity; and in unwinding the suspending fibre, the needle was brought back to the same distance from the body as formerly, and then the angle of torsion added to the distance of the needle from zero, measured the quantity of electricity which was left in the body by the other, to which part of its electricity was distributed. In this method, unless the weather is very dry, it is necessary to take into account the dissipation which happens during the interval of observation. The preceding method was employed by Coulomb, when he wished to determine the relation between the quantities of electricity in two bodies; but, in order to measure the electric density in each point of a conductor, he had recourse to the following ingenious method.

In the small balance with which he made his first experiments, he suspended his needle by a fine silver wire. He then formed a cylinder of gum lac, bent as at $ed$ in Fig. 3, and of the thickness of a hair, and to the end of it he attached a circle of gilt paper $c$. After having electrified the disc carried by the needle with an insulated pin as before, he electrified the body upon which the experiments were to be made, and then touched the circle $c$ with the point of the body, whose electrical density he wished to ascertain. He then placed this circle in the balance, and ascertained the quantity of its electricity. Now as this circle is only five or six lines in diameter, and the 18th part of a line thick, the electrical density which it acquires by the tangential contact, is either the same with that of the point which it touches, or proportional to that density. Hence by making this circle touch different points of a conductor, in succession, and by presenting it after every contact to the needle of the balance, taking care that it shall always have the same position, Coulomb was enabled to ascertain the electrical densities of different points of conductors.

In the comparison of succeeding observations, we must obviously take into account the dissipation of electricity by the contact of air, and the method by which this has been done by Coulomb is remarkably simple and ingenious. In order to compare the electrical density of two points, he first touched one of the points by the paper circle, and determined its density by placing the circle in the balance as before. He then touched the second point, and determined its density in a similar manner; and after an interval equal to that which had elapsed between the two touchings, he touched the first point anew, and again determined its density, which was of course less than before, from the effect of dissipation. He then took the mean between the two densities found for the first point, which was therefore the real density at the instant of the second observation, so that the two densities thus measured were free from any error arising from dissipation.

This method, though in general the most convenient and simple, as well as the most exact, is nevertheless affected with an error in practice, arising from the gum lac not being perfectly impenetrable to the electric matter. This error is greatest in damp weather, and with impure gum lac, the least clear being generally the most impenetrable by the electric matter. In order to get rid of this error, it is necessary always to try its non-conducting power, by touching the electrified body with the extremity $e$, and observing if it has any effect upon the needle of the balance; if any sensible change is produced upon the needle, the cylinder of gum lac must be rejected. With these precautions, Coulomb made the following experiments.

4. On the Distribution of Electricity between two Globes of different Diameters, and in Contact.

Having placed in the great balance, Fig. 1, an electrified globe six inches and three lines in circumference, he observed the force of torsion which was necessary to bring back the needle to a distance of thirty degrees from the globe. He then immediately touched the first globe with another globe 2½ inches in circumference, and observed a new force of torsion necessary to bring it back to the same distance: The following were the results which he obtained.
Descriptive Electricity.

On the distribution of electricity between two globes of different diameters, and in contact.

<table>

Now, as the quantities of electricity before and after contact, are proportional to the angles of torsion, it is very easy to ascertain these quantities. In the first experiment the force of torsion, for a distance of 30°, was 145 before contact, and 12 after contact; so that the quantity of electricity taken by the large globe will be 145 - 12 = 133, only 12° being left to the small globe, hence the quantities of electricity possessed by the two globes are as 133 to 12, or as 11.1 to 1.0. In the same manner it will be found that this is nearly the ratio in the other four experiments. Now, the surfaces of two globes, six inches and a quarter, and 24 inches in diameter, are in the ratio of 1.48 to 1.0; hence we may conclude, that the globes are not charged with electricity in a ratio as great as that of their surfaces.

In order to find the electrical densities of the two globes, we must divide the ratio of their surfaces by the ratio of the quantities of fluid which they contain, and the quotients by the ratio of the densities. Thus, in the present case, the electrical density of the small globe will be to that of the great one as 14.3 to 11.1, or as 1.33 to 1.

In this manner Coulomb has obtained the electrical densities for globes of various sizes, and has given the general result of them in the following Table. The mean results were obtained from experiments made by both the methods which we have already described.

**TABLE showing the manner in which the Electrical Fluid distributes itself between two Globes of different Diameters.**

</table>

If any two globes, for example, have radii of 10 and 40 inches, then the ratio of these numbers are as 1 to 4, so that the ratio of their electrical densities will be as 1 to 130; it being always supposed that when they are separated the electricity is distributed uniformly over their surfaces.

5. **On the Density of the Electricity in different Points of two Globes in Contact.**

In order to determine the density of the electric matter in different points of two globes in contact, Coulomb employed the small balance represented in Plate CCXLIV. He placed a small circle of gilt paper, Fig. 7, four or five lines in diameter, at the end of a thread of gum lac cde, fixed to a cylinder of glass or of well baked wood e b, coated with a non-conducting varnish. This cylinder moves up and down in the hole b of the piece of wood A b, and can be fixed in any position by means of the screw s. In comparing the electricity of any two points, the circle of tinsel on the needle of the balance was electrified, and the circle of gilt paper, after touching one of the points, was put into the balance, and the quantity of its electricity measured as before. The electricity of the second point was determined in a similar manner. The electricity of the first point was again determined, after an interval equal to that between the first and second observations, and the mean between the two determinations adopted as free from the effects of dissipation.

**Exp. 1. With two equal Globes each 6 Inches in Diameter.**

<table>
<thead>
<tr>
<th>Repulsive force.</th>

- Globe touched at 180° from the point of contact 19°
- Globe retouched at 90° from the point of contact 17°
- Globe retouched at 180° from the point of contact 18°

Hence, taking the three first observations, the density of the globe at 90° is to that at 180° as 19 to 18, or as 1 to 0.95.

Taking the last, it is to that at 180° as 18 to 17, or as 1 to 0.92.

Mean 1 to 0.95

Exp. 4. *With the same Globes.* When the globes are touched at 20°, or at any point below it, no electricity appears.

By comparing the 2d, 3d, and 4th experiments, we shall have for the ratio of the electrical densities at 20° and 90°, the mean of which and 4.72 formerly found, is 4.78.

The following Table will show at one view the results of the preceding experiments.

When the globes were unequal, and the one half the diameter of the other, the density of the small globe was almost nothing till the distance was 30°.

From 60 to 90 it increases in the ratio of 10 to 17.

From 90 to 180 it increases in the ratio of 75 to 100.

When the small globe was only 1/2 the diameter of the other, the density of the small globe increased.

In the large globe of 8 inches, the density was nothing to the 4th or 5th degrees from the point of contact. It then increased rapidly, and from 90° to 180° it was almost uniform.

From these experiments we may conclude in general, that the more the globes are unequal, the more does the density of the small globe vary from the point of contact to 180°, and the more does the distribution of the electric matter on the great globe approach to uniformity, increasing rapidly from the point of contact, where it is nothing, to the 7th or 8th degree from this point, and being uniform over all the rest of its surface.

In order to compare these experiments with the theory of the distribution of electricity after the law of the inverse duplicate ratio of the distance, Coulomb found it necessary to make some subsidiary experiments, which are well worthy of being detailed as general facts.

Exp. 1. Having placed between two electrified globes of the same size, a small globe, whose diameter was less than the sixth part of the diameter of either, so that all the three were in contact, he found that the small globe, when presented to a very sensible electrometer, gave no signs of electricity, and that however small the middle globe was it possessed no negative electricity.

Exp. 2. When three equal globes, two inches in diameter, were placed in contact in a right line, one of the globes, supported by the pincers Fig. 3, was placed successively between the two others, and on each side of both. In these different positions it was presented to the great torsion balance, and the quantity of electricity being measured, it was found, that when it was placed in the middle it took more electricity than when it was placed at either of the sides in the ratio of 100 to 134. This result is the mean of the experiments made after equal intervals, for the purpose of correcting the error arising from the dissipations.

Exp. 3. Hitherto we have seen that when two globes were in contact, the density at the point of contact and in the adjacent parts was nothing, and was never negative when the two globes were positively electrified. But the moment the two globes are separated, then if one of the globes is smaller than the other, and if the distance of the two globes is not great, the point of the little globe which was in contact with the great globe, will become negative, till they are separated to a certain distance. At this distance, the electricity is again nothing, and by increasing the distance, the same point becomes afterwards positive.

Exp. 4. Having insulated a globe of 11 inches diameter, and also another globe of a smaller size, electrify them and bring them into contact. Let the small globe be then taken to a different distance, and, by means of a very small ball of lead suspended by gum lac, or by means of a circle of gilt paper, touch the small globe at the point where it touched the great globe, and examine in the small torsion balance the nature of the electricity of that point.

When the large globe is 11 inches in diameter, and the small one 8 inches, and both positively electrified, the point of contact of the great globe is always positively electrified, whatever be the distance between the two. The point of contact of the small globe, however, will be negatively electrified, till the distance of the two is one inch. At this distance it becomes nothing, and beyond it its electricity is positive.

If the small globe is only 4 inches in diameter, the other remaining the same, the phenomena are precisely the same; but they take place at 2 inches instead of 1 inch.

When the small globe is only 2 inches in diameter, or less than 2 inches, the other remaining the same, the same phenomena take place, but at the distance of 2 inches and 5 lines.

The following Table contains some curious results, shewing the relation between the mean density D of the largest of two globes after its separation from the small globe, to the density d of the point of the small globe with which it was in contact, R being the radius of the large globe, and r that of the small one.

6. On the Distribution of Electricity among several Globes placed in Contact in a Line.

Exp. 1. When six equal globes of 2 inches in diameter were in one line and electrified, and then examined in the balance, Coulomb obtained the following results:

Density of the first is to that of the second as 1.00 to 1.00.
Density of the first is to that of the third as 1.50 to 1.00.

Hence, the density has been diminished one third from the first globe to the second, and only one fifteenth from the second to the third.

Exp. 2. When twelve globes 2 inches in diameter were placed in a row, and examined as before, the electric density of the first is to that of the second as 1.50 to 1.00.
Density of the first is to that of the sixth as 1.70 to 1.00.

Exp. 3. When twenty-four equal globes 2 inches in diameter were placed in a row, the electric density of the first is to that of the second as 1.60 to 1.00.
Density of the first is to that of the twelfth or middle globe as 1.75 to 1.00.

It follows from these two experiments, that whatever be the number of globes, the mean density varies considerably from the first to the second, but afterwards very slowly, from the second to the middle globe. At equal distances from the extremities of the row, the electric densities are equal, and therefore the density is always least in the middle.

7. Distribution of Electricity over several unequal Globes.

Exp. 1. When two globes 2 inches in diameter were placed in contact with one of 8 inches, the quantity of electricity of the small globe most distant from the great one, was to that of the one in contact with the great one as 2.54 to 1.00.

Exp. 2. When four globes of 2 inches were placed in contact with one of eight inches diameter, the quantity of electricity of the small globe, the most distant from the great one, was to that of the globe nearest the great one as 3.40 to 1.00.

Exp. 3. When five globes of 2 inches in diameter were placed beside another of 8 inches diameter, the ratio of the density of the fourth globe was to the mean density of the large globe as 2.08 to 1.00.

Exp. 4. When twenty-four globes two inches in diameter were placed in contact with one of eight inches, Coulomb compared the twenty-fourth, or the last small globe, with several of the others, and obtained the following results:

The quantity of electricity, or mean density of the electric matter in the 24th globe, is to that of the 23d as 1.49 to 1.00
The quantity in the 24th is to that of the 12th as 1.70 to 1.00
The quantity in the 21st is to that of the 21st or the one in contact with the large globe, as 2.10 to 1.00
The quantity in the 24th is to that of the large globe itself as 3.72 to 1.00.

This last result differs very little from that which we have found for the fourth globe, at the end of a line of four globes of 2 inches, in contact with a globe of eight inches.

8. Distribution of Electricity on the Surface of a Cylinder.

In the following experiments, Coulomb insulated a cylinder 30 inches long, and 2 inches in diameter; and having electrified it, he examined its electrical density in several places by a small circle of gilt paper as before, and obtained the following results:

The density of the middle of the cylinder is to that of its extremity as 1.00 to 2.30
The density of the middle of the cylinder is to that of a point 2 inches from the extremity as 1.00 to 1.25
The density in the middle of the cylinder is to that of a point situated in the hemisphere which terminated the cylinder at an inch from its extremity, as 1.00 to 1.80

Hence it follows, that upon the two last inches at the extremity of the cylinder, the electric density is much greater than towards the middle of the cylinder, and that it varies a little from the middle to within 2 inches of the extremity.

9. On the Distribution of Electricity between a Globe and Cylinders of different lengths, but of the same diameter.

Exp. 1. Having electrified a globe eight inches in diameter, and made it touch an insulated ball nine lines in diameter, Coulomb found its electrical force to be 154", or 150° when corrected for the dissipation. He then quickly touched the eight-inch globe with the cylinder two inches in diameter, and 30 inches long, and upon withdrawing the cylinder, he examined its electricity by the small ball as formerly, and found it to be 68°. Hence 150° of electricity were reduced to 68° by the contact of the cylinder, which therefore took 82° from the electricity of the globe, leaving it only 68°. The quantity of electric fluid, therefore, in the cylinder, is to that in the globe as 62 to 68, or as 1.21 to 1.00. Now, the superficial area of the globe is to that of the cylinder as 50 to 64; consequently, the mean density of the electric matter on the surface of the cylinder, or 1.21/64, will be to 1.00, or as 129 is to 100. This ratio may be stated more accurately as 1.30 to 1.00, which is the mean of a great number of experiments.

Exp. 2. When the cylinder was 15 or even 10 inches long, its electricity was divided with a globe of eight inches in such a manner, that their mean densities were almost exactly in the same ratio of 1.30 to 1.00, as in the preceding experiment. When the diameter of the globe, however, was very large compared with that of the cylinder, and when the cylinder had very little length, then the mean density of the cylinder, relative to that of the globe, was much less than when the length of the cylinder was considerable.

Exp. 3. When a small cylinder, five or six lines in length, and two lines in diameter, was put in contact with a globe of eight inches, the mean density of the electric fluid on the surface of the cylinder was to that of the globe nearly in the ratio of two to one; but
ELECTRICITY.

Descriptive

Electricity.

When the cylinder was only two lines in diameter, and six inches long, the mean density of the cylinder was to that of the globe as 8 to 1.

Exp. 4. When the globe was eight inches in diameter, and 30 inches long; then,

When the diameter of the cylinder was two inches, the mean density of the cylinder was to that of the globe as: 1.00 to 1.30.

When the diameter of the cylinder was one inch, the mean densities were: 1.00 to 2.00.

When the diameter of the cylinder was two lines, the mean densities were: 1.00 to 9.00.

Hence the augmentation of density follows a smaller ratio than the diameters of the cylinders.

Explanation of the action of points.

This experiment furnishes us with a beautiful explanation of the influence of points in dissipating electricity. Points may be considered as cylinders of small diameter and great length. Now, in the preceding experiments, we have seen that a cylinder two lines in diameter, and 30 inches long, had its electric density nine times greater than that of a globe. But when a cylinder was electrified and terminated by a hemisphere, the electrical density of the extremity was to that of the middle of the cylinder as 2.30 to 1.00.

Now, this ratio ought to be greater when the cylinder is very long, and has one of its extremities in contact with a large globe. Suppose, therefore, that the cylinder, two lines in diameter, has its extremity rounded into a hemisphere, the electrical density of the extremity of the axis will be to that on the surface of a globe of eight inches, as 9 x 2.30 = 20.7 to 1.00; but as the air is an imperfect electric, it follows, that in making the small cylinder touch a globe of eight inches diameter, the electric fluid ought to escape by the extremity of the cylinder, with a degree of rapidity proportional to the electrical density of the globe.

When the globes have a diameter much greater than that of the cylinder, eight times greater, for example, or, more, the electrical density of the different globes in contact with the cylinder being supposed equal to the same quantity D, the densities of the electric fluid on the surface of the cylinder, will be to one another as the diameters of the globes. If, for example, we take the globe of eight inches in contact with a cylinder of one inch, we have seen that the density of the globe being D, that of the cylinder is nearly 2 D; but if in place of the globe of eight inches, we put in contact with the same cylinder a globe of 23 inches, and whose electrical density we suppose to be D, then the mean electrical density of the fluid in the cylinder will be nearly equal to 6D.

From the preceding experiments, we may determine the ratio between the electrical density of a globe, and that of a cylinder of any diameter, touching the globe by one of its extremities. It follows, from the results in Exp. 4, that the electrical densities of different cylinders are in the inverse ratio of the power of their diameters, which approaches very much to unity when the diameter of the globe is very much greater than that of the cylinder. For different globes and the same cylinder, the density of the cylinder will be as the diameters of the globes, if their diameter is much greater than that of the cylinder. Supposing D, then, to be the density of the globe, R its radius, d the mean density of the cylinder, and r its radius, we shall have

\[ d = \frac{m \cdot DR}{r^2} \] or \[ d = \frac{m \cdot DR}{r} \]

when R is much greater than r. In this equation, the constant co-efficient \( m \) may be determined from experiments in the following manner.

When a globe four inches radius was in contact with a cylinder 30 inches long, and two lines in diameter, the mean density of the cylinder \( rd \) was \( d = 9 \). But in this case \( R = 4 \) inches, therefore \( d = 48 \); hence \( d = 48 \cdot m \), and \( m = \frac{9}{48} \) the constant co-efficient.

Coulomb has applied this result very beautifully to the phenomena of the electrical kite flying in a thunder-storm, and having its cord made to conduct by a wire, insulated at its lower extremity. The cord of the kite emits sparks with the greatest violence to all the conducting bodies in its neighbourhood. Let us suppose that the cloud charged with the electric fluid has the form of a globe 1000 feet radius; that the cord of the kite is one line in radius; then the mean density on the surface of the cord will be \( d = \frac{m \cdot DR}{r} \), and \( d = \frac{27000}{1000} \times \frac{12}{12} \times 12 \times 12 \times 12 \times 12 = 27000 \). But we have already seen, that the electrical density at the end of a cylinder terminated by a hemisphere, is to the density of the middle as 2.30 is to 100; consequently, \( d = 2 \cdot 30 \times 27000 = 62000 \) D, or 62000 times greater than the density of the fluid which is supposed to reside in the surface of the cloud. It is, therefore, not to be wondered at, that the electric fluid, in a state of such high condensation, should be emitted in sparks on every side.

Exp. 5. Having electrified positively, a globe eight inches in diameter, and also the needle of the balance, he found the electrical density of the globe to be \( 14^\circ \) by means of a small globe one inch in diameter, and then touched the globe with a circular plane 16 inches in diameter and \( \frac{1}{4} \) of a line thick, so that a diameter of the globe was perpendicular to the plane at the point of contact. He again determined the electrical density of the globe by the small one-inch globe, and found it equal to \( 47^\circ \). The electricity of the globe being reduced from \( 14^\circ \) to \( 47^\circ \), the plane obviously carried off \( 14^\circ - 47^\circ = 97^\circ \); so that the quantity taken by the plane was double that which it left in the globe. Now, since the area of a globe of eight inches in diameter, is \( 301.6 \), and the area of both the surfaces of the circular plane \( = 403.2 \), which is exactly double of the former, it follows, that the electricity is distributed between the plane and the globe, in the ratio of their surfaces.

The preceding result was obtained in a great number of other experiments made with globes and planes of different sizes; and the ratio above mentioned was always more exact when the plane was small in proportion to the surface of the globe. A plane, for example, six lines in diameter, when made to touch tangentially a globe of eight inches, takes upon each of its surfaces an electrical density equal to that of the globe, or, what is the same thing, the small plane is charged with a quantity of electricity double that of the portion of the surface of the globe which it touches.

Exp. 6. Having insulated an electrified globe A, eight inches in diameter, and also two equal globes B, C, two inches in diameter, placed at a distance from it, B being insulated upon a cylinder of glass coated, and C being insulated by a vertical support, the same as in Fig. 3.
ELECTRICITY.

If the needle of the balance and the globe A being electrified positively, the attractive force upon the needle of the globe c was found to be exactly equal to the repulsive force of the globe b.

Exp. 7. If we place an uninsulated cylinder at different distances from an electrified globe, so that its axis points to the centre of the globe, we shall have the following result: The electrical density of the extremity of the cylinder nearest to the globe, will be a little below the power 4 of the inverse ratio of the distance of this extremity from the globe.

Exp. 8. In placing successively two cylinders of different diameters at the same distance from an electrified globe, the electrical densities of the extremity of the two cylinders were to one another nearly in the inverse ratio of the diameters of the cylinders, provided that their diameters were much smaller than the diameter of the globe.

Exp. 9. In placing an uninsulated cylinder of a great length at a given distance from an electrified globe, Coulomb found that the electrical density of different points of the surface of this cylinder, were inversely as the square of the distance of these points from the centre of the electrified globe.

This law, however, does not hold upon a part of the cylinder near the globe, equal to four or five diameters of the cylinder. In this portion, the electrical density increases towards the extremity of the cylinder in a ratio much greater; and, if the cylinder is terminated by a hemisphere, the density at the extremity of the axis nearest the globe is nearly double that of a point whose distance from the extremity of the axis is equal to the diameter of the cylinder.

Exp. 10. If an uninsulated cylinder is placed at the same distance from the centre of two electrified globes of different diameters, then, supposing the electrical density of the globes to be the same, Coulomb found that the density of points of the cylinder placed at the same distance from the centre of the two globes, was as the square of the radius of the globes.

By combining the results in the four preceding experiments, Coulomb has found, that the electrical densities of a hemisphere which terminates different cylinders presented to an electrified globe, are of a contrary nature to that of the globe, and in the direct compound ratio of the density of the globe's surface, and the square of the globe's diameter, and in the inverse compound ratio of the power 4 of the distance of the centre of the globe from the extremity of the cylinder, and of the radius of the cylinder. Thus, if D be the positive electrical density on the surface of the globe, whose radius is R; r the radius of the cylinder; a the distance between the centre of the globe and the extremity of the cylinder; then, if d be the negative electrical density of the extremity of the cylinder, we shall have

\[ d = \frac{mDR^4}{r(R+a)^2}. \]

Now, the constant quantity \( m \) was found by experiment to be \( m = 2.07 \sqrt{1 \text{ inch}} \); hence, if the values of \( a, r \) and \( R \) be reduced to inches, we shall have

\[ d = \frac{2.07 DR^4}{r(R+a)^2}. \]

The application of this formula, deduced directly from experiment, to the explanation of the effects of conductors, will be pointed out in the next Chapter.

Exp. 11. If a plane, not insulated, is placed at any distance from an electrified globe, so that the electricity cannot be communicated from the one to the other but across the stratum of air which separates them, then Coulomb found that the electrical densities of a point in the centre of the plane, is of a nature contrary to that of the globe, and is inversely as the square of its distance from the centre of the globe.

CHAP. II.

On the Phenomena of Electricity produced without Excitation.

In the preceding Chapter we have endeavored to give a succinct view of the leading phenomena of electricity as produced by friction: We shall now proceed to direct the attention of the reader to a series of interesting electrical phenomena as produced without friction, either by a change of temperature, by a change of form, or by the contact of dissimilar bodies; or as exhibited in the phenomena of the atmosphere, or in the functions of living animals.

SECT. I. On Electrical Phenomena produced by a change of Temperature.

The property of exhibiting electrical phenomena merely by an increase of temperature, without the aid of friction, is possessed only by regularly crystallized minerals. The tournamal was, for a long time, the only substance which was known to be capable of this kind of excitation; but the same property has since been recognized in the topaz, in calamine or the oxides of zinc, in the borate of magnesia, and in mesotype.

The electrical properties of the tournamal seem to have been known to the ancients. The Lycurium is mentioned by Theophratus, as being a very hard body, as being used for making seals, as requiring a great labour to polish it, and as possessing the same property as amber of attracting light bodies: It is therefore highly probable that this substance was the tournamal of modern mineralogists. In the island of Ceylon, where it is very common, it is known by the name of tourmaline; and it is, first became acquainted with it in this island, gave it the appellation of Askhen-trikki, from its property of attracting ashes when it is thrown into the fire.

In the year 1717, Mons. Lemery of the Academy of Sciences, exhibited a stone from Ceylon, which he said attracted and repelled different light bodies, such as ashes, filings of iron, bits of paper, &c. in a manner different from a lodestone.‡ The experiments of Lemery were merely noticed by Linneus in his Flora Ceylonica, who mentions this stone by the name of Lapis electris.

When the Duke de Noya was at Naples in the year 1743, he was informed by the king's secretary, Count Pichetti, that he had seen at Constantinople, a small stone, called tournamal, which had the singular faculty

‡ This Paper is entitled Observations sur une pierre de l'Isle de Ceylon qui attire et repousse diverses corps, mais d'une maniere differente de l'oiimon.
of attracting and repelling light bodies. The Duke had completely forgotten this circumstance, till the year 1758, when he happened to see some tourmalins in Holland. He immediately purchased these stones, and, in company with Messrs Daubenton and Adanson, he made a number of experiments with them, of which he has published a particular account.

Before these experiments, however, were made, M. âœpinus had been informed by Lechman of the electrical properties of the tourmalin, and had received from him two crystals, on which he made a variety of experiments, which were published in the Memoirs of the Academy of Berlin for 1756, under the title of De quibusdam experimentis electricis notabilioribus. A series of more correct experiments were performed by Mr Benjamin Wilson, with several fine crystals belonging to Dr Heberden; and the subject was prosecuted by Dr Priestly in 1766, with the same tourmalins which had been used by Mr Wilson.

The tourmalin crystallizes in prisms usually of nine plane sides terminated by summits, with three, six, nine, or more faces, and are either of a green or blue colour. At the ordinary temperature of the atmosphere, the tourmalin may be electrified by friction, and the electricity which it thus acquires is always resonious; and when two tourmalins are rubbed against each other, the one is electrified positively and the other negatively.

If we apply different parts of a tourmalin, when excited by a heat between 291° and 212° of Fahrenheit, according to lepineus, to a delicate electrometer, it will be so excited as to exhibit two poles coinciding with the summits of the prism, and one of them possessing positive and the other negative electricity.

If one of the poles of the tourmalin be held near light bodies, such as grains of ashes or saw-dust, these minute bodies will be attracted to the stone, and sometimes repelled as soon as they have touched it.

When two tourmalins are presented to one another, so that the two positive or the negative poles are towards each other, they will mutually attract one another; but if two opposite poles are presented to one another, they will mutually repel each other. In order to make this experiment with success, the two crystals should be either balanced on a fine pivot, or suspended by a delicate fibre, or, what is the simplest method, floated upon two pieces of cork. When the two tourmalins are heated, tie one of them upon a flat piece of cork, and present to one of its poles the two poles of another tourmalin in succession. When two similar poles are towards each other, the floating tourmalin will turn round and present the opposite pole; and when two opposite poles are presented to each other, the floating tourmalin will follow the other in all its motions, just like a floating needle guided by the action of a magnet.

Mr Wilson kept a flat tourmalin about half an hour in a strong fire, but could not perceive any diminution of its electrical property; though he repeated the experiment with another tourmalin. When he brought the stone, however, to a red heat, and plunged it suddenly in cold water, it was not broken to pieces, but had the appearance of being shattered, and lost entirely its electrical property. M. Hauy, however, has found, that when the stone is more and more heated, there is a time when it will cease to yield signs of its electric virtue; and after withdrawing it from the fire, he often found it necessary to leave it to return to a moderate temperature, before it exhibited any action upon the little bodies that were presented to it. "It would seem," says that ingenious mineralogist, "that beyond the time where its electricity has become insensible through the action of too strong a heat, there is another where its effects are reproduced in an inverse sense. We have caused the foci of two burning glass-es to fall upon the extremities of a tourmalin, and have observed that each pole, after having acquired its ordinary electricity, would next cease to act, and lastly, would pass to the opposite state, so that the attraction, after having become zero, would give place to repulsion or reciprocally."

The experiments made by Canton, respecting the effect of heat upon the tourmalin, differ from those of Mr Wilson, and the Abbe Hauy. Having put a tourmalin of the common colour into the fire, and burnt it white, he found that its electrical property was completely destroyed. Another tourmalin, heated in a similar manner, lost only part of its electricity. Two tourmalins when softened by heat, were joined together without losing their electrical property. The polarity of another was increased by having one of its ends melted; and another tourmalin retained its electrical property, after being plunged into cold water when red hot.

To the Abbe Hauy we are indebted for a very beautiful discovery respecting the tourmalin. He found that the electrical density diminishes rapidly from the summits or poles towards the middle of the crystal, and is almost nothing throughout a sensible space towards the middle of the prism. The greatest density which resides in the negative and positive poles, is near the summits. This singular distribution of the electric matter is almost exactly the same as in a cylinder: (See Sect. xi. Art. 8.) In order to observe this property, present the tourmalin to the electrified needle of one of Coulomb's delicate electrometers, or to an insulated electrified needle, finely balanced upon a pivot, and the needle will always be observed to have a marked tendency to one point of the stone, but when the needle points to the middle of the prism, so that it is equidistant from the two poles, the needle will have no motion except a mere fluttering. The following curious experiment is given by the Abbe Hauy. "Let T," says he, "be a tourmalin, having its centre of resinous action placed at A, and its centre of vitreous action at a. Take a stick of sealing wax, at the end of which there is fixed a silk thread of about a centimetre, or four and a half inches in length, by heating the wax at that end, and inserting one extremity of the thread in the part thus melted. If after having rubbed the sealing wax, in which case the free extremity of the thread will acquire resinous electricity, that same extremity be brought in presence of the point R of the tourmalin, and if, at the same time, the latter be made to receive little alternate motions from right to left, and reciprocally, the thread will be seen to bend itself in a contrary direction to avoid the point R; and if the stick be brought a little nearer the tourmalin, the thread will incline all at once, by a curvilinear motion towards the point A. If we afterwards present to the thread the points situated a little beyond A, and all the succeeding ones, between that and the opposite extremity U, attractions will be manifested throughout. But if a thread possessing vitreous electricity be employed, such as that which should be attached to a glass tube, which had been rubbed, on presenting it towards the extre-
ELECTRICITY.

If a tourmalin, when in a state of excitation by heat, is broken into two parts, however small, each fragment has two opposite poles, a phenomenon analogous to what takes place in a broken magnet. Mr. Canton cut a large irregular tourmalin into three pieces, and a piece being cut from the positive, and another from the negative pole, the outer side of the piece which he cut from the negative pole was negative when cooling, and the outer side of the piece which he cut from the positive pole was positive while cooling, the opposite ends of all the pieces possessing a contrary electricity. The middle piece had the same properties as in the outer tourmalins, the positive end remaining positive, and the negative end negative. He obtained the same results from two other tourmalins that had been cut out of a large one. Dr. Priestley, who broke a tourmalin by accident into three fragments, one of which was 96 grains, another 10 grains, and another one grain, found that the largest fragment was not injured by the accident, and its two poles were unaltered.

Mr. Canton found, that if A was the positive pole, and B the negative pole, when a tourmalin was excited by heat, then when the tourmalin was not electrical, but became so by cooling, the pole A was negative, and the pole B positive. Having placed a small tin cup of boiling water on one end of his electrometer, which was supported by warm glass, while the pith balls were at the other end, he dropped a tourmalin into the water, and observed, that during the whole time of its being heated, and likewise during the operation of cooling, the balls were not at all electrified. This result seems, in some measure, to be contrary to the experiment of Mr. Wilson, who covered all his tourmalins with grease, and when each of them was so warm as to preserve the grease liquid, he found their electrical property only a small degree weakened.

The following curious experiment was made by Mr. Wilson. Having brought to a red heat one end of a glass tube, and exposed to it the negative pole of a tourmalin, about three inches of the heated part of the glass was electrified negatively, and all the glass beyond it positively; and this property continued even after the glass was cold. The positive side of the tourmalin was then applied to the same piece of heated glass; he found that the tube was electrified negatively from foot to foot, without the least appearance of positive electricity beyond it, and this negative electricity continued when the glass was nearly cold.

Dr. Priestley made a number of curious experiments with the large tourmalin, which had been used by Mr. Wilson and Mr. Canton, and which had a convex and a flat side; the convex side being always positive in cooling, and the flat side negative. In these experiments, Dr. Priestley placed the tourmalin upon a pyrometer heated by a spirit lamp, in order to ascertain with accuracy whether the temperature was increasing, decreasing, or stationary. Dr. Priestley began his experiments by laying the tourmalin on a plate of glass, and he found that the glass had acquired an electricity equal and contrary to that of the side of the tourmalin, which was in contact with it. A positively electrified feather, for example, was always repelled at the distance of two inches by the flat side of the stone when its heat was increasing, while the glass attracted the feather at the same or even at a greater distance. When the heat was decreasing, the tourmalin attracted the feather, and the glass repelled it at the distance of four or five inches. When the temperature, from increasing, began to decrease, the electricities were often reversed in less than a minute.

Dr. Priestley now tried the effect of heating and cooling the tourmalin in contact with non-conductors and conductors, and hence he was led to a method of reversing all the experiments that have been made upon the tourmalin, so that he could make the electricity of any pole just what he chose, by the application of proper substances.

Instead of the piece of glass already mentioned, Dr. Priestley used a tourmalin, which he found to be affected exactly like the glass.

He next imbedded the negative side of a tourmalin in hot sealing-wax, and when taken out of the wax it had positive, while the wax had negative electricity. The half of the tourmalin which was not in the wax was affected as if it had been in the open air, so that in cooling both sides were positive.

When the tourmalin was cooled in mercury contained in a cina cup, it was always positive when taken out, while the mercury was left negative.

Having fastened the convex side of the large tourmalin to the end of a stick of sealing wax, he allowed it to cool, and then pressed the flat side of it pretty hard against the palm of his hand, and found it to be strongly negative, contrary to what it would have been if exposed to the open air. The stone continued negative till it acquired all the heat that it could receive from his hand, when its power decreased without changing the nature of its electricity. The stone was then allowed to cool in the open air, and it became more strongly negative till it was quite cold. Hence the same side of the stone was negative, both in heating and cooling.

Dr. Priestley then heated the flat side by holding it near a red hot poker, and then touching it with the palm of his hand, and found it to be strongly positive; allowing it to cool in the open air it became negative; and by again touching it with his hand, it again became positive. In this way he made the same side of the stone alternately positive and negative for a considerable time; and when the heat was such, that he could keep it in his hand, it acquired a strong positive electricity, which continued till it was brought to the heat of his hand. Analogous results were obtained by fastening the wax to the flat side of the stone, and using the convex side.

Dr. Priestley made a tourmalin very hot, and having covered it all over to the thickness of a crown-piece with melted sealing-wax, he found that its electrical virtue was as powerful when enveloped in this coating as when exposed to the open air. Having tied the tourmalin in a silk thread, which only touched the edge of it on both sides, he suspended it before a fire, so that it might be heated equally in every part; when it was so hot that he could hardly bear to handle it, he allowed it to remain in the same situation a quarter of an hour, in order to be certain that the heat was equally diffused. By means of a bundle of fine thread which had for some time been held in the same degree of heat, he took off the electricity which the stone had acquired, and continuing it in the same situation, he found that...
ELECTRICITY.

Descriptive Electricity.

it did not receive any new electricity from the heat. Hence he was satisfied of the truth of Mr Canton's remark, that the electricity of the tourmalin derives its electricity, not from heat, but from the circumstance of its changing its temperature. In the same way Dr Priestley confirmed another observation of Mr Canton, that when the tourmalin was heated and allowed to cool without either of its sides being touched, the two sides will retain the same kind of electricity during the whole time of the heating and the cooling of the tourmalin. On some occasions the stone often changes its electricity very slowly, and the electricity which it acquires from diminution of temperature continues many hours without any very sensible increase. In some cases, the electricity acquired by heating may be so strong as to overpower the virtures acquired by cooling, so that both sides of it may exhibit the same kind of electricity during the whole operation. Hence Dr Priestley accounts for the mistake of the Duke De Noya, who asserted, in opposition to Aepinus, that both sides of the tourmalin acquired in every case a positive electricity.

Although the property which the tourmalin possesses of becoming electrical by heat, is strongest in transparent crystals, yet the black and opaque crystals often possess the same property in a high degree. In some crystals, however, which are rendered impure, by the admixture of particles of iron and other bodies, the electricity is very feeble, and sometimes imperceptible. In such cases, the Abbé Hauy frequently found that a fragment detached from the mass possessed polarity when it was not exhibited by the entire crystal, and when the fragment was taken from the part which approached most to the vitreous state. Hence mineralogists have committed a great mistake, in dividing the tourmalin into those which are electrical and those which are opaque. M. Emmerling, in his Treatise on Mineralogy, has attempted to make a different distinction, by maintaining that the electrical shool or tourmalin, is the only one which loses its electrical property by being too much heated. M. Hauy has carefully examined this supposition, and has found that green as well as black tourmalin retain their virtue after being brought to a red heat. He found also, that when the heat was very great, both the electrical and the black school were deprived of their polarity.

3. On the Electricity of the Borate of Magnesia.

In the year 1791, M. Hauy obtained two crystals of that species of the boracite or borate of magnesia, which he calls defective, (Magnesia Boraté Defective; see our article Crystallography, vol. vii. p. 474. col. 2.) He exposed them to the heat of the fire, and presented them to an electrometer. * He immediately perceived that it was electrified, and that it had several poles endowed with opposite electricities. He experienced at first considerable difficulty in determining the precise position of these poles, both from the delicacy of the experiment, and from the extreme smallness of the crystals. By comparing, however, the crystals with the tourmalins, he reasoned in the following manner: As in the case of the tourmalin, there was only one axis which coincided with that of the nucleus, there ought only to be two electrical poles situated at the extremity of this axis in the cube, on the contrary, which was the nucleus of borate of magnesia, there were four axes, each of which passed through the solid angles, and consequently there ought to be 8 electrical poles, one at the

* This electrometer will be described in Part II. of the present article.
ELECTRICITY.

On the electricity of the borate of magnesia, is, in general, perceptibly weaker than that of the tournalin; and in repeating the experiments of Hauy, particularly those which relate to the poles that exercise a repulsive force, the small needle, negatively electrified, must be directed to the negative pole; for as the repulsive forces are limited to a very small space, the least deviation of the negatively electrified needle will cause it to be attracted by the adjacent parts of the stone, which are nearly in their natural state of electricity.

M. Hauy likewise found that the centres of action of the poles of this mineral are situated very near the extremities of the axes, and that from these poles the electrical density diminishes rapidly, and disappears in other parts of the crystal, a result which he had before obtained from the tournalin. See Hauy Annales de Chimie, tom. ix. p. 59, &c.; Hauy Ann. de Mus. xvi. p. 1.; Hauy Traité de Mineralogie, tom. ii. p. 342.; and Traité de Physique, tom. i. See also Art. 6. of the present Section.

4. On the Electricity of Mesotype.

This mineral is a species of zeolite, and was found by M. Hauy to possess the property of being excited by electricity. Unfortunately he could not obtain complete crystals; but having detached from its support a crystal about 5¼ lines in length, he heated it, and presented it to a silk thread negatively electrified. The thread was instantly attracted by the pyramidal summit of the crystal, and repelled by the fractured part; hence it follows, that the pyramidal summit possessed negative electricity. Stillbite is not electrical by heat.

5. On the Electricity of Calamine.

This mineral has been long found in the mines of Spath seleniteus, and was mistaken for zeolite by several mineralogists, till M. Pelletier * proved that it was crystallized calamine. M. Hauy, so early as the year 1785, discovered the electrical property of this mineral, which is the more remarkable as it belongs to the class of metallic substances.

The crystals of calamine are so easily excited, that their polarity appears in two or three seconds after they are exposed to a fire or to the flame of a candle, and they often retain this polarity several hours after they are cold. In one group of these crystals, sensible indications of electricity were distinctly visible twelve hours after they were cold, while a tourmalin, excited at the same time, had lost all its polarity in the course of a single hour. In another species of calamine, where the crystals were similarly grouped, but presented points of octahedrons, Hauy found the same electrical property. See Hauy, Mem. Acad. Par. 1785, p. 207.; and Hauy Traité de Mineralogie, vol. iv. p. 164.

We are wholly indebted to M. Hauy for the fine discovery that the polarity which minerals receive from heat, is related to the form of their secondary crystals.

The opposite and corresponding sides of crystals are in general similar, both with respect to the number, the disposition, and the figure of their faces. The forms of crystals, however, that become electrical by a change of temperature, deviate from this symmetry of form; so that the poles or parts of the crystal where the opposite electricities reside, although they are similarly situated at the two extremities of the secondary crystal, yet they differ in their configuration; "one of them undergoing decrements which are consequent upon the opposite part, or to which decrements correspond that are subjected to another law, a circumstance which may enable an observer to predict before hand, simply from the inspection of the crystal, on what side either species of electricity will be found; when the crystal shall be submitted to the test of experiment. Thus in the variety of the tournalin which we shall call isogone, and which is represented by Fig. 5, the shape is that of a prism of nine plane sides, terminated at one end by a summit having three faces, and at the other by a summit having six faces; and experiments prove, that the first summit is the seat of resinous electricity, while the second manifests vitreous electricity.

In the new variety of topaz crystals, viz. the octosex-detenimal amethystate of silesia, M. Hauy has recently detected the same deviation from the rules of symmetry in the secondary form of its crystals. Owing probably to the imperfect state of these crystals, he has not been able to observe the same phenomena in the secondary forms of mesotype and calamine.

But of all the crystals that exhibit this co-relation between the exterior configuration and the electric virtue, the most remarkable are those which appertain to an acidulating substance, named borate of magnesia, whose form is generally that of a cube incomplete in all its edges, and farther modified by facets corresponding to the solid angles. Here the two electricities act according to the directions of four axes, each of which passes through two opposite solid angles of the cube, which is the primitive form. In one of the varieties, Fig. 6, which we shall call defective, one of the two solid angles situated at the extremities of the same axis is entire; the other has given way to a facet r. Now resinous electricity is evinced at the angle, which has not undergone any alteration; and vitreous electricity at the facet, which supplies the place of the opposite angle; thus making eight electric poles, four for each species of electricity. In another variety, Fig. 7, the solid angles analogous to those of the preceding which were supplied by the facet, continue to present the same modification. The other angles situated similarly to those which were entire, are here replaced each by a like facet s; but if it existed alone, the symmetry would be found re-established, while the law of the phenomenon requires that it should be altered. Therefore, three other facets r, r, s, are observed to be situated about each of the former; so that the angles which they modify, present in this respect a kind of superabundance, in consequence of which this variety has been denominated superabundant borate of magnesia.

* Journal de Physique, December 1783.
Sect. II. On the Electricity produced by the melting of
Resinous Bodies.

ELECTRICITY.

Mr. Stephen Gray was the first person who observed that electricity was produced, when bodies merely changed their form. He made his experiments with black and white rosin, stone pitch, shell or gum lac, bees wax, and sulphur. These bodies were compounded in different ways, so as to form the substances in the following Table: the first column of which contains the name of the substance, either simple or compound; and the second its weight.

Names of the Substances. Weight.
1. Fine black rosin 20
2. Stone pitch and black rosin 22
3. Fine rosin and bees wax 21
4. Stone pitch 17
5. Stone sulphur 30
6. Shell lac 100
7. Fine black rosin 104
8. Bees wax and rosin 90
9. Rosin 4, and gum lac 1 part, 100
10. Sulphur 180
11. Stone pitch 1012
12. Black rosin 230
13. White rosin 712
14. Gum lac 1114
15. Gum lac and black rosin 912
16. Gum lac 4 parts, rosin 1 part 178
17. Shell lac, fine black rosin 234
18. A cylinder of stone sulphur 194
19. A large cake of stone sulphur 300
20. A cake of sulphur 114

All the bodies in the preceding Table, excepting Nos. 18 and 19, were prepared in the following manner: They were melted in the proper quantities in iron ladles, and as soon as they were taken off the fire, they were set by to cool and harden. The ladle was then placed on the fire for a short time, till the substance was melted at its bottom and sides, and, by inverting the ladle, the substance was easily taken out, and had the form of nearly the section of a sphere, both the convex and the plane surfaces being polished in cooling.

When any of these substances were taken out of the ladle, and their convex surfaces hardened, they did not exhibit any electrical indications, till their temperature was diminished to nearly that of a hen's egg when newly laid. The electricity gradually increased, and when they were cold, it was nearly 10 times greater than at the preceding temperature. In order to preserve these bodies in a state of attraction, he wrapped up the larger ones in white flannel, or black worsted stockings; and the smaller ones in white paper, and placed them all in a large fir box.

The cylinder of sulphur, No. 18, was formed by melting the sulphur, and pouring it into a cylindrical glass vessel, which had been previously heated to prevent it from cracking. As soon as the sulphur was hardened, it fell out of the glass by inverting it, from having contracted during cooling, and had a surface as perfectly polished as the glass itself. The large cone of sulphur was made in a similar manner, by melting the sulphur in a large drinking glass. Mr. Gray examined all the bodies 30 days after they were made, and found that they attracted as vigorously as they did at first, and some of them did not lose their attraction till after 4 months. The cone of sulphur, No. 19, began to attract about two hours after it was taken out of the glass; and the glass itself attracted likewise, but very feebly. On the following day, when the sulphur was taken out of the glass, its attraction was very strong, and that of the glass imperceptible. The cone of sulphur was in these cases placed with its base on the top of the fir box, where the other electric bodies lay, and the glass placed over it; but finding this place inconvenient, Mr. Gray removed it to the table, between the two windows of his chamber, and whenever the glass was taken off, it attracted at as great a distance as the sulphur. Afterwards, the glass attracted at a less distance than the sulphur. The cake of sulphur, No. 20, was laid with its flat side downwards upon a table, and though it had no covering of any kind upon it, the attraction of this, as well as that of the other substances, always varied with the weather; but the attraction of the cake of sulphur was never more than one-tenth of that of the cone. Mr. Gray observed all these attractions, by the action of the electrical bodies upon a fine white thread tied to the end of a stick.

Experiments similar to those of Mr. Gray were made by M. Wilcke of Rostock, who called the electricity which was in this way produced, spontaneous electricity. Wilcke made experiments on the same subject; but as we have already given a sufficiently full account of these in our History of Electricity, p. 423, 424, it is needless to repeat them in this place.

Mr. Henley repeated the experiments of Mr. Gray, and obtained nearly similar results. He discovered that electricity was exhibited by chocolate, when it was cooled in the tin pans into which it is received. At first the electricity is strong, and it is retained for some time after it is taken out of the pans, though it soon loses it by handling. When it is again melted and allowed to cool, the electrical virtue is restored, but not to its former strength. After the third or fourth melting, however, the electricity is extremely weak. When the chocolate is mixed with a little olive oil before it is poured out of the pan, it then becomes strongly electrical.

These experiments of Mr. Henley were repeated and verified, in 1784, by M. Pabst, and in 1787 by M. Liphardt of Konigsberg. The last of these writers being at one time occupied in preparing chocolate, placed some cakes upon one another, and having held a bundle of silk threads within two inches of them, they were attracted with great velocity, and adhered to the cakes. M. Liphardt also found that tallow melted and cooled gave electrical symptoms. Thinking that electricity could not be produced without friction of some kind, M. Liphardt took four ounces of warm and liquid chocolate, and having placed them upon an iron plate, he brought near the silk threads, but observed no indications of electricity. He then put the mass into shape, and having struck it well against a flat surface, as is the custom in extending the chocolate, he took it warm out of the shape, and found it to be electrical.

M. Liphardt made also some experiments on the electrical effects produced by a sudden blow. He let fall a piece of sealing-wax, from the height of 8 inches, upon a table, and repeated this from 10 to 20 times, when it exhibited marks of electricity. Gun copal

* See Phil. Trans. 1737, vol. xxxvii. p. 293.
From these experiments their ingenious authors conclude, that the electricity is produced by the friction which the electrical bodies undergo when they are spread upon the surfaces of other bodies upon which they are poured when in a liquid state.

M. Chapital discovered, that electricity was developed during the congelation of glacial phosphoric acid. The same property has been found in calomel, when it fixes by sublimation to the bottom of a glass vessel.

Sect. III. On the Electricity produced by Evaporation.

We have already seen in our History of the Science, that Laplace, Lavoisier, and Volta discovered that electricity was generated during the evaporation of various fluids.

In their experiments they made use of two different kinds of apparatus. In both of these, the bodies that were evaporated were insulated by means of stands of glass coated with sealing wax. When the disengagement or the absorption of the electric matter was believed to be instantaneous, the body was made to communicate directly with the electrometer by means of a chain or a thread of arcell; but when the electric matter was supposed to be disengaged slowly, and continued for a certain time, they made use of Volta's condenser, which has the property of accumulating small quantities of electric matter.

Having put iron filings into a vessel with a large aperture, they poured upon them sulphuric acid weakened with three parts of water. After a brisk effervescence, and the rapid disengagement of inflammable air, the condenser was so powerfully electrified, that it afforded a lively spark, and they found from the electrometer that the electricity was negative.

When sulphuric acid was, in like manner, thrown into some vessels that contained powdered chalk, fixed air was rapidly disengaged, and the condenser and electrometer indicated that the electricity was negative. It was, however, less than in the preceding experiment, and produced no sensible spark.

When nitrous gas was produced, they obtained a similar result; but in order to increase the electricity, they used six vessels at once, each containing iron filings, and they poured over them nitrous acid dissolved with about two parts of water. The effervescence and the production of air were extremely rapid, and negative electricity was distinctly produced; but as the circumstances under which the experiment was made were not favourable, the electricity was very weak. Three small clay vessels filled with burning charcoal were next insulated, and made to communicate with Volta's condenser.

The negative electricity which was generated was so sensible, that by augmenting the quantity of charcoal they could easily have obtained from it a spark.

The next experiments were made upon the evaporation of water, produced by throwing it upon three insulated furnaces of hampered iron, which communicated with the electrometer. In three successive experiments the electricity was distinctly perceptible. In
In order to account for the positive electricity generated in the first experiment, M. Saussure conjectured that the intensity of the heat to which the water was exposed by the contact of a body brought to a white heat, was the cause of the electricity produced by the evaporation, and that a combination was then formed, by which a new quantity of the fluid was developed. The quantity of electricity was so great in the experiment, that the balls of the electrometer were separated to the greatest possible distance. In order to verify this conjecture, that the electricity was produced in some way or other by the combustion of the water or the iron, Saussure tried to procure positive electricity, by moderating the heat of the iron. Into a large insulated iron crucible, five inches high, four in diameter, and six lines thick, and made red-hot, he threw small quantities of water successively, till the crucible had the degree of heat sufficient to make water boil. The electricity produced at each projection of the water was carefully observed, and destroyed. The electricity which was exhibited was always positive. It was very strong at the first projection, and gradually diminished to the twelfth, when it was scarcely perceptible. In the repetition of this experiment, Saussure found that when a small quantity of water was thrown into the crucible the moment it was taken from the fire, and while it had a pale red colour approaching to white, he could not obtain any indication of electricity.

In order to examine the relations which existed between the periods of evaporation and the production of electricity, M. Saussure made a great variety of experiments. His apparatus consisted of a well-baked vessel of clay, 4 inches in diameter, and 15 lines thick, which he insulated upon a clean and dry goblet of glass. Upon the vessel of clay he placed a crucible, or any other body powerfully heated, and by means of a wire he connected this crucible with the electrometer. Fifty-four grains of distilled water were thrown upon the heated crucible, and by means of a time-piece and an electrometer he observed the period of evaporation, and the degree of electricity that was produced. The results which he obtained are given in the following Tables.

The first column of all the tables contains the number of projections of water that were made. The second the number of minutes and seconds that had elapsed from the commencement of the experiment, or from the time of the first projection to that of the corresponding projection. The third column expresses in seconds the time which was necessary to reduce the 54 grains of distilled water to the state of vapour. The fourth expresses in lines and tenths of a line, the distance of the balls of the electrometer. The fifth marks the character of the electricity which was produced; and the sixth contains general remarks on the state of the crucibles, the vapours, and the noise which was made during evaporation. This noise undergoes great variations. It is almost nothing when the metal is very hot, and it increases as the metal becomes colder, and dissipates more readily the projected fluid.

The following Table contains the results which were obtained, when the crucible was made of forged Iron, 2½ inches in diameter, 22 lines high, 2½ lines thick, and weighing 25½ ounces.

</table>

In the preceding Table, the electricity is still always positive, and is strongest when the time of evaporation is a mean between the shortest and longest times. When the copper was very much heated, the water, where it came in contact with the metal, was convex like a surface of mercury or glass. Sometimes the water appeared immoveable; at other times it turned horizontally upon itself with great velocity; and at other times threw from one of its points a little jet accompanied with a hissing noise, as if that point alone had been touched by
A heated body. In a second experiment made with the same Copper crucible, and under the very same circumstances, the electricity was at first negative at the end of the first projection, but afterwards became positive, and remained so till the experiment was completed.

In order to make the experiment with a metal that was not altered by the contact of water, Saussure employed a crucible of very pure Silver, 2 3/4 inches in diameter at top, 1 1/4 inch in diameter at bottom, 1 1/4 inches high, 1 1/16 line thick, and weighing 10 ounces.

| Table IV. Showing the Electricity produced by the Evaporation of Water placed on a heated Crucible of pure Silver. |
|---|---|---|---|---|
| Number of Projections | Time of the Projection | Duration of the Evaporation | Degree of Electricity | Character of the Electricity | General Observations |
| | Min. Sec. | Seconds | Lines. Tenths | | |
| 1 | 0 0 | 306 | 0 0 | Negative. | The crucible of a lively red colour; at first a small whistling noise, then silence, and a continual turning round of the water. |
| 2 | 5 30 | 73 | 0 3 | Idem. | Whistling noise, crackling, and vapour. |
| 3 | 7 30 | 19 | 0 2 | Idem. | Great noise, and great vapour. |
| 4 | 8 30 | 145 | 0 1 | Idem. | The evaporation terminates without ebullition. |

In this experiment, the evaporation was very slow, and the electricity, which was always very feeble, was thrice negative, and thrice nothing during the interval of 5 minutes and 6 seconds at the time of the greatest heat. In a second experiment with the same crucible, the evaporation lasted 6 minutes and 15 seconds, and the electricity was also negative at the first projection, but it became positive at the second projection, and vanished at the third. In a third experiment, the electricity was stronger, and was at first negative, when the balls of the electrometer separated 3 lines. It then was positive, and the balls separated 6 parts of a line, and at the third projection it was still positive, and the separation of the balls was so much as 6 lines. Saussure now employed a cup of White Porcelain, and surrounding it with sand in a clay crucible, and having brought it to a white heat, he kept it in the clay pot during the experiments.

| Table V. Showing the Electricity produced by the Evaporation of Water placed on a heated Crucible of white Porcelain. |
|---|---|---|---|---|---|
| Number of Projections | Time of the Projection | Duration of the Evaporation | Degree of Electricity | Character of the Electricity | General Observations |
| | Min. Sec. | Seconds | Lines. Tenths | | |
| 1 | 0 0 | 0 | 0 6 | Negative. | The cup reddish, with little noise. |
| 2 | 0 20 | 5 | 0 7 | Idem. | Boiling, and vapour visible. |
| 3 | 0 40 | 7 | 0 8 | Idem. | Idem. |
| 4 | 1 0 | 7 | 0 5 | Idem. | Idem. |
| 5 | 1 30 | 9 | 0 2 | Idem. | The cup ceases to be red. |
| 6 | 2 0 | 9 | 0 2 | Idem. | Constant boiling, and vapour. |
| 7 | 2 30 | 14 | 0 2 | Idem. | Idem. |
| 8 | 3 0 | 25 | 0 4 | Idem. | The cup cracks. |
| 9 | 3 30 | 35 | 0 0 | Idem. | The vapour came out of the sand. |

The rapidity of evaporation in the porcelain crucible is very remarkable. Saussure repeated the experiments twice with different porcelain crucibles, and obtained the very same results, both with regard to the evaporation, and to the degree and kind of the electricity which was produced.

Saussure made his next experiments with Alcohol instead of water. The following results were obtained with the silver crucible formerly used, and with the same quantity, viz. 5 1/2 grains of distilled water.

The interesting results given in the preceding Table, induced Saussure to try a still more volatile fluid, and he obtained the following results by means of Ether, projected in measures of 5½ grains into the same crucible of pure silver, which was placed in a clay pot and surrounded with sand, in order to preserve its heat.

ELECTRICITY.

Sauvage was greatly surprised at observing two such inflammable fluids as alcohol and ether following the same laws in their evaporation as water. The evaporation was always greater at the time of the strongest heat, than when the heat was weakest. It then diminished to a certain point, and afterwards augmented till the heat was feeblest. In the ether too, the combustion had no sensible influence on the rapidity of the evaporation.

Sauvage now wished to observe the phenomena of evaporation in a crucible almost wholly shut. He therefore took a grenade 8 inches in diameter, and brought to a white heat, and injected into it distilled water. A jet of brilliant flame was emitted from the mouth of the grenade. A similar effect was produced at the following projections, till the heated grenade had the colour of a cherry; but the brilliancy and heat of the flame diminished gradually with the heat. Sauvage supposes that the flame arose from the inflammable air, produced by the decomposition of the water, or by that of the iron. Whenever there was any flame, there was no appearance of electricity; but as soon as the flame ceased, the electricity appeared. The electricity was always positive at the first experiment, but in the second it appeared at first negative, and then nothing, when the small measure of water was projected into the grenade; but when half an ounce of water was thrown into it, the electricity was positive.

In order to explain the preceding experiments, M. Sauvage supposed that the electricity is positive with those bodies that are capable of decomposing water, or of being themselves decomposed by their contact with the water, and that it is negative with those which are not decomposed or altered. This supposition was suggested by the fact that china and silver always produced negative electricity, while iron and copper gave positive electricity. If substances capable of being oxidized, had constantly given a positive electricity, while those which do not oxidize had given a negative electricity, the preceding supposition would have acquired a great degree of probability; but the phenomena have not always followed this law, a negative electricity being sometimes produced by the iron and the copper, and a positive electricity by the silver. Sauvage remarks, that he was not much embarrassed by the first of these facts, for the iron and the copper are oxidated with great facility in a brisk fire, and become covered with a scaly crust, which, with the same degree of heat, is not susceptible of farther alteration. If this crust should therefore cover the bottom of the crucible, the drop of water will no longer be in contact with an oxidable substance, and therefore no further decomposition will take place, and consequently no farther generation of electricity. A part of the natural electricity, however, of the apparatus, will be absorbed by the vapours which are still formed, and therefore the apparatus will be electrified negatively. If, by any accident, some of the scales should be so far detached that the fluid will touch some parts of the metal, it may happen that the quantity of electricity thus generated compensates exactly for that which the vapours absorb, and consequently, the electricity will be nothing. If the scales are still more detached, the electricity will be superabundant, and consequently positive. If the same reason a larger quantity of water gives constantly a positive electricity, when it is poured into an iron or copper crucible, because it attacks the metal in a greater number of parts, and finds more easily the parts accessible to its action. Hence, also, a strong positive electricity is produced when a mass of red hot iron is thrown into water, for the points of contact being more numerous, a more abundant decomposition takes place.

Sauvage found it more difficult to explain why silver sometimes gives a positive electricity. He conjectured, however, that it arose from foreign bodies, such as copper or other oxidizable metals being mixed with the silver. This conjecture originated in his observing, that though the crucible was extremely clean, and the distilled water very pure, yet when the water was reduced to a drop, by evaporation, the drop always appeared blackest, and left a brown or black globule after the evaporation was completed.

In order to verify this explanation, he boiled spirit of salt in his silver crucible, and after having washed it with much care, he found that the electricity which it produced was always negative, even when he projected half an ounce of water into the crucible.

He also observed, that when quartz, brought to a white heat, was plunged in water, positive electricity was produced; a result which he ascribes to a small quantity of iron which may have existed in the quartz.

The production of negative electricity by burning charcoal greatly perplexed our author. In his first experiments he found the electricity to be positive, but observing that Volta had found it to be negative, he discovered the cause of his mistake, and afterwards obtained the same results as those of Volta. He supposes that it may arise from the readiness with which that substance loses its heat in contact with water.

Sauvage endeavoured to obtain electricity from combustion, but his attempts were fruitless, although Volta had obtained distinct indications of it in similar cases. He burned different bodies upon an insulated chafing-dish, sometimes with a clear, and sometimes with a smoking flame; and he endeavoured suddenly to explode small heaps of gunpowder, but no electricity whatever appeared.

His attempts to procure electricity without ebullition were equally fruitless. He exposed great surfaces, such as six square feet of wet linen, before a large fire, and insulated it by silk cords. When the linen was strongly heated, a greater quantity of vapour was produced than in a coffee-pot boiling on a chafing-dish, and though he used the most delicate electrometer, yet no electricity could be seen. He likewise spread out on the moist ground a large plate of white iron, and heated it strongly on a chafing-dish, but though the earth exhaled a great quantity of vapour, no electricity was produced. See La Place and Lavoisier, Mem. Acad. Par. 1781, p. 292; Volta, Journal de Physique, 1783; and Sauvage, Voyages dans les Alpes, 8vo, 1786, tom. iii. p. 316—347.

SECT. IV. On Electricity produced by a separation of Parts.

One of the most singular electrical phenomena which belongs to the present Section, is the evolution of electrical light by the bursting of the unannealed glass teardrop, called Prince Rupert's drops; a fact which was discovered by Dr Brewster. These drops, which he found to possess the property of transpolarizing light, were regularly crystallised, and had three different cleavages: one like that of a melon, diverging from the apex of the drop; another concentric with the surface of the drop; and a third oblique to the axis. Having laid one of these drops upon a table in a dark room, and covered it with a plate of thick glass, to prevent any of the electrical light from the bursting of unannealed glass drops.
ELECTRICITY.

Fragments from reaching the eye, the drop was burst by breaking off a part of its tail, and the whole of it appeared luminous; so that at the instant of the fracture, a quantity of light, of the same shape and size as the drop itself, was distinctly visible. The drop which gave this singular result was made of flint glass, and was the largest that he had ever seen. Every other flint glass drop produced a distinct electrical light; but in none of them, except the large one, could he see the luminous shape of the drop. The same light appeared when they were burst under water.

The small glass drops made of bottle glass never exhibited any light at the moment of bursting; but it was almost always visible in small sparks, in bottle glass drops of a larger size.

A similar phenomenon is exhibited in Muscovy tale, when its lamina are suddenly torn asunder. Electricity is immediately developed, and a bright flash of light is exhibited.

Mr. William Wilson found, that if a piece of dry and warm wood is suddenly split asunder, the two contiguous surfaces are electrified, the one positively and the other negatively.

When a stick of sealing wax is broken in two, the two fractured extremities are distinctly electrified, the one end positively, and the other negatively.

Connected in some measure with the preceding results, are those which were obtained by Mr Wilson respecting the electricity of wood shavings. Having had frequent occasion to work very dry wood that had lain for several hours over a large fire, Mr Wilson often observed the shavings adhering to the tools, and to every thing that they touched. He therefore instituted a set of experiments, for the purpose of ascertaining the origin of the electricity, and obtained the following general results. When dry wood was scraped with a piece of window glass, the shavings always exhibited positive electricity. When the wood was chipped with a knife, the electricity of the chips was positive when the wood was hot, and the edges of the knife not very sharp, but negative when the wood was perfectly cold. When the edge of the knife was very sharp, the chips were negatively electrified whatever was the temperature of the wood. Having insulated a penknife, by fixing it into a glass tube covered with sealing wax, he found that it always possessed an electricity contrary to that of the chips, which were most frequently positive. The surface of the wood from which the chips were detached was seldom electrified, and when it was, the electricity was always very weak, and of the same denomination as that of the weakest of the other two. See Thomson's Annals of Philosophy, vol. iv. p. 448. Nicholson's Journal, 8vo, vol. iv. p. 49—53.

Sect. V. On the Electricity produced by dropping Powders on a Metallic Plate.

Mr Cavallo and Mr Bennet have shewn, from numerous experiments, that when electrics or conductors are reduced to powder, the powders may be rendered electrical, merely by dropping them on an insulated plate.

Mr Cavallo insulated a metallic plate upon a glass stand, and connected it with a cork ball electrometer. He held the powder to be tried in a spoon, about one inch above the plate, and allowed it to fall gradually. The electricity acquired by the powder was thus communicated to the plate, and thence conveyed to the electrometer. When the powder of a conducting substance was used, it was placed in some electric substance, such as a glass phial, or a plate of sealing wax.

In making such experiments, it is necessary to have the powders dry and warm as possible, otherwise no signs of electricity will be observed. With these precautions, Mr Cavallo obtained the following results. Powdered resin let fall from a metal spoon, glass, or paper, communicates a strong negative electricity to the plate; and when the spoon, or body which held the powder, was insulated, it was strongly positive. Flowers of sulphur electrified the plate negatively, but not so strongly. Powdered glass, dropped from a warm and dry piece of paper, communicated a negative electricity to the plate, but it was weaker than that of the resin. When it was dropped from a brass cup, the electricity was very weak but positive. Steel filings, dropped either from paper or from a glass phial, electrified the plate negatively; but brass filings, let fall under the same circumstances, electrified it positively. Gunpowder, very fine emery, and the amalgam of tin-foil and mercury, when dropped from a glass phial, electrified the plate negatively; whereas mercury itself, let fall from a glass phial, electrified the plate positively. Soot, and the ashes of pitchcoal mixed with small cinders, when dropped from a piece of paper, electrified the plate negatively.

Mr Bennet found, that powdered chalk falling from one plate to another placed upon his electrometer, electrified it negatively; and the same effect was produced by red ochre, yellow resin, coal ashes, powdered crocus metallosum, aurum mosaicum, black lead, powdered quicklime, amber, lapis calaminaris, Spanish brown, powdered sulphur, flowers of sulphur, iron filings, rust of iron, and sand.

The most accurate experiments, however, which have been made upon this subject, we owe to Mr Singers, who employed two methods of bringing the bodies into contact: 1st, By sifting the powders on the cap of a delicate electrometer through a fine sieve, which was immediately cleaned after every experiment; and 2dly, By bringing an insulated copper plate repeatedly in contact with the powders, spread out into an extensive surface on a dry sheet of paper. By the first of these methods he obtained the following results.

Negative electricity was produced by the following bodies, when sifted on the cap of an electrometer.

Copper,
Iron,
Zinc,
Tin,
Bismuth,
Antimony,
Nickel,
Black lead,
Lime,
Magnesia,
Barytes,
Strontites,
Alumine,
Silex,
Brown oxide of copper,
White oxide of arsenic,
Red oxide of lead,
Litharge,
White lead,
Red oxide of iron,
Acetate of copper,

Sulphate of copper,
Sulphate of soda,
Phosphatic of soda,
Carbonate of soda,
Carbonate of ammonia,
Carbonate of potash,
Carbonate of lime,
Muriate of ammonia,
Common pearl ashes,
Boracic acid,
Benzolic acid,
Oxalic acid,
Citic acid,
Tartaric acid,
Cream of tartar,
Oxymuriate of potash,
Purp. vitri.of mag.,
Sulphur,
Sulphuret of lime,
Starch,
Oxypotash.
Positive electricity was produced by the following bodies when sifted on the cap of the electrometer.

- Wheat flour,
- Oatmeal,
- Lycopodium,
- Quassia,
- Powdered cardamom,
- Charcoal of wood,
- Sulphate of potash,
- Nitrate of potash,
- Acetate of lead,
- Oxide of tin.

When the bodies in the two preceding Tables were sifted either through a sieve of hair, flannel, or muslin, the same kind of electricity was always produced.

In applying the second method, Mr. Singers broke the pure alkali into small pieces, and exposed them in an open phial, for a quarter of an hour, to a moderate heat, which was not great enough to fuse the alkali. It was then quickly reduced to powder in a warm and dry mortar, and instantly distributed over a dry sheet of card paper, which, during a certain time, he found to attract the moisture from the alkali, as fast as the alkali attracted it from the air. In this way he obtained the following results, the copper plate being always electrified in an opposite manner to that of the powders.

**Positive Electricity.**

- Lime,
- Barytes,
- Strontites,
- Magnesia,
- Pure soda,
- Pure potash,
- Common pearl ashes,
- Carbonate of potash,
- Carbonate of soda,
- Tartaric acid.

**Negative Electricity.**

- Benzoic acid,

- Sulphur,
- Rosin.

From the circumstance of sulphur and rosin giving the same kind of electricity when touched with a copper plate, as that which is produced by friction, Mr. Singers supposes, that the contact of dissimilar bodies is in general the primary source of electrical excitation.

**Sect. VI. On the Electricity produced in the Electric Column discovered by De Luc.**

As the electricity generated in the electric column has no appearance of being produced by chemical action, the consideration of it belongs more properly to electricity than to galvanism.

The electric column invented by that ingenious philosopher, J. A. De Luc, consists of several hundred small discs of zinc and gilt paper placed upon each other alternately, and inclosed in a glass tube. When the number of discs amounts to 800 or 1000, the apparatus will, at any time, produce a perceptible effect upon the electrometer without any preparation. The electric column is represented in Plate CXCIV. Fig. 8. The column is represented at AB, supported horizontally on two rods 1, 1, made of solid glass, coated with sealing wax or any other insulating varnish, and fixed by female screws on the wooden bar 2, 2. It consists of 600 groups formed of plates of zinc, seven tenths of an inch in diameter, and equal pieces of plain gilt Dutch paper (which is paper covered with copper,) the upper side of which being turned towards A, thus becomes the positive extremity of the column; and since the paper seems only to separate the binary groups of zinc and copper, the latter being in each of them on the side of B, this becomes the negative extremity of the column. The groups of zinc and Dutch gilt paper are contained between three glass rods, coated with sealing wax, and fixed in holes of the brass plates A, B, where they must be inserted while the plates are hot, and the holes filled with sealing wax. In the lower part of these brass plates is a pin, which enters freely into the brass cap at the top of the pillars 1, 1. Two screws 3, 3, formed on the outside in the shape of loops, pass through the brass plates A, B, and serve both to press the groups against the glass rods, and to form a communication between the extremities of the column and the electrometers M, N, as represented in the Figure. In order to determine the electric state of different parts of the column, a third electrometer P is used. It is shown in the Figure as connected with the centre of the column by a loop upon a thick brass plate, but when it is required to examine the state of other parts of the column, it may be removed to communicate with any point of it by the insertion of a soft wire held in the middle by an insulating handle. For some experiments, brass hooks 5 and 6 are fixed to the brass plates A, B, and project about an inch; and in experiments on the conducting faculty of glass tubes filled with water, the tube TU may be hung at the point of a hook upon the wire suspended by silk threads 7, 10, 11 passing over the pulley 10, and descending to a thin brass plate 11 fixed at the base of the instrument. The other wire 9 of the tube is hooked to the projecting wire 6.

In order to accommodate the instrument for exhibiting the electrical state of the atmosphere, De Luc fixed at the top of one of the pillars of the column at its positive extremity, a brass piece 13 held by a female screw, and projecting forwards about 1½ inch. On this projection is fixed, by means of a screw, another brass piece, having on one side a vertical groove 14. A brass rod is held in this by a pin, and at the lower end of the rod is a brass ball 15, which can be brought backwards and forwards. From the top of the rod projects a brass loop 16, to which is suspended by the finest silver wire a gold ball 17. The ball is fixed at one extremity of a piece of brass 18, lying on two insulating pillars 27, 27, upon the lead bars 19, 19. A brass spring 23, movable backwards and forwards upon pins 20, 20, about half an inch in breadth, at the base 24, is fixed into the piece 24, where it passes under the bent part of an upright brass piece 25. The breadth of the spring 23 diminishes towards its end, where it is terminated by a brass bow 22, across which is stretched a fine silver wire 21. At the top of the upright brass piece 25, is a screw 26, which presses the spring 23 for the purpose of giving a small motion of adjustment to the wire 21.

When the instrument is thus constructed, the leaves of the electrometer M will diverge with positive, and those in N with negative electricity; but when the finger is laid on either of them, in order to produce a communication with the ground, the divergence will cease in that electrometer, and become nearly double in the other. When the finger is removed, and the column left, to its own operation, the divergencies are not restored to their former state, half an hour or an hour being necessary to reproduce them. If an insulated body, however, electrified either positively or negatively,
so as merely to affect the gold leaf electrometer, is applied to one extremity when the column is in this state, the effect will be instantly perceived at the other end. In order to restore quickly the state of the divergencies, the fingers should be laid on both extremities of the column together, and then removed at the same instant, when the original state of divergency will be restored. By means of the third electrometer P, De Luc has shown that the negative effect goes on increasing from the zinc to the copper end of the column, while the positive effect increases from the copper to the zinc extremity, so that the electric state of each intermediate point is the sum of the corresponding terms of two inverse progressions represented by determined, though, in some respects, variable numbers. When the divergencies at both extremities are equal, there is no divergency at C, which is in a neutral state. When a communication is made with the ground at B, the electrometer at C diverges with positive electricity in the same degree as it did before at A, and the divergence of A is now nearly double. It is now found that the whole column is in a positive state increasing towards A, excepting the very extremity B, which is neutral from communicating with the ground. When the communication with the ground is made at A, the electric states of the column are all reversed. The electrometer C being now negative, and equal to that at B in the insulated state of the column, the negative state increases towards B, A being neutral. When the glass tube TU is filled with water, suspended as in the Figure, the column being insulated, the electrometers continue in the state of equal divergence; but when the hook of the wire 8 is disengaged from the silk thread, and fixed to the hook 5, the circulation of the electric fluid through the glass tube is so rapid, that the divergencies in the electrometers entirely cease, and return only when the extremity of the wire 8 is again lifted up. In this way De Luc tried the conducting powers of various bodies, which are reduced to slips or rods, and laid on the hooks 5, 6. The rods are first laid upon two brass wire brackets 12, 12, fixed on the front of the instrument, and they are taken up by two glass hooks covered with sealing wax, in order that they may be placed on the hooks 5, 6, without disturbing the electrical state of the column. As these substances have more or less a conducting quality, they diminish in different degrees the divergence of the electrometer, by transmitting more or less of the electric fluid from A to B. In this way De Luc made a very curious experiment. A thin slip of deal cut along the fibres was applied to the column, and almost no divergence remained in the electrometer, while another slip of the same wood, and of the same thickness and breadth, but cut across, produced much less diminution in the divergence.

De Luc has likewise applied his column to the purpose of determining the insulating qualities of bodies. These bodies should be placed upon the brackets 12, 12, and after being allowed to remain there a little time, they should be breathed upon, in order that the moisture of the breath may dissipate any electricity they contain, and conduct it to the ground. As soon as the moisture is evaporated, the body must be taken up with insulated hooks, and then applied to the column upon the hooks 5, 6. A naked glass rod, placed in this way upon the hooks, sensibly diminishes, in a short time, the divergence of the electrometer. In this way De Luc found that sealing-wax was the best electrical varnish, but that the finest kind was not the most perfect insulator.

In converting this instrument into an aerial electroscope, as De Luc calls it, for observing the electrical changes which take place in our atmosphere, he employed the apparatus connected with the gold ball 17, which we have already described. When the ball 17 was suspended without the apparatus at 21, 22, it often stuck to the large ball 18; but when the horizontal silver wire 21 is so adjusted to the position of the suspending wire 16, 17, that the two meet, the very instant before the ball 17 strikes the ball 18, the sudden jerk which is thus produced effectually prevents the sticking of the ball. As the strikings of the ball 17 are disturbed by the least shaking motion, De Luc found it necessary to place the instrument in a glazed box, and his apparatus was then ready for use. The following observations made on the 10th of May, will show the nature of the observations which our ingenious author made with his electroscope, after having placed some additional columns for the purpose of increasing its power.

The strikings of the balls having ceased on the 14th of May, and on other subsequent days, De Luc was induced to think of connecting the ball 18 with the negative extremity of the columns, in order to observe if the strikings would thus be more numerous; and it occurred to him, at the same time, that, by quickly changing the connection of the ball for that with the ground, and inversely, he would be enabled to discover variations in the electric state of the ground, by comparing, in a short time, its effect on the strikings with that of the negative extremity of the columns. This he accomplished by means of the insulating pillars 27, 27, and by changing the position of the brass wire 29, he was enabled, in a moment, to form a communication either with the ground, or with the negative end of the columns. The following observations, made on the 20th, 27th, and 28th of May, will show the kind of information which the column affords, when the ball is connected with the ground, or with the negative extremity of the columns.
When M. De Luc was engaged in these experiments, Mr. B. M. Forster succeeded in producing a constant electrical column, by making the action of the column set in motion a brass ball, suspended by a silk thread between two small insulated bells, connected with the two extremities of a column, consisting of 1500 groups of the same diameter as those used by De Luc. The apparatus of the bells is represented in Plate CCXLV. Fig. 9, where A, B are the two bells, supported on glass pillars, and c the small brass ball which acts as a clapper in ringing the bells. On the 14th of March 1810, Mr. Forster put this apparatus into a closet, and connected it with the three columns AB, CD, EF, represented in Fig. 10. The bells immediately began to ring, and continued till the 24th March, when the ringing ceased about a minute. This ringing continued without ceasing till the 4th of September, when it ceased about 10 minutes. They began again to ring at intervals, stopping, perhaps, half a second or more at a time. After this they stopped for several days, and at other times for hours, and on the 18th of November Mr. Forster removed them from the column.

Mr. Forster made also a number of experiments with the electric column. He found, that the electricity of the column acted through a portion of air; and he communicated a slight charge to a coated jar.

Mr. Singers, to whom electricity is under great obligations, constructed an apparatus with the electric column, which never ceased to ring for 14 months, except during its removal from one place to another. During an interval of 6 months, when it was not disturbed, there was no interruption in the ringing. M. De Luc has a pendulum, which has vibrated between two balls for more than two years, and still continues.

In Plate CCXLV, we have shewn the different ways in which the electric column is fitted up for different purposes. The figures are taken from Mr. Singers' Elements of Electricity. Fig. 11 represents a column of 1000 series, lying horizontally upon the caps of two delicate gold leaf electrometers. Fig. 12, represents the apparatus for ringing, which consists of two vertical columns inclosed in a glass receiver, having a bell fixed at the lower extremity of each, and having suspended between them, by a very fine thread of raw silk, a brass ball. Fig. 13 represents De Luc's aerial electroscope, which consists of a vertical column insulated and enclosed in a glass receiver. The column consists of one to two thousand series. A bent wire having a ball a at its lower end, is connected with the upper extremity of the column, so as to hang parallel to the column, and at some distance from it. Opposite to this ball a is a similar ball b, screwed into the lower cap of the column, and into the same cap is screwed a brass fork f, with a fine silver wire stretched between its prongs, for the purpose of preventing the little ball from sticking, as formerly described. The pendulum d consists of a fine silver wire d, suspending a gilt pith ball, which would always be in contact with the brass ball b if influenced only by gravity.

M. De Luc has recently observed, that the power of electric columns, (as pointed out by the oscillation of a pendulum,) is increased by the action of the sun's rays; and this remark has recently been confirmed by Mr. Hausmann. M. De Luc imagined, that this effect was not produced by the heat of the sun; for he remarked, that a column composed of paper discs thoroughly dried had very little power. Mr. Singers, however, has found that the power of the bell-ringing apparatus is increased by a moderate heat. It always pulsates most slowly in winter; and whenever a fire was made in the room, the ringing became more rapid. When the temperature of his apartment was 50°, Mr. Singers applied a column of 1000 series to the cap of a gold leaf electrometer, and he found that the gold leaf struck the sides of the glass nine times in 60 seconds. He then placed the columns during 10 minutes before a fire, so that the electrometer rose to 85°. When the column was now applied to the electrometer, the gold leaves struck the side 37 times in 60 seconds. When it was removed to another part of the room, so as to recover its original temperature of 50°, the gold leaves struck only nine times in 60 seconds as before.

As the following observations on the electric column are both new and ingenious, we shall make no apology for presenting them in Mr. Singers' own words. "There appears every reason to believe, that the action of a well constructed column will be permanent. I have several that have been constructed nearly three years, and they are still as active as at first. There is, however, a precaution necessary to their constant and immediate action. The two ends of a column should never be connected by a conducting substance for any length of time; for if, after such continued communication, it be applied to an electrometer, it will scarcely affect it for some time. It is therefore necessary when a column is laid by, that it be placed upon two sticks of sealing-wax, so as to keep its brass caps at the distance of about half an inch from the table, or other conducting surface on which it is laid; and if a column, which appears to have lost its action by lying by, be insulated in this way for a few days, it will usually recover its full power.

There is another cause of deterioration which is more fatal; it is the presence of too much moisture. If the paper be perfectly dry, it is a non-conductor, and will not therefore produce any action in the column. But this perfect dryness can only be obtained, by exposing the paper to a heat nearly sufficient to scorch it; and in its slightest natural state I have always found the paper sufficiently a conductor, even when, by exposing the paper discs to the heat of the sun, they have been so dried as to warp considerably. When the paper is sufficiently dry, the action of the column continues without diminution;
ELECTRICITY.

The remarkable property of this fish to produce a sensation of numbness on those who touch it, was known to Aristotle and Pliny, who considered it as a mode of defence against fish of a large size, and as a method of catching the smaller fish, upon which it subsisted. Oppian informs us, that the torpedo, when caught by the hook, exerts itself in such a manner, that its influence passing along the line benumbs and stupefies the fisherman.

Among modern naturalists, it appears to have been first observed in the year 1676 by Liedi, who relates, that it was a prevailing opinion among the fishermen, that the shock of the torpedo was communicated to the hand and arm of the person catching the fish, by means of the line and rod to which it was suspended. A few years afterwards, the anatomy of this animal was examined by Lorenzini, who published engravings of its electrical organs. From this benumbing faculty, the fish received the name of Torpedo; and while the philosophers of Europe were perplexing themselves about the cause of this extraordinary property, the Arabians had identified its action with that of atmospheric electricity, by giving it the name of _faraç_, or _rasch_, which in their language signifies lightning.

Reaumur seems to have been the first philosopher, who examined with any thing like accuracy the properties of the torpedo; but he committed a great mistake in ascribing them to the force of its muscles. He observed, that when the torpedo wished to exercise its electrical organs, it first sensibly diminished the curve on its back, till the surface became flat, or even concave, and then by a sudden motion it raised it again to its former convexity. If the fish in this state was
touched by the finger, a sensation resembling numbness was immediately experienced.

Kempler, in his *Annales Exotica*, published in 1702, has given a good description of the effects of the torpedo; and without imagining them to be similar to those of electricity, he compares them to the effects of lightning. He states, however, that the benumbing influence could be evaded if the person held in his breath, a circumstance which Mr. Walsh afterwards found to be correct.

Dr. Bancroft was the first philosopher who suspected, that an analogy existed between the effects of the torpedo and those of electricity, and he has mentioned this supposition in his Natural History of Guiana. Mr. Walsh, however, had the merit of ascertaining this important point; and in his valuable paper on the torpedo, he has made us acquainted with the leading properties of that singular animal. In order to verify the suspected resemblance between the torpedo and the Leyden phial, Mr. Walsh placed a live torpedo upon a table covered with a wet napkin, around which stood five persons insulated. Two brass wires, each 13 feet in length, were suspended to the ceiling by silken strings. The extremity of one of them was placed on the wet napkin, while its other extremity was immersed in a basin full of water placed on a second table, on which stood four other basins full of water. The first person plunged a finger of one hand in the basin in which the wire communicating with the wet napkin was immersed, and a finger of the other hand into the second basin. The second person put a finger of one hand in this last basin, and a finger of the other hand into the third basin; and so on in succession, till the five persons communicated with one another by the wires in the basons. The extremity of the second wire was immersed in the last basin of all; and Mr. Walsh having taken the other end of this wire in his hand, touched the back of the torpedo, when all the five persons experienced a commotion, which differed only in force from that produced by the Leyden phial: Mr. Walsh being out of the circuit, received no shock. This experiment was repeated frequently with the same result, even when eight persons were in the circuit. In other experiments, the shock of the torpedo was communicated through iron wires, and a great many other conductors; and it was found to be incommunicable through air, glass, and other electrices. Mr. Walsh was never able to produce an electric spark, nor to communicate any electricity to the pith balls of the electrometer.

In general, the shock of the torpedo is not sensible beyond the touching finger; and out of 200 shocks, only one extended above the elbow. When the torpedo was insulated, it was able to give 40 or 50 shocks without any diminution of force to persons likewise insulated. Every shock of the animal is attended with a depression of its eyes, by means of which Mr. Walsh observed its attempts to give them even to non-conductors.

These experiments having been made solely in air, Mr. Walsh was anxious to examine its effects in water. A large torpedo, very prolific in shocks, was held in both hands by his electric organs above and below, and was then suddenly plunged a foot under water, and instantly raised to the same height in the air. This operation was continued for a minute. The moment his lower surface touched the water in descending, he always gave a violent shock, and the moment that surface quitted the water upon its ascent, a still more violent shock was experienced. Both of these shocks, but particularly the last, were always accompanied with a writing in his body, as if he was anxious to make his escape. When the animal was wholly in the air, he almost always gave two shocks, and constantly one, and sometimes two, when he was below water. The intensity of the shock under water was scarcely one-fourth of that at the surface, and not much more than one-fourth of those given in the air. The number of shocks appeared to be about 20 in a minute.

Mr. Walsh next put the torpedo into a flat basket, open at the top, but secured by a net with wide meshes, and in this state the animal was let down about a foot into the water. When it was now touched through the meshes with only a single finger on one of its electric organs, while the other hand was held at a distance in the water, he gave shocks which were distinctly felt in both hands. When the circuit for the passage of the electricity was contracted to the finger and thumb of one hand, the finger being applied above, and the thumb below, to a single organ, a shock was experienced twice as great as that which was received when the two arms formed the circuit.

When the torpedo in the basket was raised to within three inches of the surface of the water, and was then touched with a short iron bolt held in one hand, half out and half in the water, while the other hand was dipped into the water at a distance, strong shocks passing through the iron bolt were experienced in both hands. When the communication between the bolt and the hand was made by a wet hempen cord, the shock was conveyed as before.

When a powerful torpedo was suspended in a net, and frequently dipped into water, as already described, slight shocks were communicated through the net to the persons that held it.

In order to explain the difference between the electricity of the torpedo and the Leyden phial, Mr. Walsh observes, that the same quantity of electricity will produce very different effects, according as it is used in a dense or a rare state. A small phial, with a coated surface of six square inches, will be able to force its charge through an inch of air, and exhibit attraction and repulsion, as well as the electric snap and the electric spark. But if this same quantity of electricity is diffused over two large connected jars with a coated surface, with an area 400 times larger than that of the phial, it will exhibit the effects of the torpedo. The charge in this diluted state will not pass through the hundredth part of an inch of air, it will even refuse to pass through the minute interruption in the strip of tinfoil; the spark and snap, and the approach and recession of light bodies, will no longer be produced; a point brought near will not be able to draw off the charge, and yet in this attenuated state it will run through a considerable circuit of conducting bodies, and during its passage will make us sensible of its impulse.

A number of experiments on the torpedo were made at Leghorn by Dr. Ingenhouz, in 1773. His results were nearly the same as those obtained by Mr. Walsh. He describes the shocks or tremors, as giving the same sensation as if a great number of very small electrical bottles were discharged through his hand very quickly one after another. Sometimes he found the shock very weak, and at other times it was so strong that he was nearly obliged to quit his hold of the animal. When he pinched the fish with his nails, it did not give more or fewer shocks than when it was not pinched; but by folding his body, or by bending his right side to his left side, he experienced the shocks more frequently.
The electricity of the torpedo was examined with great care in the year 1805, by Messrs Humboldt and Gay Lussac, who procured several torpedoes at Naples. The following are the principal results which were obtained by these distinguished philosophers.

1. A person much in the habit of receiving electric shocks, can support with some difficulty the shock of a vigorous torpedo 14 inches long. The action of the torpedo below water is not perceptible, till it is raised above the surface of the water.

2. Before each shock, the torpedo moves its pectoral fins in a convulsive manner, and the violence of the shock is always proportional to the extent of the surface of contact with the water.

3. The organs of the torpedo cannot be discharged by us at our pleasure, nor does it always communicate a shock when touched. It must be irritated before it gives the shock, and, in all probability, it does not keep its electric organs charged. It charges them, however, with astonishing quickness, and is thence capable of giving a long series of shocks.

4. The shock is experienced, when a single finger is applied to a single surface of the electric organs, or when the hands are placed once on the upper and one on the under surface at the same time, and in both these cases the shock is equally communicated, whether the person is insulated or not.

5. If an insulated person touches the torpedo with his finger, it must be in immediate contact, as no shock is received if the animal is touched with a key, or any other conducting body.

6. When the torpedo was placed upon a metallic plate, so that the inferior surface of its electric organ touched the metal, the hand which supported the plate felt no shock, although the animal was irritated by another insulated person, and when it was obvious, from the convulsive motions of its pectoral fins, that it was in a state of powerful action.

7. If a person, on the contrary, support with his left hand the torpedo placed on a metallic plate, and if he touches, with his right hand the upper surface of the electric organ, a violent sensation will be felt in both his arms at the same instant.

8. A similar shock will be received, if the fish is placed between two metallic plates, the edges of which do not touch, and if a person applies a hand to each plate at the same instant.

9. If, under the circumstances of the preceding experiments, there is a connection between the edges of the two plates, no shock will be experienced, as a communication is now formed between the two surfaces of the organ.

10. The organs of the torpedo do not affect the most delicate electrometer. Every method was tried in vain of communicating electricity to the condenser of Volta.

11. A circle of connection being formed, by a number of persons, between the upper and under surfaces of the organs, they received no shock till their hands were moistened in water. The shock was equally felt, when two persons, who had their right hand applied to the torpedo, instead of taking hold of each other's left hands, plunged a pointed piece of metal into a drop of water placed upon an insulating body.

12. By substituting flame in place of a drop of water, no sensation was experienced till the two pointed pieces of metal came in contact with the flame.

13. No shock will be experienced, either in air or below water, unless the body of the electric fish is immediately touched. The torpedo is unable to communicate its shock through a layer of water, however thin.

14. The least injury done to the brain of this animal prevents its electrical action.

A number of curious experiments on the torpedo were made by the Abbé Spallanzani. He observed, that when the animal was laid upon a plate of glass, the shock was then the strongest. "In irritating the back of the torpedo," he remarks, "I always obtained the shock whether it was out of the water or in it. If, instead of irritating the back, I gently irritated the breast, I also received a shock, but not so frequently as in irritating the back. If I irritated the back with one hand, and the breast with another, the hand which touched the back received the shock but not the other. But when I irritated the back with two fingers of one hand, and the breast with four fingers of the other, then I received the shock from the breast, and obtained all these results whether I was insulated or not." M. Spallanzani observed, that some minutes before the torpedo expired, the shocks were not given at intervals, as in the healthy state of the animal, but were changed into a continual battery of small shocks; and he compares the sensation to that which would be produced by laying the fingers upon a heart in a state of pulsation. The battery continued seven minutes, and during this short space of time his fingers experienced 316 shocks; the shocks then suffered an interruption, and the animal, immediately before it died, gave a few very languid shocks. We are indebted to Spallanzani for the knowledge of a still more curious fact. He found, that even the fuses of a torpedo, when in the womb of the mother, possess the same electrical property as after they are born. Having dissected a female torpedo, when she was about to expire, he saw in the ovarium eggs almost round and of different magnitudes, and on opening two vessels which shutted against the rectum, he found two perfectly formed fuses, which he detached from their envelopes, and submitted to the same experiments which he had made upon the mother. These fuses gave a perceptible shock, which was strongest when they were laid upon a plate of glass.

The common experiments on the torpedo were repeated and verified at Narbonne in the month of August 1779, by the Abbé Berthon.

At the request of Mr Walsh, the celebrated anatomist Dr Hunter examined carefully the electrical organs of a torpedo about 18 inches long and 12 broad, and about two inches thick in its thickest part. The following were the results of his examination.

"The electric organs of the torpedo are placed on each side of the cranium and gills, reaching from thence to the semicircular cartilages of each great fin, and extending longitudinally from the anterior extremity of the animal, to the transverse cartilage which divides the thorax from the abdomen; and within these limits they occupy the whole space between the skin of the upper and under surfaces; they are thickest at the edges near the centre of the fish, and become gradually thinner towards the extremities. Each electric organ, at its inner longitudinal edge, is unequally hollowed, being exactly fitted to the irregular projection of the cranium and gills. The outer longitudinal edge is a convex elliptic curve. The anterior extremity of each organ makes the section of a small circle; and the posterior extremity makes nearly a right angle with the inner edge. Each organ is attached to the surrounding parts by a close cellular membrane, and also by short and strong tendinous fibres, which pass di-
rectly across from its outer edge to the semicircular cartilages. They are covered, above and below, by the common skin of the animal, under which there is a thin fascia spread over the whole organ. This is composed of fibres, which run longitudinally, and in the direction of the body of the animal. These fibres appear to be perforated in innumerable places, which gives the fascia the appearance of being fasciculated. Its edges all around are closely connected to the skin, and at last appear to be lost, or to degenerate into the common cellular membrane of the skin. Immediately under this is another membrane exactly of the same kind; the fibres of which, in some measure, decussate those of the former, passing from the middle line of the body outwards and backwards. The inner edge of this is lost with the first described; the anterior, outer, and posterior edges, are partly attached to the semicircular cartilages, and partly lost in the common cellular membrane.

This inner fascia appears to be continued into the electric organ by so many processes, and thereby makes the membranous sides, or sheaths of the columns, which are presently to be described; and between these processes the fascia covers the end of each column, making the outermost, or first partition. Each organ of the fish under consideration is about five inches in length, and at the anterior end three in breadth, though it is but little more than half an inch broad at the posterior extremity. Each consists wholly of perpendicular columns, reaching from the upper to the under surface of the body, and varying in their length, according to the thickness of the parts of the body where they are placed; the longest column being about an inch and a half, the shortest about one-fourth of an inch in length, and their diameter about two-tenths of an inch.

The figures of the columns are very irregular, varying according to situation, and other circumstances. The greatest number of them are either irregular hexagons, or irregular pentagons; but, from the irregularity of some of them, it happens, that a pretty regular quadrangular column is sometimes formed. Those of the exterior one are either quadrangular or hexagonal; having one side external, two lateral, and either one or two internal. In the second row they are mostly pentagonal. Their costs are very thin, and seem transparent, closely connected with each other, having a kind of loose network of tendinous fibres passing transversely and obliquely between the columns, and uniting them more firmly together. These are mostly observable where the large trunks of the nerves pass. The columns are also attached by strong inelastic fibres passing directly from the one to the other.

The number of columns in different torpedos, of the size of that now offered to the Society, appeared to be about 470 in each organ; but the number varies according to the size of the fish. These columns increase, not only in size, but in number, during the growth of the animal; new ones forming perhaps every year on the exterior edges, as they are much the smallest. This process may be similar to the formation of new teeth in the human jaw, as it increases. Each column is divided by horizontal partitions placed over each other at very small distances, and forming numerous interstices, which appear to contain a fluid. These partitions consist of a very thin membrane, considerably transparent. Their edges appear to be attached to one another, and the whole is attached by a fine cellular membrane to the inside of the columns. They are not totally detached from one another. I have found them adhering at different places, by blood-vessels passing from one another.

The number of partitions contained in a column of one inch in length, of a torpedo which had been preserved in proof's spirit, appeared, on a careful examination, to be 150; and the number in a given length of column, appears to be common to all sizes in the same state of humidity; for by drying them they may be greatly altered. Whence it appears probable, that the increase in the length of a column, during the growth of the animal, does not enlarge the distance between each partition in proportion to that growth; but that new partitions are formed and added to the extremity of the column from the fascia.

The partitions are very vascular; the arteries are branches from the veins of the gills, which convey the blood that has received the influence of respiration. They pass along with the nerves to the electric organ, and enter with them; they then ramify, in every direction, into innumerable small branches on the sides of the columns, sending in from the circumference all around, on each partition, small arteries, which ramify and Anastomose on it; and passing also from one partition to another, Anastomose with the vessels of the adjacent partitions. The veins of the electric organ pass out close to the nerves, and run between the gills to the auricle of the heart.

The nerves inserted into each electric organ, arise by three very large trunks from the lateral and posterior part of the brain. The first of these, in its passage outwards, turns round a cartilage of the cranium, and sends a few branches to the first gill, and to the anterior part of the head, and then passes into the organ towards its anterior extremity. The second trunk enters the gills between the first and second openings, and, after furnishing it with small branches, passes into the organ near the middle. The third trunk, after leaving the skull, divides two branches which pass to the electric organ through the gills; one between the second and third openings, the other between the third and fourth, giving small branches to the gill itself. These nerves having entered the organs, ramify in every direction between the columns, and send in small branches on each partition, where they are lost.

The nerves bestowed on these organs, in proportion to their size, must, on reflection, appear as extraordinary as the phenomena they afford. Nerves are given to parts either for sensation or action. Now, if we except the more important senses of seeing, hearing, smelling, and tasting, which do not belong to the electric organs, there is no part, even of the most perfect animal, which, in proportion to its size, is so liberally supplied with nerves; nor do the nerves seem necessary for any sensation which can be supposed to belong to the electric organs. And, with respect to action, there is no part of any animal, with which I am acquainted, however strong and constant its natural actions may be, which has so great a proportion of nerves. If it be then probable, that these nerves are not necessary for the purposes of sensation or action, may we not conclude, that they are subservient to the formation, collection, or
management of the electric fluid; especially as it appears evident, from Mr Walsh's experiments, that the will of the animal does absolutely controul the electric powers of its body, which must depend on the energy of the nerves.

In Fig. 1. we have given a representation of the under surface of a female torpedo. Below a is seen the right electric organ displayed by flaying off the skin b, c are the nostrils in the form of a crescent, d the mouth in a crescent contrary to that of the nostrils, and furnish ed with several rows of small hooked teeth, e the bronchial apertures, five being on each side, f the place of the heart, g g g the place of the anterior transverse cartilages, h h the exterior margin of the great lateral fin, i i its inner margin confining with the electric organ, k the articulation of the great lateral fin with the scapula, l the abdomen, m m the place of the posterior transverse cartilage, which is single, united with the spine, and supports the smaller lateral fins on each side, n n n the two smaller lateral fins, o the anus, and p the fin of the tail.

Mr. Geoffroy has more recently examined the anatomy of the other electric fishes, and has not obtained, in the case of the torpedo, results differing greatly from those of Dr. Hunter. He has analysed the fluid which is contained in the cells of the hexagonal tubes, and has found that it is composed of albumen and gelatine; he also found organs analogous to those of the torpedo in other species of the ray, which do not exhibit any electrical properties. This transparent gelatinous fluid was considered by Dr. Ingenhousz as the reservoir of the electric power.

As the experiments of Mr Walsh were not considered as affording a sufficient proof of the identity of the shock of the torpedo with that produced by a Leyden phial, Mr Cavendish made an attempt to imitate the effects of the torpedo by electricity. The principal difficulty that required explanation was the production of a shock when the fish was held under water, and in other circumstances, where the electricity had a much greater passage than through the person's body. Mr Cavendish explains this by stating, that when a communication is made between the positive and negative side of a jar by any number of different circuits, some electricity will pass along each, and a greater quantity through those in which it meets with the least resistance. In like manner, when any person lays one hand on one surface of the electric organ of the torpedo, and his other hand on the other surface of the organ, a part of the fluid will pass through his body; but if one of his hands is laid on the tail instead of the other surface of the organ, part of the fluid will still pass through him, though less in this case than before. Owing to the moistness of the body of the torpedo, some electricity will pass through him even if his hands are laid upon any two parts of the animal, provided one of these parts is nearer to the upper surface of the organs than the other. Upon the same principle, if the torpedo is plunged in water, the electricity will pass through the water in all directions, and even to great distances from the body of the animal; and the nearer any part of the water is to the fish's body, the greater quantity of fluid will be transmitted. Hence if any person touches the fish in this situation, either with one of his hands on the superior surface of its electric organ, and the other on the inferior one, or in any of the other ways formerly mentioned, a certain quantity of the electricity will pass through his body, but certainly less than when the shock is received in the air; and the same thing will happen, even if he does not touch the fish at all, but plunges his hands in the water; so that one hand is nearer the upper surface of the electrified organs than the other. The second difficulty which requires explanation, is, that no spark, or sound, or electrical attraction is perceived. In order to explain this, Mr Cavendish made experiments with a number of jars, for the purpose of finding through what distance the electric spark will fly when a shock of a given magnitude is contained in one or more jars. The result of these experiments was, "that the distance to which the spark will fly is inversely in a rather greater proportion than the square root of the number of jars." That is, a charge of a certain magnitude contained in 4 jars passes through a space of \( \frac{1}{\sqrt{4}} \) of an inch. The same charge when contained in 100 jars will scarcely pass through \( \frac{1}{\sqrt{100}} \) of an inch. Hence the torpedo may contain as much electricity as will give a shock, without being able to make it pass through such a space of air as is necessary to produce the electric spark. Mr Cavendish explains the absence of attraction and repulsion by the analogous fact, that, in a large battery, so weakly electrified, that its shock will not pass through a chain, which is the case with the torpedo, a pair of pith balls suspended from the discharging rod will not exhibit any divergence.

In order to establish these conclusions more completely, Mr Cavendish endeavoured to make an artificial artificial torpedo of wood, connected with glass tubes and wires, and covered with a piece of sheep skin leather. The difference, however, between the shock given through this torpedo, by means of the charge of a battery, in air, and in water, was too great, and therefore Mr Cavendish substituted thick leather for the wood. This instrument was almost an exact imitation of the real torpedo. In air, the shock was felt chiefly in the elbows, whereas under water it was felt chiefly in the hands. A weaker shock, but one of the same kind, was experienced when Mr Cavendish, instead of touching his artificial torpedo, held his hands under water at two or three inches distance from it. When this torpedo was touched below water with only one hand, a shock was experienced as strong as if it had been touched by both. When it was touched below water with two metallic spoons, it gave no shock; but in the air it was very strong.

Mr Cavendish was likewise able to imitate the torpedo in its power of giving a shock to those who trample upon it with shoes on their feet, and when it is buried in sand; but he could not sufficiently explain the remarkable fact stated by the fishermen, that they often received a shock through their nets when the fish was 12 feet distant from their hands. As it is necessary to suppose that the torpedo is provided with a large battery, Mr Cavendish has endeavoured to compute its magnitude in the torpedo examined by Mr Hunter. Mr Cavendish's battery was composed of 49 jars of very thin glass, and appears to have contained about 76 feet of coated surface; and he calculates that the torpedo allowed to contain 14 times as much electricity as this battery, or was equal to 106 feet of coated glass.

Mr Nicholson has followed Mr Cavendish, with much ingenuity, in explaining the anomalous phenomena of the torpedo, by the principles of common electricity; but we cannot find room for prosecuting this subject any further.

When the Galvanic or Voltaic pile was discovered, philosophers imagined that they would find a striking analogy between its action and that of the torpedo, as
fluids seemed in both cases necessary to the development of the electrical effects. Volta, himself, believed, that among the humid substances of which the electric organ of the torpedo is composed, are some adapted to excite the electric virtue by their mutual contact, and others to transmit it; and hence he supposes, that the superposition of the different cells formed by those substances corresponds to that of the metallic and moist conductors, of which the pile consists. This analogy, however, is more imaginary than real. Messer Humboldt and Gay Lussac remark, "that they would rather be inclined to compare their action to a chain of small Leyden phials than to the pile of Volta." - The nerves,"say they, "without doubt, act the chief part in the production of these phenomena; and the physiologist, who takes a general and enlarged view of the vital actions, would, with reason, oppose the ideas of the philosopher, who conceives he can explain the whole by the contact of the albumino-gelatinous pulp with the tenacious sepa which nature has conferred in the formation of the organs of the torpedo."

2. On the Electricity of the Gymnotus Electricus.

The gymnotus electricus, or the electrical eel of Surinam, possesses electrical properties different from those of the torpedo. The properties of this fish were first made known to philosophers by M. Richer, upon his return from measuring the length of the pendulum at Cayenne. This fish was mentioned by Condamine, under the name of Purana, and its electrical properties have been successively noticed by Perrere, Fermin, Bancroft, and Vanderlott, the latter of whom speaks of its medicinal effects. At the desire of the Academy of Sciences, the experiments of Vanderlott were repeated and confirmed by M. Bajon, at Cayenne, in 1773. The most correct experiments, however, which have been made with it, owe to Dr Hugh Williamson of Philadelphia, Dr Martin of Charleston, and Mr Walsh. The following are the most interesting results which they obtained:

1. When the eel was touched with the hand, a shock was experienced in the fingers, and often in the wrist and elbow.

2. When the gymnotus was touched with an iron rod 12 inches long, the shock was experienced in the finger and thumb which held the rod.

3. If the hand of any person is held in the water, at the distance of three feet, when another person provokes the eel by touching it, he will feel a less painful sensation than if he had touched the eel itself.

4. When a cat-fish was thrown into the water to the eel, Dr Williamson put his hand in the water at some distance, and watched what took place. The gymnotus swam up to the cat, but turned away without offering any violence. It soon returned, however, and viewing the cat-fish for some seconds, gave it a shock which made it turn up its belly and continue motionless. At this time Dr Williamson felt a shock in his fingers, as in experiment 3. When any of the fish that were thus rendered motionless by the eel were taken into another vessel, they always recovered.

5. When the eel was touched and provoked with one hand, and the other was held in the water at a small distance, a shock passed through both arms, as with the Leyden phial.

6. When the end of a wet stick was held in the water with one hand, and the eel was touched with the other, a shock passed through both arms.

7. When the preceding experiment was made by two persons joining hands, the shock passed through them both.

8. When one of two persons joining hands touched the head roughly, while the other touched the tail gently, they both received a severe shock.

9. When the first of 8 or 10 persons joining hands touched the eel, while the last put his hand in the water at some distance from it, they all received a gentle shock.

10. When the first of the 8 pinched the tail, while the last touched the head, they all received a severe shock.

11. When two persons laid hold of the two extremities of a brass chain, and one of them put his hand in the water, while the other touched and irritated the eel, the shock passed through both.

12. If a silk handkerchief is wrapped round the hand, and the eel is touched with it, no shock is experienced, though another person will feel the shock, who puts his hand into the water at a little distance from the eel.

13. The communication between two persons was formed by various bodies, such as charcoal, iron, brass, dry wood, glass, silk, &c. and it was always found that the shock of the eel was conveyed through those substances that conduct common electricity, while it refused to pass through non-conductors.

14. The shock was not conveyed by a brass chain, unless the chain was stretched, or the shock severe.

15. When an insulated person was electrified by the eel, he exhibited no marks of electricity, nor did cork balls diverge when suspended by silk threads over the eel's back, or when touched by the insulated person when he received the shock.

16. A person, holding a Leyden phial in one hand, put his hand to the tail of the fish, while another, holding a short wire in one hand that communicated with the inside of the phial, grasped the fish near its head, he received a severe shock in his hand and arms.

17. Two pieces of brass wire, about one-sixth of an inch thick, were rounded at the ends, and fixed at the distance of the hundredth part of an inch in a frame of wood, then when one person held the farther end of one of the wires, while a second person held the end of
ELECTRICITY.

the other, as soon as one of them touched the eel, the other having his hand in the water near it, they received a shock. This experiment was repeated 15 or 20 times with various success. When the distance of the wires was one-thirteenth of an inch, the shock never passed between them. Dr. Williamson, however, was not able to see the electric spark between the two metallic points, which he described to the bad state of health of his gymnotus. Mr. Walsh repeated this experiment in a different manner. He applied to a piece of glass a sheet of pewter, in which he had left a small separation or slit. This sheet had its two edges in communication with the body, through which the electricity of the fish was discharged. At the instant of the discharge, he perceived an electric spark, which went beyond the little interval made in the sheet. The success of this experiment depends on the fish being in the open air; for when it is immersed in water, the spark is not visible. M. Humboldt observed when he was in South America, that the gymnotus gave the most frightful shocks, without making any external motion of the eyes, head, or fins, like the torpedoes.

The preceding experiments were made upon a gymnotus kept in a large vessel, and supported by pieces of dry timber about 3 feet above the floor. A small hole was bored in the vessel, and when any person provoked the eel, another person holding his finger in the stream running through this hole received the shock. From the different experiments which he made, Dr. Williamson concludes, that the gymnotus has the power of communicating a painful sensation to animals that touch or come near it; that this effect depends solely on the will of the eel; that it has the power of giving a small shock, a severe one, or none at all; that the shock does not depend on the muscular action of the eel, but has the same effect as that produced by common electricity.

In order to convey to our readers an idea of the structure of the gymnotus, we have given a representation of it in Plate CCXVI. Fig. 2, where the skin is removed to shew the electrical organs. The lower surface of the head is shewn at A; the cavity of the belly at B; the anus at C; the fin at D; the back of the fish, when the skin has not been removed, at E; the fin which extends along the lower edge of the fish at FF; H, H, H, are the lateral muscles of the above fin, removed and carried back with the skin to expose the small organs; I is part of the muscle left in its place; KKK is the large electrical organ; LLL the small electrical organs; m m m the substance which separates the large organ from the small one; and n the place where this substance is removed.

From a minute examination of the electrical organs of the gymnotus, Dr. Hunter found, that they occupy nearly one half of that part of the fish in which they are placed, and constitute perhaps more than one-third of the whole fish. The animal possesses two pairs of electrical organs of different sizes, and placed on different sides. The large organ KKK occupies the whole of the lower and the lateral part of the body, constituting the thickness of the fore part of the animal, and stretching from the abdomen to near the end of the tail, where it terminates almost in a point. The two organs are separated at the upper part by the muscles of the back, at the middle part by the air bag, and at the lower part by the middle partition. The small organ extends along the lower edge of the animal almost as far as the other, terminating almost insensibly near the end of the tail. The two small organs are separated from one another by the middle muscle, and by the bones in which the fins are articulated. In order to perceive the large organ, it is necessary merely to remove the skin, which adheres to it by a loose cellular membrane; but in order to perceive the small organ, we must remove the long row of small muscles which move the fin. The organs consist of two parts, viz. flat partitions or septa, and cross divisions between them. These septa are very thin and tender membranes placed parallel to one another; they stretch in the direction of the length of the fish; and having their breadth nearly equal to the semi-diameter of the animal's body, the length of the septa are different, some of them being as long as the whole body. The distances between the septa vary with the size of the fish. In one two feet four inches long, their distance was nearly 1/4 of an inch; and in the broadest part of the organ, which was an inch and a quarter, there were 34 septa. The small organ has the same kind of septa, but they stretch in a direction somewhat serpentine. Their distance is only about 1/14 part of an inch; and in the breadth of the organ, which is half an inch, there are fourteen septa. Mr. Hunter is of opinion, that the septa answer the same purpose as the columns in the torpedoes, forming walls or abutments for the subdivisions, and constituting so many distinct organs. These septa are intersected transversely by very thin plates or membranes, whose breadth is the distance between any two septa, and therefore of different breadths in different parts; broadest at the edge, which is next to the skin; and narrowest at that next to the centre of the body, or to the middle division which divides the two organs. The lengths of these membranes are equal to the breadths of the septa between which they are situated, and there is a regular series of them from one end of any two septa to the other end. In one inch, there are no fewer than 540 of these transverse membranes.

The gymnotus examined by Dr. Hunter was not of a large size. Dr. Garden saw one 3 feet 8 inches long; and Dr. Bancroft was told when he was at Guiana, that some of these fish have been seen in the Surinam river upwards of 20 feet long, whose shock proved immediately fatal to those who received it.

Redi, Perrault, and Lorenzini, believed that the electricity of the torpedoes was owing to the emission of an infinite number of corpuscles continually proceeding from the fish, and which, by penetrating animal bodies, benumbed them by their accumulation. It was the opinion of Borelli, that it communicated a trembling to the nerves, which deadened the member in which it was produced. The most extraordinary notion, however, was that of Schilling, who imagined that he had discovered sensible magnetic effects in the gymnotus. He maintains, that when this eel was placed near a loadstone, it was attracted by it, and adhered to it; and became so languid when separated from the loadstone, that it might be touched with impunity. He observes, also, that the loadstone which he used appeared to be covered with particles of iron; and that, when the fish was placed in water containing iron filings, it became lively and vigorous. These experiments were carefully repeated by Ingenhouz and Spallanzani, who were unable to perceive any such magntetical effects. M. Hahn, professor of medicine at Leyden, remarks, that the rivers in America in which the gymnotus is found, carry along in their current a magnetic sand; and he supposes, that grains of this sand adhering to the glutinous skin of the fish, might have been the cause of the illusions by which Schilling was misled in his experiments.
ELECTRICITY.

478

For further information respecting the gymnotis electricus, see Richer, Mem. Acad. Par. 1677, tom. i. p. 116.

3. On the Electricity of the Sillurus Electricus.

The sillurus electricus is a fish about 20 inches long, very broad in the fore part, and of a circumstance colour, with a few blackish spots towards the tail. It was found in some of the rivers of Africa, particularly in the Niger by Adanson, and in the Nile by Forskal; and when it is touched it gives an electrical shock; which is much feebleer than that of the torpedo or the gymnotus. When laid on the hand, and touched with an iron rod six feet long held in the other, the shock is distinctly felt. The inhabitants on the Nile call it Reusch, the same name which they give to the torpedo; and the Egyptians eat its flesh, and salt its skin, to which they ascribe an aphrodisiac quality. This fish is described by Forskal under a wrong name, and was found to be a sillurus by Brossonet. This fish is called Onaeniam by the Negroes, from its electrical property; and Le Trembleur du Senegal by the French. The fish is represented in Plate CCXLVI. Fig. 3.

According to M. Geoffroy, who examined the electrical organs of this fish, they are much less complicated than those of the torpedo and gymnotus. In the sillurus, this organ lies immediately below the skin, and stretches all round the body of the animal. The organ is composed of a collection of cellular tissue, so extremely thick and compact, that it resembles at first a stratum of lard, till the microscope informs us that it is composed of tendinous or aponeurotic fibres, interwoven with each other, and forming a reticulated mass, of which the meshes may be distinctly seen. As in the torpedo and gymnotus, these cells are filled with an albuminous gelatinous matter. All communication is prevented in the inside by a very strong aponeurosis, extending over the whole reticulation, and adhering very closely to it. It is also covered above this with a thick layer of fat. The nerves distributed over the electric organ of this fish proceed from the brain, and are the same with those found in all other fishes under the lateral line of the body. The two nerves of the eighth pair have a direction and nature peculiar to this species. Approaching each other as they issue from the cranium, they descend and traverse the body of the first vertebra. They first introduce themselves through an orifice peculiar to each other, and then issue by one aperture on the opposite side. After reascending, they suddenly separate, and proceed under each of the lateral lines. They are then found lodged between the abdominal muscles, and the aponeurosis which extends over the articulated organ. They then send long branches beneath the skin, which proceed to the right and left to the principal nerve. These branches, which amount to twelve or fifteen on each side, penetrate the aponeurosis which lines the inner surface of the reticular tissue, and they are lost in the latter. See Adanson, Voyage au Senegal, 1757, p. 135; Bourdonnet, Mem. Acad. Par. 1782, p. 692; Rouzet, Observations, &c. vol. xxvii. p. 139; Geoffroy, Bulletin de la Société Philomatique, tom. iii. p. 169; Annales du Museum d'Hist. Nat.; and Phil. Mag. vol. xv. p. 126.

4. On the Electricity of the Trichurus Indicus.

This fish inhabits the Indian seas, and possesses the electrical faculty like the sillurus electricus. So far as we know, its electrical organs have not been examined by anatomists.

5. On the Electricity of the Tetraodon Electricus.

This fish was discovered, by Lieutenant William Patterson, to possess the power of giving an electrical shock. He met with it on his way to the East Indies, in the Island of Johanna, one of the Comoro Isles. It is 7 inches long, 2½ inches broad, and has a long projecting mouth. It is of a dark brown colour on the back, of a sea green colour on the belly, yellow on the sides, and of a sandy green on the fins and tail. The body is covered over with red, green, and white spots, the latter being particularly bright. The eyes of the fish are large, and the iris is red, having its outer edge tinged with yellow. Mr. Patterson caught this fish in the cavities of the coral rocks, where the temperature of the water was 56° or 60° of Fahrenheit. Having caught two of them in a linen bag, he attempted to take one of them in his hand, when he received so severe an electrical shock, that he was obliged to quit his hold. He then carried them to the camp, which was about two miles distant, but on his arrival one of them was unfortunately dead, and the other in such a state of debility, that he was very desirous to establish without delay the existence of the electrical faculty, by the evidence of others. He therefore put it into a tub of water, and when the surgeon of the regiment endeavoured to lay hold of it by his hands, he received a distinct electrical shock. The adjutant afterwards touched it on the back with his finger, and experienced a slight shock. See the Philosophical Transactions for 1780. vol. xxxv. p. 382.

SECT. VIII. On the Spontaneous Electricity of the Human Body.

We have already had occasion, in our history of the science, to mention several electrical phenomena produced on the human body. These, however, were obviously generated by friction, and have therefore no connection with the present subject. Various instances have occurred in which sparks of electric light have been evolved during the combing of the hair, the rubbing of the breast and arms, and the pulling off of the under garments; but in these cases the electricity is excited by friction, and is strong or weak in different cases, according to the constitution of the individual, the dryness of the skin, the nature of the clothes, and the state of the surrounding air.

M. de Saussure made a great number of experiments on the electricity of his own body, which he examined by means of Volta's electrometer and condenser, but he does not seem to have observed that kind of electricity which is properly entitled to the name of spontaneous. As he never could discover any electricity in his own body when he was perfectly naked, he concluded that it was produced by the friction of the clothes against the skin. He could never find any electrical indications when his clothes were cold, or when his body was in a state of
ELECTRICITY.

1. The electricity, he observes, was sometimes positive, and at other times negative, without my being able to ascertain the cause of these variations. It sometimes happened that the balls of the electroscope separated and collapsed in succession, when, being in a state of insulation, I made a great motion, and kept one of my hands applied to the electroscope. If, for example, after having bent my body forwards, I raised myself suddenly, I saw the balls diverge to a considerable distance, and then collapse, unless when I drew away my hand when they were in a state of divergence, and then continued in this state of divergence, and exhibited positive electricity. The electricity which appears in these experiments is obviously produced by the friction of the body against the clothes which cover it. The motion produced by respiration is sufficient of itself to excite a little electricity, for when a person remains upon the insulated stool in a state of the most complete repose that can be observed by a living being, sensible indications of electricity will be exhibited, if the hand is laid for some time on one of Volta's condensers. In order to succeed in these experiments, the clothes of the person must be warm by the heat of the body; for whenever cold clothes are put on, no electricity appears. The same thing takes place when the body is covered with perspiration. It must also be observed, that there are some individuals who give no signs of electricity. The knowledge of spontaneous electricity is not a matter of indifference in medicine; for however weak it may be, the action of it is anything necessary to influence the animal economy. Is it not, in part, this electricity which renders moderate exercise, and clothes moderately warm and dry, so favourable to insensible perspiration, and to all the secretions of the human body? These experiments of Saussure were repeated with the same results by Volta, Landriani, and the Abbe Bertholon.

The most successful experimenter, however, on this branch of electricity was M. J. J. Hemmer, who has published a full account of his experiments in the 6th volume of the Transactions of the Electoral Academy of Sciences at Mannheim. In order to examine the electricity of his own body, he insulated himself upon a board supported by glass feet, and then touched for half a minute; or less, the plate of a condenser of his own invention. The condenser was then applied to a glass electroscope, as improved by Saussure, and by means of a glass tube rubbed with woollen cloth, he examined the electricity of the diverging balls. His experiments were made on the 21st February 1786, and have since been repeated, both upon himself and upon persons of various ages and constitutions, upon persons in motion and at rest, dressed or undressed, fatigued or in good spirits, hot or cold, fasting or full, and sleeping or waking. The following are the principal results obtained by Mr Hemmer.

1. The electricity of the human body is common to all men, and it was found in 40 persons of all ages and both sexes; but in different persons it has different degrees of strength, and is positive in some and negative in others.

2. The strength and character of the electricity is often different in the same person. In 2422 experiments, M. Hemmer found it 1252 times positive, 771 times negative, and 399 times imperceptible. Out of 74 experiments made upon his maid, it was 17 times positive, 33 times negative, and 44 times imperceptible.

3. Although the electricity often changes in the course of the experiment, and even becomes imperceptible, yet the electricity of the human body appears to be naturally positive; for it always possesses this kind of electricity when exposed to no violent exertion. Out of 356 experiments made when he was sitting at rest, and when the natural heat of his body was not disturbed, M. Hemmer was 332 times in a state of positive electricity, 14 times in a state of negative electricity, and 10 times the electricity of his body was not perceptible.

4. Cold changes the natural or positive electricity into negative, or, at least, diminishes its intensity. Out of 62 experiments made upon himself, when he came from a temperature of about 82° of Fahrenheit, his electricity was 38 times negative, 15 times positive, and 7 times imperceptible.

5. Latitude impedes the positive electricity of the body, and changes it into the opposite. Out of 16 times that he walked backwards and forwards in his apartment, or was otherwise employed, Hemmer found the electricity only once weakly positive, ten times negative, and five times imperceptible. In 92 experiments made when he was standing at rest, the electricity was two times weakly positive, and 30 times imperceptible.

Sect. IX. On the Negative Electricity of Vitiated Air.

The production of negative electricity by the vitiation of atmospheric air, was first observed by Mr John Read of Knightsbridge. Having often noticed that the electricity of a small room in which he sat was negative, when that of the external air, and even that of the adjoining apartment, was positive, he began to suspect that this difference was owing to the vitiation of the air by respiration. In order to determine this point, he invited a friend into his room on the 9th of July 1793, when the weather was hot and serene, and the thermometer at 75°; and having shut up the doors and windows, he placed himself nearly in the middle of the room, and his companion at the side of it. At the end of 20 minutes, Mr Read was in a profuse perspiration, and having worked the doubler, he found the electricity negative. He then examined the electricity of his bedroom a little while before he went to rest, and found it positive; but when he rose at six o'clock next morning, he found that it had become negatively electrified. In a room which had been newly white washed and painted, and was therefore full of noxious effluvia, he also found the electricity negative.

Mr Read examined the electricity of the air in the charity-school at Knightsbridge, when it was vitiated by a great number of children, and he always found it strongly negative, while the schoolmaster's parlour adjoining to it was in a positive state; and on the 6th of July, when the thermometer was at 76°, Mr Read went to the same school, but finding the doors and windows open to admit fresh air, and experiencing no disagreeable smell, he thought it unnecessary to make the experiment. The schoolmaster, however, remarked that
there was one end of the room which was never free of smell, and Mr Read was therefore induced to work his doubled in that end. The electricity was here negative while in the other end of the school, and in the school-master's parlour it was positive. From these and other experiments, Mr Read concludes, that air infected with animal respiration or vegetable putrefaction is always electrified negatively, when at the same time the surrounding atmosphere is electrified positively. See the Philosophical Transactions, 1754, vol. lxxxiv. p. 266.

SECT. X. On the Electricity of the Atmosphere.

As the electrical phenomena which appear in the atmosphere, either during the ordinary changes to which it is subject, or during the violent perturbations into which it is thrown by the production of thunder and lightning, are evidently not produced by friction, or any similar cause, the consideration of this important subject belongs properly to the present Chapter. We shall, therefore, endeavour to include all the phenomena under three heads: 1. On the electricity produced in the atmosphere during its ordinary changes; 2. On the electricity exhibited during thunder and lightning; and, 3. On the electricity exhibited in luminous meteors.

1. On the Electricity of the Atmosphere during its ordinary Changes.

The earliest experiments on the spontaneous electricity of the atmosphere, were made in September 1752 by M. Le Monnier, at St Germain en Lay, and were laid before the Academy of Sciences in 1752. His apparatus consisted of a pole 32 feet high, insulated in the middle of a piece of turf. At its upper extremity was fixed a large and strong tube of glass, which carried a tube of white iron terminating in a point. Towards the middle of this tube was tied a small iron wire about 50 lines long, which was connected, without touching any other body, to a silk cord stretched in a horizontal position. M. Le Monnier observed, that there was always more or less electricity in the atmosphere, and he discovered that in dry weather, it increased from sun-ris when it was scarcely perceptible, to three or four o'clock in the afternoon when it was strongest, and that it afterwards gradually diminished till the fall of the dew, when it again increased, and afterwards diminished till it became almost insensible at midnight. This diurnal period was afterwards confirmed by Saussure and Beccaria.

In the following year, the same subject was prosecuted by the Abbé Mazeez at the Château de Maintenon, in the months of June and July. His apparatus consisted of an iron wire about 370 feet long, raised to the height of 90 feet above the horizon. It was brought down from a very high room in the castle, where it was fastened to a silk cord 6 feet long, and was carried from this to the steeple of the town, where it was fixed to another silk cord 3 feet long, and protected from rain. A large key was then suspended at the end of this wire to receive the electric matter.

From the 17th of June, when his experiments commenced, the electricity of the air was distinctly perceived, every day, from the rising of the sun to 7 or 8 o'clock in the evening, excepting in damp weather, when no indications of electricity appeared. When the weather was dry, minute bodies were attracted by the wire, if their distance was not greater than three or four lines, and he always found in weather not stormy that the electricity of the air was half as great as that of a stick of sealing wax 2 inches long. When he grasped the wire firmly in his hand, the electricity immediately ceased, and did not reappear till after an interval of 3 or 4 minutes. With the view of collecting a greater quantity of electricity, he added another wire, which communicated with an electrical-machine composed of pieces of iron, tin plates, gilt paper, &c. supported by silk cords; but he did not find that the electricity had become stronger. When he now grasped the wire firmly in his hand, it did not return till after a longer interval than before. The Abbé Mazeez likewise observed, that the electricity of the air was not increased with storms and hurricanes unattended with rain; for during a violent storm of wind, which continued without interruption for three days, in the month of July, he found it necessary to place the dust within four or five lines of the conductor, before it experienced a sensible attraction. No change was produced by the different directions of the winds. In the driest nights of summer, he was never able to observe any electricity in the air, but it always began to appear in the morning at sunrise, and vanished again in the evening at half an hour after the setting of the sun. In the month of July, in a very dry day, when the sky was serene, and the heat of the sun intense, he found the electricity to be stronger than he had ever observed it. The dust was then attracted at the distance of 10 or 12 lines from the conductor.

The electricity of the atmosphere, in its ordinary state, was observed also by Mr Kinnersley. He found that when the air was very dry, it always contained electricity, and he rendered this electricity visible by electrifying himself negatively, and extending his arm into the air when it was dark, with a long sharp needle. The electricity then appeared luminous as it converged to the point of the needle.

Signor Beccaria examined the subject of atmospheric electricity with particular attention, both by means of rods and electrical kites. He found that there was no perceptible electricity in the air, when the atmosphere was in the three following states. 1. When the weather was clear and windy. 2. When the sky was covered with slow moving clouds, and black clouds; and 3dly, When the weather was moist, and not actually raining. The electricity was always perceptible in a clear, calm, and calm weather and in rainy weather, without lightning, the electricity always appeared a little while before the rain fell, and when the rain was actually falling, but it disappeared a short time before the rain had ceased. These signs of electricity were always stronger, when his rods reached higher into the air, and when his electrical kites flew to the greatest height. Insulated strings extended in the open air acquired a degree of electricity which increased with the length. Having extended across the river Po a cord 1500 Paris feet in length, he found it as strongly electrified during a shower, unattended with thunder, as a rod of metal had been during a thunder storm.

The most complete series of observations on atmospheric electricity was made by M. de Saussure. The general results which he obtained are highly interesting, and although they are not given by him as completely established, yet they are well worthy of the attention of philosophers. He found that the electricity of the atmosphere varied with the situation. It was generally stronger in places the most elevated and isolated. It was imperceptible under trees, in the streets, in courts, and in general in any inclosed place.
It was, however, perceptible in towns, in the middle of large squares, on the sides of quays, but principally on bridges, where he found it much stronger than in the open country. It is more the relative than the absolute height of the place of observation that affects the intensity of atmospheric electricity. It is strongest, for example, at the angle of a terrace raised about 15 or 20 feet above the level of the country, than in the middle of a flat plain, or the top of a high hill; for as the angle of the terrace is more insulated, it has with the earth fewer points of contact, which deprive it of its electricity.

The intensity of atmospheric electricity is subject to great changes in the same place. When the weather is not serene, it is impossible to assign the law of these variations, as it does not seem to depend upon the time of the day, or upon any of the known modifications of the atmosphere. The reason of this is obvious. When contrary and variable winds prevail at different heights, when clouds are rolling above other clouds, those winds and clouds, which we cannot perceive, influence the stratum of air in which the experiment is made, and produce changes, of which we see only the effects. In stormy weather, for example, we observe the electricity strong, then become imperceptible, and afterwards recover its strength, become positive, and the next moment negative, without any apparent cause for these variations, which sometimes occur so rapidly that it is impossible even to note them down. When the weather is rainy, without being stormy, these variations are less sudden. The intensity of the electricity alone varies, being almost always positive in rainy or snowy weather. In cloudy weather, when it is neither rainy nor stormy, the electricity follows nearly the same laws as when the weather is serene. The intensity of the electricity is commonly diminished by strong winds, which bring the different strata of the atmosphere successively towards the ground, and this promotes the uniform distribution of the electric fluid between the air and the earth.

The state of the air, with the exception of stormy weather, when the electricity of the atmosphere is strongest, is during the prevalence of fogs, which are always accompanied with a very perceptible electricity, unless when they resolve themselves into rain, when sometimes no electricity is visible. At Geneva, the fogs are a pretty certain sign of good weather. They often do not rise to a great height above the surface of the earth; and when the low grounds are completely obscured, the sky is clear on the mountains. In these cases the fogs conduct to the earth the electricity of the serene air which reigns above them.

In winter and in clear weather, Saussure found that the electricity of the air was generally weakest in the interval which elapsed between the time when the falling of the dew had ceased in the evening, and the instant of the rising of the sun. Its intensity then gradually increased, and sooner or later, but almost always before mid-day, it reached a certain maximum, after which it diminished till the fall of the dew, when it is sometimes stronger than it has been during the whole day. It then gradually decreases during the night, but never becomes imperceptible, if the weather is perfectly clear. The electricity of the atmosphere has, therefore, a diurnal period like the sea, increasing and decreasing twice in 24 hours. Its intensity is a maximum some hours after the rising and setting of the sun; and it is weakest before the rising and setting of that luminary.

In order to give an example of this diurnal period, M. Saussure has selected the observations of the 22d of February 1785, which was one of the coldest days ever remarked at Geneva; and he has also given the observations made on the day which preceded and followed it. These results are contained in the following Table. The observations were made 60 feet above the level of the Lake of Geneva. The thermometer and hygrometer were suspended in the open air on a south-west terrace, and the electrometer gave the same electricity as if it had been placed under similar circumstances in an open plain, for the wall of the terrace increased this electricity as much as the neighbourhood of this house diminished it. The height of the barometer is reduced, according to the method of M. De Luc, to what it would have been if the mercury had been constantly at the temperature of 10° of Reaumur. A weak wind from the southeast prevailed almost constantly on the 21st, 22d, and 23d of February, when the observations were made.

Table, shewing the Electricity of the Atmosphere during three Days, at various Hours of the Day and Night.

</table>
It appears from the first 18 observations of the preceding Table, which were made in an interval of 26 or 25 hours, during which the sky was perfectly serene, that the electricity of the atmosphere was very strong about nine o'clock in the morning; that it diminished gradually till six o'clock in the evening, when the first minimum took place; that it afterwards increased till eight o'clock, when it reached its second maximum; that it then diminished again, making some oscillations, till six o'clock of the following morning, when it reached its second minimum; and then increased again till ten o'clock in the evening, when it was again at a maximum.

The weather, however, being how cloudy, the periods became less regular.

In summer, the electricity of clear weather is much weaker than in winter. Saussure has observed the pith balls diverge two lines in winter in an open country; whereas in summer their greatest divergence did not exceed a line, at least when the sky was perfectly serene, for in the time of a storm they often diverged as remote as the threads permitted them. The weakness of the electricity of clear weather in summer renders the diurnal period less regular and less distinct; for since its fundamental quantity is very small, accidental causes, such as winds, and different quantities of humid vapour and dry exhalations that exist in the air, disturb the regularity of the diurnal period, and make the maximum and minimum fall in points opposite to what they would have done in cloudy weather.

In summer, when the ground has been dry for some days, the electricity of a dry and warm day generally increases from the rising of the sun, when it is almost insensible, to three or four o'clock in the afternoon, when it attains its greatest force. It then gradually diminishes till the fall of the dew, when it recovers its strength; and afterwards becomes almost imperceptible during the night. We have already seen that this diurnal period was first noticed by Le Monnier. It was afterwards determined with more exactness by Becquerel, and Dr. Cardini obtained a similar result. None of these writers, however, have noticed the diurnal period in winter which we have just described from Saussure. It is very remarkable, also, that this period is the same in summer in those clear days which follow rainy days, the electricity diminishing towards the middle of the day.

In serene weather the electricity of the atmosphere is invariably positive, both in summer and in winter, during the day and night, at the rising of the sun and at the falling of the dew; and in short at every time when there are no clouds in the sky. It is impossible, therefore, not to conclude with Volta, that the electricity of the atmosphere is essentially positive, and that when negative electricity does exhibit itself in snow, rain, and in storms, it arises from the clouds being exposed to the pressure of the electric fluid contained in the upper regions of the atmosphere, or in clouds more elevated than themselves. These clouds discharge a part of their electricity into the earth or into other clouds, and are thus electrified negatively by the effect of an electricity originally positive, in the same manner as an electrometer acquires a permanent negative electricity when it is touched at the instant that the air is positively electrified.

The interesting results obtained by Saussure of which we have given a very full account, cannot be considered as of general application to climates different from that of Geneva. Hence it becomes a matter of importance to have observations made in different parts of the globe, in order to ascertain the local causes by which the electricity of the atmosphere may be affected. Mr. Thomas Ronayne made a series of observations on the electricity of the atmosphere in Ireland, and obtained the following results: He found that the air in Ireland was always charged with positive electricity in winter, at a proper distance from buildings, masts of ships, &c. The electricity was diminished in frost, foggy, or misty weather, and in calm and cloudy weather it was still perceptible. In summer he was never able to discover any electricity, excepting when a fog came on in the cool of the evening, or at night, and then it was always positive, but weaker than in winter fogs. When a fog became very thick, Mr. Ronayne remarked that the electricity diminished, but again recovered its strength when the fog returned to its former state. When rain fell in foggy weather, the electricity became imperceptible, but reappeared with the fog. When fogs, floating near the earth, became very dense, the electricity is...
ELECTRICITY.

imperceptible, but when the fogs were situated high in the air the reverse took place. Mr. Henley found from 20 experiments, that the electricity of a thick fog separated the balls of an electroscope from \( \frac{1}{2} \) to \( \frac{1}{4} \) of an inch.

Mr. Cavallo made a great number of valuable experiments on atmospheric electricity, both with an electrical kite, and another instrument of his own invention, which he calls an atmospheric electrometer. * These experiments with the electrical kite afforded the following general results:

1. The air appears to be at all times charged with positive electricity, which is stronger in frosty than in warm weather, and is by no means less in the night than in the day time.

2. The electricity of the kite is generally diminished by the presence of clouds. They very seldom increase it, and produce sometimes no effect whatever.

3. The electricity of the kite is generally negative, and very seldom positive in the time of rain.

4. The electricity of the kite is not affected by the aurora borealis.

5. The electrical spark from the string of the kite, or any insulated conductor connected with it, is seldom longer than a quarter of an inch, but is extremely puny. When the index of the electrometer does not indicate more than 20°, the person who receives the shock feels its effect in his legs, and the effect of it resembles more the discharge of the Leyden phial, than a spark taken from the prime conductor.

6. The electricity of the kite is in general stronger or weaker, according as the string is longer or shorter.

In the course of the experiments from which these conclusions were deduced, Mr. Cavallo met with a singular example of a powerful electricity existing in the atmosphere, when there was neither thunder nor lightning, and when there was none either for three days before or three days after the observation. Independent of the importance of the observation itself, it affords a useful lesson respecting the precaution which ought at all times to be taken by those who are engaged in examining the electricity of the atmosphere. As the account of it, given by Cavallo, will not admit of abridgment, we shall present it in his own words.

"October the 18th. After having rained a great deal in the morning and night before, the weather became a little clear in the afternoon, the clouds appearing separated, and pretty well defined. The wind was west, and rather strong, and the atmosphere in a temperate degree of heat. In these circumstances, at three P.M. I raised my electrical kite with three hundred and sixty feet of string. After that the end of the string had been insulated, and a leather ball, covered with tinfoil, had been hung to it, I tried the power and quality of the electricity, which appeared to be positive, and pretty strong. In a short time a small cloud passing over, the electricity increased a little; but the cloud being gone, it decreased again to its former degree. The string of the kite was now fastened by the silk lace to a post in the yard of the house wherein I lived, which was situated near Islington, and I was repeatedly charging two coated phials, and giving shocks with them. While I was so doing, the electricity, which was still positive, began to decrease, and in two or three minutes it became so weak, that it could be hardly perceived with a very sensible cork ball electrometer. Observing at the same time that a large and black cloud was approaching the zenith (which, no doubt, caused the decrease of the electricity) indicating imminent rain, I introduced the end of the string through a window, in a first-floor room, wherein I fastened it by the silk lace to an old chair. The quadrant electrometer was set upon the same window, and was, by means of a wire, connected with the string of the kite. Being now three quarters of an hour after three o'clock, the electricity was absolutely imperceptible; however, in about three minutes time, it became again perceivable, but now upon trial was found to be negative; it is therefore plain, that its stopping was nothing more than a change from positive to negative, which was evidently occasioned by the approach of the cloud, part of which by this time had reached the zenith of the kite, and the rain also had begun to fall in large drops. The cloud came farther on, the rain increased, and the electricity keeping pace with it, the electrometer soon arrived to 15°. Seeing now that the electricity was pretty strong, I began again to charge the two coated phials, and to give shocks with them; but the phials had not been charged above three or four times, before I perceived that the index of the electrometer was arrived at 35°, and was keeping still increasing. The shocks now being very smart, I desisted from charging the phials any longer; and, considering the rapid advance of the electricity, thought to take off the insulation of the string, in case that if it should increase farther, it might be silently conducted to the earth, without causing any bad accident, by being accumulated in the insulated string. To effect this, as I had no proper apparatus near me, I thought to remove the silk lace, and fasten the string itself to the chair; accordingly I disengaged the wire that connected the electrometer with the string, laid hold of the string, untied it from the silk lace, and fastened it to the chair; but while I effected this, which took up less than half a minute of time, I received about a dozen or fifteen very strong shocks, which I felt all along my arms, in my breast, and legs, shaking me in such a manner, that I had hardly power enough to express my purpose, and to warn the people in the room to keep their distance. As soon as I took my hands off the string, the electricity (in consequence of the chair being a bad conductor) began to snap between the string and the shutter of the window, which was the nearest body to it. The snapping, which were audible at a good distance out of the room, seemed first isochronous with the shocks which I had received, but in about a minute's time it altered; so that the people of the house compared their sound to the rattling noise of a jack going when the fly is off. The cloud now was just over the kite; it was black, and well defined, of almost a circular form, its diameter appearing to be about 40°; the rain was copious, but not remarkably heavy. As the cloud was going off, the electrical snapping began to weaken, and in a short time became unnoticeable. I went then near the string, and finding the electricity weak, but still negative, I insulated it again, thinking to keep the kite up some time longer; but observing that another larger and denser cloud was approaching space towards the zenith, as I closed then no proper apparatus at hand, to prevent every possible bad accident, I resolved to pull the kite in; accordingly a gentleman who was by me began pulling it in, while I was winding up the string. The cloud was now very nearly over the kite, and the gentleman, who

* A description of these instruments will be found in Part II. of the present article.
ELECTRICITY.

Descriptive Electricity.

was pulling in the string, told me that he had received one or two slight shocks in his arms, and that if he were to feel one more, he would certainly let the string go; upon which I laid hold of the string, and pulled the kite in as fast as I could, without any farther observation, being then ten minutes after four o'clock."

By means of the atmospheric electrometer, with which Cavallo made experiments several times a-day, during many months, he obtained the following additional results:

1. The electricity of fogs is always positive, like that of the atmosphere.

2. The electricity is always strongest in thick fogs, and in frosty weather, and weakest when it is cloudy and warm, and about to rain.

3. The electricity is strongest in elevated situations.

A series of interesting observations on the electricity of the atmosphere, were made by Mr John Read, at Knightsbridge, in the year 1789, 1790, and 1791, by means of an ingenious apparatus which we shall afterwards describe. The monthly results of his experiments in the year 1790, are given in the following Table, which was formed principally from the electrical signs afforded by the pith balls within his apartment. When the balls collapsed, and were not attracted by the finger, he wrote down that there were no signs of electricity. When they were attracted on the approach of the finger, but were not so strongly charged as to produce a divergence, he wrote down weak signs of electricity. When the balls diverged and collapsed on the approach of excited glass, he wrote down that the electricity was positive; but when the balls diverged still more, by the application of the excited glass, he wrote down that they were electrified negatively. When the divergence of the balls was one inch and upwards, visible sparks were drawn from a brass ball connected with the apparatus. The utmost limit of regular divergence was about 5 or 6 inches, above which it was very unsteady. The pith balls were nearly 1/64ths of an inch in diameter, and were suspended by very fine flaxen threads 5 inches in length. In carrying on these experiments, Mr Read was seldom absent one hour, excepting during the time of sleep; but whenever he left the apparatus for the evening, he examined the state of the electricity, and when the rod was unelectrified, he connected with it a Leyden phial, and next morning if the bottle was charged, he marked down the kind of electricity with which it was charged. In Mr Read's journal, is marked the state of the wind, the barometer, and thermometer for every day in the year, and the electric spark, the kind of electricity exhibited by pith balls, and the state of the balls themselves, and of the weather.

It appears from Mr Read's Journal, that there were only 7 days in the year in which the electricity was imperceptible, and only 73 in which weak signs of electricity appeared. The days in which no electricity appeared, were the 14th, 15th, and 23d of November, and the 6th, 15th, 17th, 21st, and 22d of December.

The following Table contains the summary of Mr Read's observations in 1791.

* This instrument will be described in Part II of the present article.

</table>

By comparing this Table with the preceding, it will appear that the differences in the electrical state of the atmosphere have been very considerable. Positive electricity appeared only 241 times in 1790, whereas it appeared 423 times in 1791. The number of times in which negative electricity appeared was nearly equal, being 156 times in 1790, and 157 times in 1791. The number of days in which sparks were drawn was 58 in 1790, and 106 in 1791. Mr Read, however, states, that the greater number of times in which positive electricity appeared in 1791, was partly owing to his having employed a better apparatus.

Mr Read has drawn the following conclusions from his numerous experiments on atmospheric electricity.

1. In a course of moderate weather, the electricity of the atmosphere is invariably positive, and exhibits a flux and reflux, in which it undergoes an increase and a decrease twice in every 24 hours.

2. The electricity is strongest about 2 or 3 hours after the rising of the sun, and some time before and after sunset; and it is generally weakest between noon and 4 o'clock.

3. The periodical electricity of the atmosphere seems to be manifestly influenced by heat and cold. Hence, it is obvious, why warm small rain is weakly electrified, while cold rain which falls in large drops is the most intensely electrified of any.

The most recent experiments on the electricity of the atmosphere have been made by Andrew Crosse, Esq. of Broomfield, near Taunton, by a very extensive atmospheric conductor, consisting of an insulated copper wire, 1/4th of an inch thick, extended between two vertical masts from 100 to 110 feet high. No exertion was spared to render this apparatus the most extensive and perfect that has been constructed. The insulated wire was made no less than one mile and a quarter in length, but having been exposed to depredations, and liable to injury from other causes, it was shortened to 1800 feet. Every contrivance has been tried to insulate this wire, but Mr Crosse has not yet been able to preserve the insulation during a dense fog or a driving snow. A contrivance was adopted to lower the insulators, for the purpose of cleansing them from spiders' webs; and it was necessary to fix the wire very securely, in order that it might be able to resist the weight of innumerable swallows that often perched upon it, and of wood pigeons and owls that often flew against it with considerable force.

This apparatus has been in use more than eighteen months, and has enabled Mr Crosse to draw the following important conclusions, many of which confirm the observations of preceding authors.

1st. The electricity is invariably positive in the ordinary state of the atmosphere. It is always weakest during the night. It increases at sunrise, then decreases towards the middle of the day; and regaining its strength as the sun declines, it again diminishes, and continues feeble during the night.

2d. Fogs, rain, snow, hail, and sleet, produce changes in the electrical state of the wire. The electricity is negative when they first appear. It frequently changes to positive, gradually increasing in strength; and then decreasing in a similar manner, and changing from positive to negative every three or four minutes. Those phenomena have been so constantly observed, that whenever the wire appears negatively electrified, it is considered as a certain indication, that either rain, snow, hail, mist, or a thunder cloud, is in the neighbourhood.

3d. The approach of a charged cloud at first sometimes produces positive and sometimes negative electricity; but whatever be the kind of the electricity which first appears, its intensity increases to a certain degree, and then diminishes and disappears, and is succeeded by the opposite electricity; which increases to a higher degree than the first had done, and then diminishes, and vanishes, and is again succeeded by the electricity which first appeared. These varying alternations of positive and negative electricity are often very numerous, and on different occasions succeed one another with different degrees of rapidity. The electricity, in general, becomes more intense at every repetition, till a copious and dense stream of sparks issues from the atmospheric conductor to the receiving ball, stopping at intervals, and returning with redoubled energy. Under these circumstances, a strong current of air proceeds from the wire, and the apparatus connected with it. Whenever the lightning flashes, an explosive stream, attended with a peculiar noise, passes between the balls of the apparatus, and throws a brilliant light on every surrounding object. When
the lightning is too powerful to permit the observer to carry on the operation in safety, he connects the insulated wire with the ground, and transmits the accumulated electricity in silence to the earth.

4th. During a driving fog, or a smart rain, the wire is electrified almost as powerfully as during a thunder-storm, and the electricity exhibits similar changes.

5th. A weak positive electricity generally prevails in cloudy weather. It often changes to negative when rain falls; but the positive electricity reappears when the rain has ceased to fall.

6th. The positive electricity is more intense in clear frosty weather than in a fine summer's day.

In the following Table, Mr. Crosse has given the different states of the air in which electricity appears, beginning with those in which it is most powerful.

1. During the occurrence of regular thunder clouds.
2. A driving fog accompanied by small rain.
3. A fall of snow, or a brisk hail storm.
4. A smart shower, especially in a hot day.
5. Hot weather succeeding a series of wet days.
6. Wet weather following a series of dry days.
7. Clear frosty weather, either in the night or day.
8. Clear warm summer weather.
9. A mackerel back or mottled sky.
10. A mackerel back or mottled sky.
11. Sultry weather, the sky covered with light hazy clouds.
12. A cold damp night.

13. A peculiar state of the atmosphere, which occurs during north-easterly winds, and which is regarded as particularly unhealthy, producing a sensation of dryness and extreme cold, which is not indicated by a depression of the thermometer.

A great number of experiments on atmospheric electricity have been made by Mr. Henley, Mr. Bennet, M. Achatel. M. Cotte. M. Erman, and various other authors, but we cannot find room to do any thing more than refer to their respective works.

2. On the Electricity of the Atmosphere as exhibited in Thunder and Lightning.

Although the existence of electricity in thunder storms is a modern discovery, yet there can be no doubt that the ancients were well acquainted with numerous phenomena that had the same origin.

Herodotus informs us, that the Thracians disarmed the heavens of its thunder, by throwing their arrows in the air; and that the Hyperboreans produced the same effect, by launching among the clouds darts armed with points of iron.

During the night before the battle which Postumius gained over the Sabines, the Roman javelins emitted a light like torches; and when Gylippus went to Syracuse, he perceived a flame upon his spear.* According to Procopius, the same appearance was seen in the war which Belisarius waged against the Vandals.† Livy ‡ informs us, that Lucius Atneas having bought a javelin for his son, who was about to be enrolled as a soldier, it threw out flames during two hours without being consumed by the fire. Similar facts are mentioned in Plutarch. and Pliny, and the last of whom observed the phenomenon himself. Cæsar informs us in his Commentaries, that in the African war, after a tremendous storm, which threw the Roman army into great disorder, the points of the darts of a great number of the soldiers shone with a spontaneous light. In the month of February, says he, about the second watch of the night, there suddenly arose a great cloud, followed by a dreadful storm of hail, and in the same night the points of the darts of the fifth legion appeared to be on fire. ¶

A very singular fact, analogous to those which we have now stated, is mentioned by Bianchini. There had existed from time immemorial, in one of the bastions of the castle of Duino, situated in the Frioul, on the banks of the Adriatic Sea, a pointed iron rod standing in a vertical position. In summer, when the weather had the appearance of being stormy, the soldier who mounted guard in this bastion, examined the iron rod, and presented to it the point of an iron halbert, which was always ready for this purpose, and whenever he perceived that the iron rod gave sparks, or displayed a small gerb of fire at its point, he rang a bell to give notice to the country people who were working in the fields, or to the fishermen who were at sea, that stormy weather was approaching. This custom was of great antiquity, and is mentioned by Imperati in a letter dated 1602. **

The production of electric light was no sooner discovered by Dr. Wall,†† than he noticed its resemblance to lightning; and the same remark was afterwards made by Gray,‡‡ who imagined that both the thunder and the

On the electricity of the atmosphere as exhibited in thunder and lightning.
lightning were imitated in the artificial production of electricity.

The Abbé Nollet spoke still more decidedly respecting the analogy of electricity with lightning; and his opinion was probably formed from the following singular fact, which is related by Saussure: In the summer of 1732, when M. Paccard, the secretary of the parish of Chamouni, was excavating the foundation of a château, which he wished to erect in the meadow of l'Impré, upon Mount Breven, a violent thunder storm came on, and compelled him to take refuge under a neighbouring rock. In the place where he had been working he had left a large iron lever standing vertically in the ground, and he was astonished to observe the thunder and lightning, as he called it, fall several times upon the head of the lever. On the following winter M. Paccard went to Paris, and attended a course of lectures given by the Abbé Nollet; and as soon as he perceived the sparks from an electrifying machine, he was so struck with their resemblance to the fire which had fallen upon his lever, that he immediately communicated the observation to the Abbé Nollet. In the possession of such information, it is unaccountable how this learned philosopher should have neglected to try the experiments which, after the lapse of eighteen years, were made by his countryman Dalibard.

Dr Franklin, some time afterwards, drew up a list of the points of resemblance between electricity and lightning. Still, however, these conjectures had no solid foundation; and it is a singular fact, that no experiment had been made to verify a theory of such vast importance.

The celebrated naturalist Buffon, seems to have been the first person who made any attempt to draw down lightning from the heavens. Upon the tower of Montbar, he raised an insulated bar of iron, which he connected with a conductor and with balls, to give him notice at a distance of the presence of the electric fluid, and he waited with anxiety for the first storm of thunder.

At the recommendation of Buffon, M. Dalibard constructed a similar apparatus at Marly la Ville, about six leagues from Paris. It consisted of an iron rod 40 feet long and about an inch in diameter, and pointed at its upper extremity. The rod was bent at its lower end into two acute angles, and was placed in a garden upon three large poles, and insulated by means of silk strings, and a stool with glass feet. M. Dalibard, during his absence, entrusted the charge of his apparatus to a joiner named Coiffier, who had served 14 years in the dragoons, and who was supposed to have sufficient courage for such an undertaking. Dalibard had given him every requisite instruction, and had desired him, in the event of a thunder storm, to call in some of his neighbours, but particularly M. Raulet, the curate of the parish. In Dalibard's absence, the thunder storm made its appearance on Wednesday the 10th of May 1752, and between two and three o'clock in the afternoon, after a pretty loud clap of thunder, Coiffier ran to the apparatus, and presenting it to the end of an iron wire, insulated by a glass handle, he perceived a small spark attended with a cracking noise. He then drew a second spark, more brilliant than the first, and attended with a louder noise, and instantly called his neighbours as he was desired. The curate ran towards the apparatus with great impetuosity, and his parishioners imagined, from his great hurry, that Coiffier had been killed by the thunder. The alarm spread through the village, and in spite of the hail which followed the thunder, all the inhabitants flocked after their pastor. As soon as the curate arrived at the apparatus, he presented the insulated brass wire at the distance of about an inch and a half, and received a strong spark, which he describes as a small column of bluish fire, which smelt of sulphur, and which struck the end of the brass wire with great force. He repeated the experiment more than six times in the space of about four minutes, before several persons, and every experiment, to use his own words, "continued during the space of a pater and an ave." The sparks gradually diminished, and upon bringing the wire nearer the rod, he was able to draw only a few sparks, which soon disappeared. As soon as the cloud had passed, the curate dispatched Coiffier with a letter to Dalibard, containing the preceding statement. In the course of the experiments, M. Raulet had somehow or other received a stroke upon the arm, either from the rod or from the brass wire. Upon uncovering it, he perceived a mark, as if it had been made by a blow from the wire upon his naked skin.

A few days after the preceding experiment had been made, M. Delors, Demonstrator of Physics in Paris, who lived in one of the most elevated quarters of the town, had raised a bar of iron 90 feet high, insulated upon a cake of resin two feet square and three inches thick. On the 18th of May, between four and five o'clock in the afternoon, a stormy cloud passed over the apparatus, and M. Delors received several sparks from his rod, which resembled, in every respect, those which issued from ordinary electrifying machines. The strongest sparks were drawn at the distance of nine lines, whilst a shower of rain, mixed with a little hail, fell from the cloud, without either thunder or lightning. The conductor even gave sparks, when the cloud was over Vincennes, at least two leagues from the place of observation.

Buffon, though he had the merit of erecting the first thunder rod, was unluckily the last to observe any of its electrical phenomena. On the 19th of May, however, a stormy cloud at length passed over Montbar, and Buffon obtained from his rod several electrical sparks.

All these experiments were made in France, before Dr Franklin had raised his electrical kite in America; but without any knowledge of what had been done by the French philosophers, he succeeded in establishing the identity of lightning and electricity in the month of June 1752, and posterity have unanimously agreed in associating his name with that brilliant discovery. In our History of Electricity, we have already given a full account of the method by which he succeeded in bringing lightning from the clouds, and of the fatal accident which happened to Professor Richman of St Petersburg, in repeating that grand experiment.

No sooner was this great discovery published, than numerous attempts were made, in different parts of Europe, to obtain the same result. The Abbé Mazeau, Le Monnier, Rosas, Cassini, Bertier, Canton, Bevis, Wilson, Becarria, Muschenbroek, Kinnerley, Prince Gallitzin, van Swinden, Bertholon, De la Garde, Ver- rat, Marin, Zanotti, Bosc, Cordon, and other philosophers, succeeded in bringing down the electric fluid from the clouds, and have established, on the firmest basis, the identity of lightning and electricity.

The most successful, as well as the most meritorious

* See Saussure, Voyages dans les Alpes, 8vo edit. 1786, vol. iii. p. 79.
† See the History of Electricity, p. 417.
ELECTRICITY.

...of all these philosophers, was undoubtedly M. de Romas, who had not only the merit of having first invented and used the electrical kite, but obtained, with it, a series of results, far surpassing, in magnitude and grandeur, those which had been obtained by Dr Franklin, or by any other philosopher.

Having observed, on the 12th of July 1753, that insulated rods gave stronger sparks, in proportion to their height in the atmosphere, M. Romas resolved to elevate a kite to the height of more than 600 feet, and he stated this plan in a letter to the Academy of Bourdeaux, on the 13th July 1752; and also mentioned it distinctly to M. le Chevalier Vivens, and several other individuals. This kite was seven feet five inches high, and three feet in its greatest width, with a surface of 18 square feet. The string of the kite was of cord, wrapped round with copper wire. On the 14th of May 1753, he raised it in the atmosphere without obtaining any indication of electricity, but on the 7th of June 1753, he was more successful. At one o’clock it thundered a little in the east, and at half past two, M. Romas had elevated his kite with a cord 750 feet long, and inclined at an angle of 45° nearly, so that the elevation of the kite was about 500 feet. To the extremity of the string he fixed a silk-en cord 3½ feet long, which was placed under the cover of a pent house, and had suspended to it a large stone, for the purpose of governing the motion of the kite. Near the junction of the string and the silk cord, was placed a tube of white iron, about a foot long and an inch in diameter. From which the sparks were to be seen as soon as the kite and the string were electrified. M. Romas also prepared a discharging rod, formed of a tube of glass 12 inches long and 3 lines in diameter, having at its end a tube of white iron, to which was fixed a chain of brass wire sufficiently long to touch the ground, when sparks were drawn from the first white-iron tube. By means of the discharging rod, he at first obtained sparks “as large as those produced by means of a good globe,” and several of his assistants drew sparks with a key and with the naked finger. These electrical phenomena were observed during about 22 minutes, and then disappeared. In the space of seven minutes the electricity reappeared, and again decreased, but only to manifest itself with additional force. New sparks were drawn by the fingers, the keys, the swords, and the canes of the spectators; and M. de Romas having presented the middle knuckle of his right hand, received a terrible shock, which struck him in the elbows, shoulders, knees, and the joints of his feet. Seven or eight of the bystanders, though they saw, from the convulsive motions of M. Romas, that he had received a very violent blow, did not hesitate to join hands, and received the sparks, which struck the feet even of the fifth person. The storm now increased—not a drop of rain had fallen; but in the zenith of the kite, and about 60° round it, there were black clouds, which indicated a great increase of electricity. Romas had therefore the prudence to receive sparks only by the discharger. At the distance of four inches, a spark, more than an inch long and two lines broad, was drawn in this manner, and, at the distance of six inches, Romas obtained several sparks two inches long. After this the electricity became so powerful, that instead of sparks, flashes of fire, about a foot long, three inches wide, and three lines in diameter, were repeatedly received, and the accompanying noise was heard at the distance of more than 500 feet. At this time, when he was more than three feet from the cord, Romas felt a sensation as if a spider’s web had been upon his face. He advised his assistants to keep at a greater distance, and when he himself was 5 feet from the string, he experienced the same sensation. He then retired still farther, and watched the phenomena which took place. There was no lightning, almost no sound of thunder, and no rain. The wind—which was in the east, blew strong, and supported the kite at an altitude of about 650 feet. Upon casting his eyes to the white-iron tube, at the junction of the string and the silk cord, which was about three feet distant from the ground, he was surprised to observe three straws standing erect, and dancing up and down below the white-iron tube. One of the straws was a foot long, another 5 inches, and the third 4 inches. This dance of the straws, which gave great delight to the spectators, lasted about a quarter of an hour, when a few drops of rain fell, and Romas again felt the former sensation upon his face, which indicated a new increase of electricity, and prevented him from drawing sparks even with the discharging rod. Having advised every person to keep at a greater distance, he perceived the longest straw attracted by the white-iron tube, and immediately heard three loud noises, which some compared to the crack of a postilion’s whip, and others to the sound of a large pot of earthenware dashed in pieces on the pavement. This clash was heard even in the centre of the town, and the experiment was made out of the town, in spite of the great noise which prevailed. The flash, which accompanied this explosion, had the shape of a spindle 8 inches long, and 4 or 5 lines in diameter. The straw which occasioned this noise, followed the string of the kite, and was seen even at the distance of 45 and 50 toises, going with great rapidity, being sometimes attracted, and sometimes repelled, and every attraction being accompanied with long plates of fire, attended with continual explosions. After the first spontaneous explosion, till the end of the experiment, there was no lightning, and almost no thunder. A phosphoric odour, peculiar to the electric matter, was distinctly smelt. Around the string there appeared a cylinder of permanent light, about three or four inches in diameter; and when the experiment was finished, they perceived in the ground, in a perpendicular direction, below the tube, a hole about an inch deep, and half an inch wide, which had probably been made by the large flashes of fire which accompanied the explosion. The wind having turned to the east, there was a heavy shower of rain, which was succeeded by hail, and it was no longer possible to keep the kite in the air. When the kite fell, the straw touched the roof of a house, and about 60 feet from the string being drawn in, the person who held it made the kite rise again, and immediately received such a violent shock in his arm, and throughout his whole body, that he was obliged to let it go. The string then fell upon the feet of one of the assistants, who also received a very violent shock.

On the 16th of August 1757, M. Romas was still more successful in his experiments. Although the storm was not great, there being almost no thunder, and very little rain, yet he obtained beams of fire nine or ten feet long, and about an inch thick, which were accompanied with a noise equal to that of a pistol. In less than an hour he obtained no fewer than 30 beams of this size, without reckoning a thousand others that were below...
Electricity.

7 feet in length. These great flashes were spontaneous, and in spite of the abundance of fire which they formed, they constantly fell upon the nearest living body. This circumstance inspired M. Romas with confidence, and he did not hesitate to excite the fire with his discharging rod, at the time when the storm was most violent; and when the glass of which it was composed was two feet long, he was able to conduct, without feeling the slightest shock, beams of fire 6 and 7 feet long, with as much facility as he formerly conducted those which were scarcely 7 or 8 inches. In this experiment, the string of the kite was one half longer than it was in his other experiment; and he attributes the magnitude of the effects to the three following causes: 1. To the great length of the string. 2. To the continuity of the metallic wire which the string was wrapped round. And, 3. To the peculiar disposition of the clouds.

The identity of electricity being thus established by numerous and direct experiments, philosophers next attempted to observe the phenomena which accompanied the production of thunder and lightning, and to ascertain the manner in which they were generated by the electricity of the atmosphere.

When the sky is clear and serene, low and dense clouds begin to form in the atmosphere. They are spread over the heavens by a wind more or less violent, and are succeeded by others more thick and obscure. These clouds are agitated with various motions. While some of them are moving above in one direction, others are moving below them in an opposite direction. One cloud is seen to attract another, while others are separated by a repulsive force, and, in the midst of this universal agitation, other clouds are resisting immovable, in virtue of the opposing forces with which they are influenced. Amidst this conflict of opposite forces, flashes of blue light are seen to dart with inconceivable rapidity from one cloud to another, and, after the lapse of several seconds, the rumbling noise of distant thunder is faintly distinguished. The sky soon becomes more obscure, the lightning more frequent and vivid, and the thunder more loud, and succeeding the flashes of lightning at a shorter interval. A dreadful gloom is now spread over nature, and the sun almost seems to threaten the extinction of his feeble light. The husbandman retires from the fields; the fisherman forsakes his nets; the birds of the air desert their native element; the brate creation run up and down in wild dismay, or seek for shelter from the impending danger; and the sky and the fields are thus left unpeopled during this dreadful strife of the elements. The storm is now at its height, the accumulated electricity of the clouds is seen to strike towards the earth, striking the tallest oak in its passage. Such a stroke is often accompanied with actual danger, man himself begins to partake in the general dread, and amidst this play of celestial artillery, he often feels for the first time the true rank which he holds in the scale of being. These tremendous phenomena often make the circuit of the whole horizon, and are frequently interrupted by heavy showers of rain or hail, till the atmosphere resumes its wonted serenity.

The lesser phenomena which appear in a storm, do not merit any particular description. The flashes of lightning sometimes appear on an angular or zigzag form, and are then called forked lightning. At other times, particularly when it strikes the earth, there is the appearance of a dense globe of fire; and at other times it is a sudden and universal flash, which has received the name of sheet lightning. The sheet lightning is most frequently seen in fine summer evenings, and is on these occasions never accompanied with thunder. The colour of lightning is sometimes of various shades of blue, at other times of a vivid yellow colour, and at other times of a pale straw colour; and it is probable, that the nature and intensity of its colour depends on the nature and density of the stratum of air which it traverses.

The noise of the thunder, which in general follows the flash of lightning, has various characters, depending on the situation of the person who hears it, and probably on the state of the clouds in which it is produced. Sometimes it resembles a sudden crash, like the sound of a piece of artillery, which is not repeated or prolonged by reflection. Sometimes the noise is rumbling and irregular, like the prolonged and dying echoes of a pistol when discharged in a mountainous country; and at other times it resembles the series of sounds, which are produced by the successive discharge of a great number of muskets. The first of these sounds generally takes place when the thunder is near, and the second is generally the character of distant thunder. The distance of the thunder stroke may be easily computed, by multiplying 1142 by the number of seconds which elapse between the flash and the thunder; the product is the number of feet at which the stroke has taken place.

In the preceding observations, we have spoken only of that kind of lightning which either flashes from cloud to cloud, or descends in a thunder bolt to the earth, destroying every non-conducting body that resists its passage. Another kind of thunderbolt, however, has been observed, which rises from the earth, and has therefore received the name of the ascending thunderbolt. This species of thunder appears to have been observed by the ancients; and the Tuscanians have even divided thunder into two kinds, viz. celestial and terrestrial, or that which falls from the clouds and that which rises from the earth. The first modern writer who noticed this species of thunderbolt was the Marquis de Maffei, who wrote a letter on the subject on the 10th Sept. 1713 to M. Vallisnieri, professor in the university of Padua. When living at the chateau of Foslinovo, situated on a mountain, he observed in the time of a storm the lightning issue from the ground, attended with a loud noise. The Abbé Jerome Lioni di Ceneda† witnessed the very same phenomenon in a violent storm. A brilliant flame rose rapidly from the earth to the height of two yards, and disappeared with a loud noise.

George Frederick Richter‡ relates, that in the cellar of the Benedictines of Potigno, when the servants were pouring into a cask some wine which had been boiled, a light flame shone round the funnel, and the operation was scarcely finished, when a frightful noise, similar to that of loud thunder, was heard. The cellar was filled with fire, the bottom of the cask was found pierced

† "Subito ascendit flamman vividaissimam conspecto, duos paulo minus subito supra terram tenue traecus ascendens, et etiam quam paro evanescens, relicto terribilissima fragore." Journal de Venise, tom. xxxii. art. 8. § 41.
‡ Richter De nativibus fulminum tractatus physicus. Leips. 1725.
with a hole three inches in diameter, the staves were broken, and in spite of the iron hoops which retained them, they were dashed with violence against the walls. In 1725, M. Seguier of Nismes, when he was at a country house about a league from the town, observed during a thunderstorm the lightning to rise from the houses in the form of a flame about 6 feet wide. This phenomenon soon disappeared, and was followed by a loud clap of thunder. Similar phenomena have been noticed and described by many distinguished philosophers, so that there can be no doubt that lightning often rises both from the surface of the earth and from the surface of water in the time of thunder storms. The Abbé Bertholon has collected, with great care, numerous examples of this phenomenon, but we can only find room for the references to the works in which they are contained.

The Marquis Maffei and several other authors have concluded from the preceding facts, that lightning has its origin in the earth, and always ascends into the atmosphere. This conclusion, however, is obviously too general, and is directly opposed by facts more numerous than those which are brought to support it.

Having thus described the general phenomena which accompany a storm of thunder and lightning, we shall conclude this Section by an account of some electrical appearances, of a very singular character, which have been observed by individuals when overtaen by thunder storms on the tops of lofty mountains.

In the year 1767, M. de Saussure, M. Pictet, and M. Jalabert ascended to Mont Breven, which is situated nearly in the middle of the valley of Chamouni, and almost exactly opposite to Mont Blanc. Their object was to take a general view of the form and position of the glaciers which descend from this celebrated mountain. When they reached the summit, M. Jalabert began to take a drawing of the glaciers, M. Pictet was engaged in the geographical part, and M. de Saussure was preparing to make his experiments on natural and artificial electricity. When M. Pictet was laying down upon his plan some particular mountains by means of a graphometer, he had occasion to ask the names of them from the guides, and was therefore obliged to point out the individual mountains with his finger. Every time that he raised his hand for that purpose, he felt at the extremity of his finger a kind of tremulous and prickly sensation, similar to that which is experienced upon presenting the finger to a globe of glass highly electrified. M. Pictet soon perceived the origin of this phenomenon. He observed a stormy cloud in the middle region of Mont Blanc, directly opposite to Mont Breven, and it instantly occurred to him that he had been affected with the electricity of the cloud. He then requested M. de Saussure and Jalabert to repeat the experiment, and as soon as they extended their hands, they experienced the same sensation, which they described as resembling a number of small electric sparks; but fearing that they might be seduced by their imagination, they made their guides and their servants stretch out their hand, and they felt the same sensation. The electricity of the atmosphere having now begun to increase, the sensation became stronger, and was even accompanied with a kind of whistling noise. M. Jalabert, who had a gold band upon his hat, was alarmed with a buzzing noise about his head, and having taken off his hat, and put it successively upon the heads of Pictet and Saussure, they heard distinctly the same sound, and even obtained sparks from the golden button of the hat. The thunder cloud had now moved across the valley, and was directly above their heads. The thunder was loud, and the flashes of lightning so frequent, that the travellers found it prudent to descend about 20 or 30 yards, where no electricity could be perceived. The guides, however, were so much delighted with the experiments, that it was with great difficulty they were persuaded to abandon such a dangerous amusement. A shower of rain soon afterwards fell, and the storm ceased. The travellers reascended to the summit, and although they elevated an electric kite, they were unable to perceive any indications of electricity in the atmosphere.

A series of electrical phenomena, very similar to those which we have now described, were recently observed by a party of Englishmen, when they were descending Mount Etna, during a storm of thunder and lightning. I have been indebted for the particulars of the following account of them to my friend Dr Gordon, to whom it was communicated through the medium of a letter to Dr Moncrieff, by Mr Gillies, surgeon to his majesty's ship Partridge. This gentleman not only read a detail of the phenomena in a Sicilian journal, entitled Specchio della scienza e Giornale Encyclopedic de Sicilia, which was published in July 1814, but received an account of them from Mr Tupper, one of the party, coinciding in every respect with that which was given in the Sicilian Journal. On the 2d of June 1814, Mr Tupper and Mr Lanfear, accompanied by a guide, ascended Mount Etna. During their descent, when they were at a little distance from the place called the English House in the regio deserta, they were over taken with a storm of thunder and lighting, accompanied with a heavy fall of snow; and while running over an extensive field of snow, they were struck by a flash of lightning, from which, however, they experienced no serious injury. Mr Tupper felt a painful sensation in his back, which gradually ascended towards his head, and occasioned a sensation as if his hair was moving, an effect exactly similar to that which is produced either when a person is electrified upon an insulated support, or when his head is presented to the prime conductor of an electrifying machine. This sensation induced Mr Tupper to raise his hand to his head, upon which he was surprised to hear a buzzing noise proceeding from his finger. Upon raising and extending his arm the noise still continued, but upon moving his hand and fingers in different directions, and with different degrees of velocity, he found that he could produce, at pleasure, a great variety of musical sounds, differing in their tone as well as in their intensity, and so loud that they could be distinctly heard at the distance of 40 feet. The Sicilian guide witnessed these phenomena with extreme dismay, and imagining that Mr Tupper produced the sounds in virtue of some supernatural power, he immediately began to cross himself, and invoke the protection of his saint. His alarm, however, speedily subsided, when, upon being desired to elevate his own arm, he found it as musical as that of Mr Tupper. Mr Lanfear, who was a little behind the rest of the party, now joined them, and found that his fingers possessed a similar property. In the course of five minutes, reckoning, we presume, from the arrival of Mr Lanfear, their fingers lost their acoustic property, the cloud having by this time passed to a considerable distance. Mr Tupper had received an injury in his left shoulder joint by a fall from his horse, but he never afterwards experienced any return of the pain after the copious electrification which he received upon Mount Etna.
ELECTRICITY.

The preceding phenomena admit of a ready explanation, upon the simplest principles of electricity. As snow is a conductor next in order to water, and very little inferior to it in its power of transmitting electricity, it is quite obvious that the bodies of the travellers were not overcharged with the electric fluid in consequence of any difficulty which they experienced in passing into the earth. Their fingers therefore acted like so many points in drawing electricity from an atmosphere highly charged, just in the same manner as when the hand or the head is presented to an electrified prime conductor. The variety in the character, as well as in the intensity, of the sounds which were produced at the points of their fingers, arose from the different velocities of their fingers, and may be readily imitated by any other species of sound. The buzzing noise which M. Jalabert heard round his head had a different origin, having been produced by the discharge of the electric matter which had been accumulated in the gold band, and which found a ready escape into the atmosphere by the numerous points of gold thread, than by the imperfect conducting power of the hat which it encircled.

For further information on the subject of this Section, see Nollet's Leçons de Physique, tom. iv. p. 34; Paccard in Saussure's Voyages dans les Alpes, tom. iii. p. 79. Trans., vol. xlvii. p. 272; Gallitzin, Observations sur l'Électricité Naturelle par le moyen d'un ceint-électrique; Bertholom, De l'Électricité des Meteors, tom. i. p. 66.

3. On the Electricity exhibited in the production of luminous Meteors.

The Aurora borealis is undeniably the most magnificent of all the luminous meteors, which appear to be produced by the agency of electricity. In our article on that subject, (See Aurora Borealis,) we have already given an account of the various theories which have been brought forward to explain this remarkable appearance, and have pointed out its connection with the phenomena of electricity. Almost every philosopher, indeed, has adopted this opinion, and all the theories of the aurora borealis, with the exception of that of Monge, have called in the aid of electricity, either as a primary or a secondary agent. In the theory of M. Libes, for example, he supposes that a mixture of azote and hydrogen is inflamed by the action of the electric spark; and M. Dalton, who considers the aurora borealis as a magnetic phenomenon, still supposes that the light is produced by the transmission of the electric fluid.

Monge has ascribed the aurora borealis to the light of the sun as successively reflected from clouds placed at different distances in the heavens; but if this were the case, it is obvious that the light thus reflected would be either wholly or partly polarised, and if the light were not incident on the clouds at the polarising angle, the polarisation would still be effected by the number of reflections which it undergoes. Dr Brewster, however, has shown, from immediate observation, that the light of the aurora borealis has none of the properties of reflected light, and must therefore be direct light generated in our own atmosphere.

Mr Ronayne, Mr Cavallo, and some other authors, have often observed the state of the air during an aurora borealis, with electrical kites and thunder rods, but they were not able to procure any indication of electricity. On the other hand, a hissing and crackling noise has been heard by Mr Nairne and by Mr Cavallo, and Canton and Volta have obtained unusual degrees of electricity during the prevalence of this meteor. It must be remarked, however, that neither the existence nor non-existence of an unusual degree of electricity in the atmosphere, during an aurora borealis, could be considered as an argument, either against or in favour of its electrical origin; for it will appear, from the following Table, that the phenomenon takes place at such a height above the surface of the earth, that the regions in which it is formed might be highly charged with electric matter without imparting it in an unusual degree to the lower strata of the atmosphere.

In our article AURORA BOREALIS we have mentioned the method of imitating that phenomenon by electrical experiments. But the following experiment, conceived by the Abbé Bertholom, affords the best representation of the luminous columns by which the northern lights are generally distinguished. Let RR, Plate CCXLVI. Fig. 4. be the receiver of an air pump, and let a rod TT be screwed into a hole E, in a crescent of metal CD, whose lower surface consists of a number of angular projections; let a circular segment SS, of metal, having corresponding angular projections, be placed on the plate of the air pump, with the receiver being exhausted, and the metallic shoulder A is electrified, the whole of the receiver will be filled with a superb light, and columns of fire will dart from the angular projections in the crescent, to those of the plate SS.

The following Table contains the height of the aurora borealis at various times, and according to different observers. Excepting two or three numbers, the Table is taken from Bergman.

### TABLE shewing the heights of the Aurora Borealis.

The other luminous meteors, which have been considered as electrical, are fire balls or globes of fire, shooting stars, and the fire of St Elm. Fire balls are less frequent than other meteors, and generally consist of large globes of fire advancing with a progressive motion. The fire ball which appeared on the 17th July 1771, was seen by a great number of philosophers in various parts of England and France. It appeared to be about a foot in diameter, or larger than the full moon, and had a progressive motion from north-west to south-east. The light, which was very intense, lasted only a few seconds, and two minutes after it had.
ELECTRICITY.

Another species of meteors, called falling or shooting stars, are of very frequent occurrence. They have been observed at all seasons of the year, and during ev ery kind of weather; but they certainly occur most frequently at the season when the aurora borealis is visible, and are always seen in a lower region of the atmosphere. Mr Singer has counted no fewer than 80 of them in a single hour, and sometimes nearly twice that number.

The fire of St Elm, or Castor and Pollux, as it has been called, is a bright light, which often appears at the tops of ship masts, on the points of bayonets, and on the summits of spires. This phenomenon is obviously nothing more than the electricity of the atmosphere discharging itself into the earth by a pointed body elevated in the air.

Several authors have employed the electric fluid, for the purpose of accounting for volc anoes, earthquakes, fog s, and wa ter-spouts; but no facts have yet been established, which entitle us to consider these phenomena as of electrical origin. See Bergman, Opuscula, tom. v. p. 291. Dalton, Meteorological Essays. Ronayne, Phil. Trans. 1772, vol. lxii. Cavallo's Electricity, vol. ii.; Cavallo's Natural Philosophy, tom. iv. p. 559. Bertholot, De l'Electricité des Meteores; tom. ii. and Singer's Elements of Electricity, p. 261. See Meteoric Stones.

CHAP. III.

On the Effects of Electricity.

SECT. I. On the Mechanical Effects of Electricity.

In the transmission of the electric fluid through bodies that have the power of conducting it with facility, its passage is not marked with any mechanical effect; but when electricity is accumulated to such a degree as to be capable of passing through a non-conducting substance, it experiences such a resistance in its passage, that it can only be overcome either by expanding or shattering the substance itself. It is thus that the accumulated electricity of the atmosphere is carried off in silence and safety when it strikes upon a rod of iron, while a beam of wood or a tree is shivered into a thousand fragments. The mechanical effects of electricity are exhibited in its power of impelling and dispersing light bodies, of perforating, expanding, compressing, tearing, and breaking to pieces, all conducting substances through which it is sufficiently powerful to force its passage.

Exp. 1. If a light wheel, having its vanes made of card paper, be made to turn freely upon a centre, it will be put in motion when it is presented to an electrified point. The wheel will always move from the electrified point, whether its electricity is positive or negative. In this experiment, the current seems to be produced by the recession of the similarly electrified air in contact with the point; and, therefore, the circumstance of the wheel turning in the same direction when the electricity is negative, cannot, as Mr Singer has remarked, be considered as any proof of the existence of a double current of the electric fluid.

Exp. 2. Having formed a groove, either by bending a piece of clean card paper, or by hollowing out a piece of baked wood, or by placing parallel to each other two straight sticks of sealing wax, lay the groove upon the plate of Henley's universal discharger, and place a large pith ball, about half an inch in diameter, so as to be at equal distances from the two brass knobs of the discharger. The distance of these knobs should be about four inches, and the groove placed on the line joining the knobs. If one of the wires is connected with the outside of a charged jar, while the knob of the jar is brought into contact with the other wire of the discharger, so that a small spark may pass from the one knob of the discharger to the other, the pith ball will be impelled from the positive to the negative knob; that is, to the knob which communicates with the negative side of the jar. Mr Singer recommends the use of points instead of the knobs employed by Cavallo; and he has shown, we think satisfactorily, that the transmission of the charge is prevented by the use of knobbled wires; and that the motion of the ball is, in that case, produced by attraction, whereas, with pointed wires, the effect is produced solely by a continued current of electricity.

Exp. 3. Place upon an insulating stem a light wheel of card paper, properly suspended upon pivots, as represented in Fig. 5. Plate CCXLVI. and introduce it between the pointed wires A B of the universal discharger, placed exactly opposite to each other, and at the distance of little more than an inch from the upper vanes. Then having connected the wire A with the positive conductor, and the wire B with the negative conductor of an electrical machine, the little wheel will revolve in the direction AB; and if the wire B is con-

* See Part II. of this article for a description of this ingenious instrument.
ELECTRICITY.

Perforation of non-conducting bodies.

Exp. 4. Place a piece of card against the outside coating of a Leyden phial, and bring the lower knob of the discharging rod towards the outside coating, so that the thickness of the card is interposed between it and the tinfoil; then, when the jar is discharged by bringing the upper knob in contact with the knob of the jar, the charge will pass through the card and perforate it. On the side of the card, next the discharging rod, there will be a small burr or protrusion, and on the other side a larger bur. The holes in the card will be larger or smaller, according to the humidity or dryness of the card. A quire of paper, or the board of a book, may also be perforated by a great charge, and if the paper be freely suspended, it will be perforated without receiving the least motion, in the same manner as a ball will pass through an open door without turning it on its hinges. When this experiment was made by Mr Symmer, the paper was laid in a horizontal position, and he found that the ragged edges pointed mostly outwards from the body of the quire. When he turned over the leaves, however, he found that the edges of the holes were bent regularly in two different ways, and more remarkably so, about the middle of the quire, one part of each hole upwards, and the other part downwards, so that tracing any particular hole as it traversed the quire, he found that on one side the fibres pointed one way, and on the other side the other way, as if the hole had been made in the paper, by drawing through it two threads in opposite directions.

Mr Gough has lately shewn, that when the preceding experiment is accurately performed, the bur on the negative side is always the largest.

Exp. 5. Place in the middle of a paper book, about the thickness of a quire, a slip of tinfoil, and, in another paper book of the same thickness, place two other slips of the same kind of tinfoil, separated by the two middle leaves of the book. Let a strong charge be now made to pass through these two books in succession, and the following effects will be visible. In the first book, the paper leaves on each side of the tinfoil will be perforated, while the tinfoil itself is merely indented in opposite directions, and the burrs and the perforation will point different ways. In the second book, all the leaves of paper will be penetrated, excepting the two that are included between the slips of tinfoil, and in these two leaves there will be two impressions or indentations, in opposite directions.

Mr Symmer, who made the experiment in the presence of Dr Franklin, concluded from it, that there were two opposite currents of electricity arising from electric fluids, and the same conclusion has been drawn by Mr Ezekiel Walker. Mr Singer, however, has endeavoured to shew, that these effects are produced solely by an expansion of the paper.

Exp. 6. Take a small phial, or a glass tube sealed hermetically at one end, and fill it nearly with olive oil. Having put a cork into the phial or tube, introduce a wire through it, so that its sharp point may touch the inside of the phial or tube beneath the surface of the oil. Let the vessel be now suspended to the prime conductor of an electrifying machine, and the machine being worked, bring either the knuckle or a brass ball exactly opposite to the point of the wire within, so that a spark may pass between the wire and the knuckle, the passage of the electricity through the glass will perforate it completely. By bringing the wire in contact with different parts of the glass, a great number of holes may be made in it.

Exp. 7. Place the ends of the two wires at the distance of an inch from each other, and experiment under the receiver of an air pump, and, in proportion as the air is exhausted, the place of perforation will happen nearer the positive wire. When the air is half exhausted, the hole is precisely half way between the two wires. At every discharge, a flash passes from each conductor to the place of perforation. This experiment was confirmed by M. Trenerry.

Exp. 8. Make the preceding experiment under the receiver of a pump, and, in proportion as the air is exhausted, the place of perforation will happen nearer the positive wire. When the air is half exhausted, the hole is precisely half way between the two wires. At every discharge, a flash passes from each conductor to the place of perforation. This experiment was confirmed by M. Trenerry.

Exp. 9. Into a piece of soft tobacco-pipe clay, or any other kind which is neither too dry nor too moist, introduce two wires, so that their distance within the clay is not very great. Let a shock be passed through the wire, as already described, and it will be found that the clay is curiously expanded in the interval between the wires. If the clay is too dry, or the shock too strong, it will be shivered into innumerable fragments. If the clay is placed in the tube of a tobacco pipe, or in a glass tube, and if the shock is sent through it as before, the expansion of the clay will be so powerful as to shatter the tube which contains it.

In the course of his experiments on the effects of explosion through metallic substances, Dr Priestley observed, that a chain through which he had sent the charge of a battery was shorter than it was before. He then measured two feet four inches of the chain when it lay upon the table, and having sent through it a charge of 46 square feet of coated glass, it was shortened a quarter of an inch in its whole length.

Mr Nairne repeated the experiment with a piece of hard drawn iron wire 10 inches long, and 1/4th of an inch in diameter. He discharged 26 feet of coated glass nine times through the wire; after the sixth and

ninth time the wire was measured, and was found to be
shortened in the proportion of \(\frac{1}{4}\)th of an inch at each dis-
charge. The same battery was then discharged six times
more through the same wire, which continued to short-
ened in the same proportion, the total diminu-
tion of length being \(\frac{1}{4}\)th inch and \(\frac{3}{4}\)th of an
inch. It could not be found, by a pair of scales that
turned with less than \(\frac{3}{4}\)th of a grain, that there was any difference in its
weight. It appeared, however, to have increased in
thickness, and it is probable, that its contraction in
length was owing to successive expansions. Mr Nairne
also found, that a piece of copper wire plated with
silver, and of the same dimensions as the iron wire,
was shortened only \(\frac{1}{10}\)th of an inch by one charge of
26 feet of coated glass, which is only \(\frac{3}{4}\) of the effect
produced upon the iron wire.

Mr Brooke found, that a battery of nine bottles, ex-
posing 16 square feet of coated surface, when disch-
raged nine times through a piece of steel wire 12 inches
long, and \(\frac{3}{4}\)th of an inch thick, diminished its length
one inch and a half.

**Exp. 10.** If any other substance, inferior in conduct-
ing power to the metals, such as water, be placed in a
glass tube, and if a shock is sent through the wires as
formerly, the tube will be broken in pieces by the ex-
pansion of the water. The same result will be obtained
if a common drinking glass, filled with water, is need
instead of the tube.

Beccaria made this experiment with a drop of water
in the centre of a solid glass ball, and the ball was brok-
en in pieces. In the same way Mr Morgan has suc-
ceded in breaking green glass bottles filled with water,
when the distance of the wires, between which the
shock passed, exceeded two inches; and Mr Singer
has burst glass tubes half an inch thick in the sides
with a bar of the same size: Beccaria varied the ex-
periment in a very pretty manner, by constructing a small
mortal with a ball, and placing behind the ball a drop of
water, so as to be between the two wires which pas-
sed through the side of the mortar. The charge being
sent through the two wires, the drop of water was
expanded with such force, as to drive out the ball with
great velocity. By a drop of oil, M. Lullin of Geneva
projected the ball with still greater velocity.

**Exp. 11.** Into the mouth of a mortar of ivory with
a cavity an inch deep, and half an inch wide, fit a cork cap,
so as to shut up the aperture without much friction,
and having made the wires pass through the sides of
the mortar, a shock sent through the wires will sud-
denly expand the air, and drive out the cork with
considerable violence.

**Exp. 12.** Fill a capillary tube with mercury, and
make the charge pass through it by means of wires, as
formerly, and the expansion of the mercury will be suf-
ficient to burst the tube.

**Exp. 13.** If the charge of a jar is made to pass over
the surface of a piece of soft dough, the tract of the
fluid will be marked with a permanent depression.

**Exp. 14.** If a clean brass chain, dipped in melted
rosin, is laid upon paper, and if the charge of a battery
of 52 square feet is sent through it, the resinous coat-
ing will be driven off from every part of the chain which
will be left as clean as if no rosin had been upon it.

**Exp. 15.** If the brass chain is laid upon a piece of
glass, and a similar charge passed through it, the glass
will be marked in a beautiful manner on every part of
its surface where it had been touched by the chain,
every spot having the width and colour of the link.

The metal could be scraped off the glass at the outside
of the marks, but in the middle part it was forced with-
in the pores of the glass.

Dr Priestley, to whom we are indebted for the two
preceding experiments, gave the same tinge to glass
with a silver chain, and small pieces of other metals,
but he could not obtain large pieces.

**Exp. 16.** Place a piece of dry writing paper upon
the table of Henley's discharger, and having taken off the
balls, place the ends of the wires against the paper, so
that the distance between the wires may be two inches.
If a powerful shock is now sent from one wire to the
other, the paper will be torn in pieces.

**Exp. 17.** In a piece of wood, half an inch long, and
a quarter of an inch thick, drill two holes at its oppo-
site ends, and insert the ends of two wires in the holes,
so that the points of the wires are at the distance of a
quarter of an inch. If a strong charge is now passed
through the wire, the wood will be split in pieces.

Stones, sugar, and other non-conducting and brittle sub-
stances, may be broken in a similar manner.

**Exp. 18.** Having placed a piece of plate glass, about
an inch square, and half an inch broad, upon the table
of Henley's discharger, and having pressed it (down
with a weight, set the points of the wires opposite to each
other, and against the under surface of the glass. If
the charge of a large jar is now sent through the wires,
the glass will be broken into innumerable fragments,
and some of it reduced even to an impalpable powder.
When the glass is very thick, so as to resist the effects
of the shock, it will be found marked with vivid priz-
matic colours, which, Mr Henley imagines, are produ-
ced by thin laminae of the glass separated from it by
the shock; but it is more probable that it is an oxidation.

**Exp. 19.** If a very large charged jar has its outside
coating connected with the outside coating of another
jar about ten times less, and if a communication is made
by the discharging rod with their inside coatings, the
small jar will be broken, from the great quantity of elec-
tricity which is suddenly transferred to it.

The curious experiments of Professor Lichtenberg
of Gottenburg, on the arrangement of powders upon an
electrified plate, may be given without much impro-
propriety under the present Section.

Let a plate of any resinous substance, as rosin, gum
lac, &c. be excited either by friction or otherwise,
and let any metallic body of any shape whatever, a brass
ring for example, be placed upon the plate. Let this
ring be then electrified with an electricity opposite to
that of the plate, and afterwards removed from the plate
by a stick of sealing-wax, or any other non-conducting
body. Let some powder of rosin, kept in a linen bag,
be now shaken upon the resinous plate, then if the plate
is excited negatively, and the brass ring positively, the
powder will fall only on those points of the plate that
were touched by the brass ring, and will form beauti-
fully radiating appearances like stars, while almost no
powder will be found on any other part of the plate.

If, on the other hand, the plate is electrified positively,
while the ring is electrified negatively, then the pow-
dered rosin will fall only on the parts of the plate which
were formerly uncovered, the figures of stars being now
indicated by the absence of the powder.

These experiments, which were first known in Eng-
lnd in 1771, were immediately repeated and varied by
the Rev. A. Bennet, and M. Cavallo. Mr Bennet has
given the following account of his method of rendering
these figures permanent. "To make red figures, take
a pound of rasped Brazil wood, put it into a kettle with
as much water as will cover it, or rather more; also put

---

**Note:** The text contains a mix of historical and scientific observations related to electricity, including experiments involving glass, water, and metallic chains, as well as descriptions of the effects of electric discharges on various materials and structures.
In about an ounce of gum arabic, and a lump of alum about as big as a large nut; let it boil about two hours, or till the water is strongly coloured; strain off the extract into a broad dish, and set it in an iron oven, where it is to remain till all the water be evaporated, which with me was effected in about twelve hours; but this depends on the heat of the oven, which should not be so hot as to endanger its burning. Sometimes I have boiled the strained extract till it was considerably inspissated before it was placed in the oven, that it might be sooner dry.

When it is quite dry but not burnt, scrape it out of the dish, and grind it in a mortar till it be finely pulverized. In doing this, it is proper to cover the mortar with a cloth, leaving a hole through to prevent the powder from flying away and offending the nose, and also to do it out of doors if the weather be dry and calm, that the air may carry away the powder necessarily escaping, and which otherwise is very disagreeable. When ground fine, let it be sifted through a fine hair sieve, returning the coarser part into the mortar to be ground again. When the grinding and sifting are finished, the powder is ready for use. The resinous plate I have mostly used, was composed of five pounds of resin, half a pound of bees-wax, and two ounces of lamp-black, melted together, and poured upon a board sixteen inches square, with ribs upon the edges at least half an inch high, to confine the composition whilst fluid: thus the resinous plate was half an inch thick, which is better than a thinner plate, the figures being more distinct. After the composition is cold, it will be found covered with small blisters, which may be taken out by holding the plate before the fire till the surface be melted, then let it cool again, and upon holding it a second time to the fire, more blisters will appear; but by thus repeatedly heating and cooling the surface, it will at last become perfectly smooth. Some plates were made smaller, and the resinous composition confined to the form of an ellipse, a circle, or escutcheon, by a rim of tin half an inch broad; and fixed upon a board.

The next thing to be done is to prepare the paper, which is to be softened in water, either by laying the pieces upon each other in a vessel of cold water, or first pouring a little hot water upon the bottom of a large dish, then laying upon it a piece of paper, so that one edge of the paper may lie over the edge of the dish, to remain dry, that it may afterwards be more conveniently taken up. Then pour more hot water upon its upper surface. Upon this place another piece in the same manner, again pouring on more water, and thus proceed till all the pieces are laid in. By using hot water, the paper will be more softened in a few minutes than if it remains in cold water a whole day.

When the figures are to be made, the resinous plate must lie horizontally, whilst the electricity is communicated, if the experiment requires any thing to be placed upon the plate; but it is convenient afterwards to hang it up in a vertical position whilst the powder is projected, lest too much powder should fall where it is not required. A little of the powder may be taken between a finger and thumb, and projected by drawing it over a brush; or, what is better, a quantity of powder may be put into the bellows and blown towards the plate. When the figure is sufficiently covered with powder, let the plate be laid horizontally upon a table; then take one of the softened papers out of the water by its dry edge, and lay it carefully between the leaves of a book, pressing the book together, and let it lie in this situation about half a minute. Then remove the paper to a dry place in the book, and press it again about the same time, which will generally be sufficient to take off the superfluous moisture. Then take up the paper by the two corners of its dry edge, and place the wet edge a little beyond the figure on the resinous plate, lowering the rest of the piece gradually till it covers the figure without sliding; then lay over it a piece of clean dry paper, and press it gently; let it remain a short time, and then rub it closer to the plate with a cloth, or, which is better, press it down by means of a wooden roller covered with cloth, taking care that the paper be not moved from its first position. When the paper is sufficiently pressed, let it be taken up by its dry edge, and laid upon the surface of a vessel of water with the printed side downwards; by this means the superfluous powder will sink in the water, and the figure will not be so liable afterwards to spread in the paper. After the paper has remained on the water during a few minutes, take it up and place it between the leaves of a book, removing it frequently to a dry place. If it be desired that the paper should be speedily dry, let the book-leaves in which it is to be placed be previously warmed, and by removing it to several places it will be dry much sooner than by holding it near a fire, and without drawing the paper crooked.

Sect. II. On the Chemical effects of Electricity.

The effects of electricity as a powerful chemical agent, constitute one of the most interesting portions of the science. As these effects, however, are produced to a greater extent by the Galvanic apparatus, we shall have occasion to treat the subject at greater length under the article Galvanism. At present we shall confine ourselves to a few details respecting the action of the electric fluid in inflaming combustible bodies, in fusing and oxidizing metals, in promoting the combination and decomposition of different bodies, and in rendering them phosphorescent.

Exp. 1. Having placed warmed alcohol or ether in an insulated metallic cup, electrify the cup, draw a spark from the bottom of the cup either by the knuckle or any other conducting body, and the alcohol will be set on fire by the transmission of the spark.

Exp. 2. Place powdered rosin, or phosphorus, or camphor, on some cotton wool, and wrap it round one of the knobs of a discharging rod. Then having charged a Leyden jar, apply the naked knob to the external coating, and the covered knob to the ball of the phial, and the rosin, phosphorus, or camphor, will be set on fire by the discharge. Powdered rosin laid on the surface of water may also be inflamed by passing a charge over the surface of the water between two points.
ELECTRICITY.

Exp. 3. Into a clean wine glass well dried on the outside, and nearly full of water, pour a stratum of ether, which will of course lie upon the surface of the water. When the water is connected with the electrified conductor, and the knuckle presented to the surface of the ether, the spark which passes from the water to the knuckle will inflame the ether.

Exp. 4. Fix a small cartridge containing gunpowder upon a metallic wire, insulated at the extremity of a handle of glass or baked wood, and having presented the cartridge to the knob of a charged Leyden phial, the gunpowder will be exploded.

Exp. 5. In order to light a candle by electricity, thrust a wire up the middle of the candle to within a little distance of the wick, and having connected by a chain the outside coating of a charged Leyden jar with the lower extremity of the wire, bring the knob of the jar to the wick, and the candle will instantly be lighted. This experiment is represented in Plate CCXLVI, Fig. 6.

Exp. 6. In order to light a candle without a wire penetrating it, wrap some loose cotton over the end of a long brass pin or wire, and roll the cotton in some fine powdered resin. Having then charged a jar whose knob is bent outwards, so as to hang a little over the body of the phial, apply the naked extremity of the wire to the external coating, and the cotton end to the projecting knob, and the resin, and consequently the cotton, will be set on fire, and will burn long enough to light a candle. This experiment is by M. Ingenhouz, who recommends the use of the powder of white or yellow resin. If the cotton is dipped in oil of turpentine, the same effect will be produced by the aid of a larger jar; and it is singular, that the inflammation of the turpentine will be assisted by strewing upon it fine particles of brass dust.

The power of electricity in fusing metals was first observed by Dr Franklin, who placed thin pieces of them between two plates of glass bound fast together, and then passed an electric shock through them. The plates of glass were often shattered by the discharge; and when they remained unbroken, they were covered with metallic stains. A piece of gold leaf was thus driven into the pores of the glass, so as to be protected from the action of the strongest aqua regia. Fine gold made a reddish stain, and silver a greenish one. Mr Kinnersley, in the presence of Dr Franklin, exploded a case of bottles through a fine iron wire. The wire appeared at first red hot, and then fell into drops, which assumed a spherical form like small-shot. Mr Canton repeated this experiment, and found that with a case of 35 bottles, he could entirely destroy brass wire 1-330th of an inch in thickness. Beccaria succeeded in melting small stripes of metals, without placing them between panes of glass; and he imagined that all metals impressed the same colours upon a surface of glass. Dr Priestley having failed in repeating Mr Canton’s experiments, he inclosed the wire in small tubes of glass, and having sent through them the charge of a battery of 32 square feet, the wire was melted into globules of various sizes. He also inclosed his wires in paper; and on one occasion he melted an iron wire 1-70th of an inch in diameter with the same battery. Dr Priestley likewise succeeded in melting pieces of leaf brass, and driving them into the surface of the glass, so as to give them a metallic tinge. For this purpose he took three pieces of glass, and placed one of them on each side of that to which he proposed to communicate the tinge. A piece of leaf brass was then placed on each side of the middle plate. He then sent the charge of a battery through the two stripes of leaf brass, which projected a little over the glass plates. The upper and lower pieces of glass were shattered to pieces; but the middle piece being equally affected on both sides, remained unbroken, and had both its sides covered with a metallic tinge. These metallic colours have been employed to impress letters or ornaments on paper and silk. “The outline of the required figure,” says Mr Singer, “is first traced on thick drawing paper, and afterwards cut out in the manner of tinwell plates. The drawing paper is then placed on the silk or paper intended to be marked, a leaf of gold is laid upon it, and a card over that; the whole is then placed in a press or under a weight, and a charge from a battery sent through the gold leaf. The stain is confined by the interposition of the drawing paper to the limit of the design, and, in this way, a profile, a flower, or any other outline figure, may be very neatly impressed.”

The most accurate experiments on the fusion of metals by electricity have been made by Mr Brooke, Van Marum, Kienmayer, Mr Cuthbertson, and Mr Singer. The object of Mr Brooke was to determine the relation between the force of a battery and the quantity of wire which it was able to fuse. Mr Singer recommends as the best wire for experiments of this kind, the finest flattened steel wire sold at the watch-maker’s tool shops, by the name of watch pendulum wire. The circuit between the two coatings of the jar should be made as short as possible, and the wire should be placed in a straight line, and confined at the ends between small wire forceps. We have condensed the results obtained by Mr Brooke into the following Table. The two last experiments but one are by Mr Cuthbertson, and the last by Mr Singer.

These experiments of Mr Brooke, and those which were made by Mr Cuthbertson, prove, that the action of electricity in wires increases in the ratio of the square of the increased power, since two jars charged to any degree will melt 4 times the length of wire that is melted by one jar, and this will be again quadrupled by doubling the height of the charge. Mr Singer has found this law accurate with moderate lengths of wire, and he observes, that it varies with the thickness of the jars employed. A large jar, for example, in his possession, which, from the extent of its coated surface, should melt 26 inches of wire with a charge of 30 grains, only melts 18 inches, which is a striking proof of the correctness of Mr Cavendish’s conclusion, that the quantity of electricity necessary to charge different coated jars of the same extent, is inversely as the thickness of the jars. The progressive effects produced upon iron and General steel wire, by increasing the charge which is sent through them, are very singular. With a low charge, the colour is first changed to yellow, then becomes blue by a higher charge, then red hot, then red hot and melted into balls; and if we increase the charge still farther, it becomes red hot and drops into balls, then disperses in a shower of balls, and lastly disappears with a bright flash, producing apparently a smoke, which turns out when collected to be a fine powder, consisting of the metal combined with oxygen, and weighing more than the metal which was fused. Singer’s Elem. of Elec. p. 180.

The experiments of Van Marum were conducted on Van Marum a greater scale than those which we have already mentioned. The following is a short summary of the principal results which he obtained.

### TABLE containing the Experiments of Van Marum on the Fusion of Metals.

When Van Marum transmitted a charge of 225 square feet through 50 feet of iron wire 1/24 of an inch in diameter, he found that the jars were not entirely discharged, and that the residuum was capable of melting two feet of the same wire. When the explosion was sent through 180 feet of the same wire, the residuum was discharged through 12 inches of the same wire, but it merely blued it.

Baron Kienmayer employed in his experiments the Kienmayer plate glass machine described by Ingenhousz, with his experiment a battery of 1/6 square feet of coated glass, and he obtained the following results, when the barometer was at
The effect of lightning in fusing metals is so familiar to every reader, that it is scarcely necessary to mention it. Money is often melted in the pockets of those struck with lightning; swords have been melted in their scabbards; and the leaden frames of church windows have been frequently fused. There is in the possession of Thomas Allan, Esq. of Edinburgh, a curious parcel of nails, which were struck with lightning on the road between Oxford and London. They have a very singular appearance, and are obviously expanded into twice their original diameter.

The power of electricity to oxidate metals, was observed by Bectaria and other electricians; but it is to Mr Cuthbertson that we are indebted for the most complete series of experiments upon this subject. The apparatus which he employed is represented in Plate CCXLVI. Fig. 7, and consists of a cylinder of glass ab, 8 inches high, and 2½ inches in diameter. On the lower brass cap b is screwed a stop-cock, and in the inside of the vessel is fixed a small roller, on which a quantity of wire, attached to a push-rod at intervals of 4 inches, is coiled. A brass tube a, about 3 inches long, is screwed into the centre of the upper cap b, and, by means of a long needle, the end of the push-rod and wire is thrust through it, and hog's lard is placed in the tube, so that the wire and push-thread may move through it air-tight. In this way the wire is extended in the centre of the glass cylinder, and when one length of it is exploded, another may be drawn forward by means of the contiguous push-thread without opening the cylinder. In order to ascertain the quantity of air absorbed during the process, a gauge, shown separately at A, about 10 inches long, and made of a glass tube, is screwed into the lower end of the stop-cock, and immersed in a vessel of quicksilver, the rise of which, when the stop-cock is opened, will be a measure of the air absorbed.

The air left in the receiver after a number of explosions, is always found to have been deprived of a portion of its oxygen; and if hydrogen or nitrogen be substituted in place of atmospheric air, the metal will not suffer any oxidation, but will be melted, and minutely divided.

The following Table contains the results of Mr Cuthbertson's experiments:

In these experiments, Mr Cuthbertson employed very high charges, which is attended with great risk to the jars. Mr Singer repeated the experiments with shorter and finer wires, and with a moderate charge, and obtained the following results:

Mr Singer's experiments were not performed in receivers. The wires were stretched parallel to the surface of a sheet of paper, at the distance from it of ⅙ of an inch. When the explosion is made over glass, a part of the metal, in an unoxidated state, appears immediately under the wire, while the part of it which is oxidized produces around the other a figure of some width. In this case the figures are more beautiful, but less permanent than when they are impressed on paper. These experiments are generally made with high
of the Leyden jar being nearly one half. Dr. Pearson, who, after great labour, succeeded in decomposing water by electricity, made use of another method, which differs only from the preceding in the construction of the tube DE. Dr. Pearson fixed a glass tube DE, Plate CCXLVI. Fig. 9, or 5 inches long, and 4th or 5th of an inch in diameter, into the end of a brass tube EF, and placed the wire at the top D, as formerly described, making it extend to the brass tube, so as to be almost in contact with it, when the explosion is made. Care must be taken, however, to prevent the wire from touching the tube, for in this case no gas will be evolved. The tube being filled with water, and set in a cup of the same fluid, may be applied to the conductor, as already described; the insulated ball, however, must be placed at a greater distance from the prime conductor, and with a jar of only 50 inches of coated surface, gas will be produced in the brass tube at each discharge, in greater quantities, and with much less trouble than in the apparatus of the Dutch chemists, in consequence of there being no electricity left in the jar after each discharge.

Mr. Cuthbertson invented another very simple apparatus, shown in Plate CCXLVI. Fig. 10, where DE is a glass tube, 5 inches long, and half an inch wide, blown funnel-shaped at the end A. The other end has a wire ¼ of an inch thick sealed into it, as formerly described, and extending nearly to the bottom of the brass dish V, (generally within ¼ of an inch of it,) on which the tube rests. The coated surface of the jar requires to be about 150 inches, and the distance of the brass ball C from the conductor A was about ¼ th of an inch. From experiments made with these instruments, Dr. Pearson concluded, that the gas evolved from water consisted of oxygen and nitrogen, or azotic gas.

The apparatus for decomposing water was greatly simplified by Dr. Wollaston. This ingenious philosopher inserted two finely pointed wires, made either of gold or platinum, into capillary tubes. Each wire was introduced into the tube till it nearly reached the end of it, and the glass was softened by heat till it adhered to the point of the wire, and covered it. The glass was then gradually ground away, till the point of the wire could be seen through a magnifying lens. One of these wires communicating with the ground, or with the negative conductor of the machine, and the other with an insulated ball placed near the positive conductor, the two points were placed near each other in a vessel of water; when a current of sparks is discharged through the wires, a series of minute bubbles of gas rise from the points of the gold wires, and, when collected in an inverted receiver, they explode on the application of a lighted taper. Dr. Wollaston found by experiment, that a point ¼ th of an inch in diameter, decomposed the water when the spark which passed from the conductor to the insulated ball was ¼ th of an inch in length; and that a point ¼ th of an inch in diameter, produced a similar effect when the sparks were only ¼ th of an inch in length. Hence the rapidity of the decomposition was proportional to the limited size of the points of the wire. We are indebted also to Dr. Wollaston, for the following interesting experiments of Dr. Wollaston with the preceding apparatus. Having transposed a current of electric sparks, by means of two fine gold points, along the surface of a moistened card tinged with litmus, and placed between the points, a redness appeared about the positive wire after a few turns of the machine. By placing the negative wire upon the red spot, it was soon restored to its original...
blue colour. Hence it appears, that the positive effect of an acid is produced with wire, and that the opposite electricity counteracts this effect. Having coated two wires with sealing wax, so that the extremities only appeared, Dr Wollaston inserted them into a solution of copper, and, upon transmitting a current of sparks between the two wires, the negative wire was coated with copper. When the electricity of the wire was reversed, the coating of copper was immediately removed.

The agency of electricity, in combining and decomposing the gases, has presented chemistry with very interesting results. We are informed in Priestley’s experiments on air, that Mr Warltire fired a mixture of common and inflammable air by means of electricity, in a close copper vessel holding about three pints. A loss of weight, amounting at an average to two grains, was always perceived, although no air could escape by the explosion. When this experiment was repeated in glass vessels, clean and dry, the inside of the glass immediately became dewy. Mr Cavendish repeated these experiments in 1781. He exploded 500,000 grain measures of inflammable air with about 22 times that quantity of common air, and he, by this means, obtained 185 grains of pure water. Mr Cavendish then exploded a mixture of 19,500 grain measures of oxygen gas with 37,000 of hydrogen gas, and found that they were condensed into a liquor which weighed about 30 grains, which was sensibly acid to the taste, and which yielded two grains of nitre. By varying the proportions of the gases, he found, that as he increased the proportion of the hydrogen the acidity of the liquor was diminished, till, with certain proportions, the liquor differed in no respect from pure water. In the repetition of these experiments, Mr Cavendish confined the mixture of oxygen and hydrogen in a glass tube A, bent into an angle, as in Plate CCXLVI, Fig. 11; and which, after being filled with quicksilver, was inverted into two vessels of mercury. The gases were then introduced by a small thermometer tube, so as to occupy about one inch and a half in the angular part of the tube. He then connected the quicksilver in one of the glasses with an insulated ball, placed at a small distance from the prime conductor, while the quicksilver in the other glass communicated with the ground. Mr Cavendish found, that the experiment succeeded best when a mixture of five parts of oxygen with three parts of common air, was used instead of atmospheric air. He then introduced a little soap ley along with the air, and having sent through it a current of electric sparks, he continued adding more air as the air was diminished. The soap ley being then poured out of the tube, and separated from the quicksilver, were evaporated to dryness, and left a quantity of salt, which was evidently pure nitrate of potash. In consequence of several learned foreigners having failed in the repetition of this experiment, particularly Van Marum, Troostwyk, Lavoisier, Hassencratz, and Monge, Mr Cavendish wished to authenticate it in a public manner, and he therefore requested Mr Gilpin to repeat the experiment on the 6th of December 1787, before Sir Joseph Banks and the leading members of the Royal Society. The experiments were in every respect successful; and though there were some trifling differences in the proportions of the gases absorbed, yet he obtained the following average result, that seven measures of oxygen unite with nearly three measures of nitrogen to form nitric acid. Van Marum had written to Mr Cavendish, to learn the cause to which he attributed the failure of the continental philosophers in repeating this experiment. Mr Cavendish replied in a very handsome manner, and communicated to him every information on the subject. Van Marum, however, from some strange misconception, has represented Mr Cavendish, as having refused to comply with his request. Mr Cavendish has replied with great propriety to this charge, by publishing his own letter to Van Marum.

We cannot find room for any further details upon this subject; but the following Table, for which we are indebted to Mr Singer, will exhibit the principal results which have been obtained. When the mixture consists of inflammable gases and oxygen, the change is generally effected by a single spark; but in other cases, the current of sparks must frequently be continued for many hours.

The phosphorescent effects of electricity have been successively investigated by Mr Canton, Mr Lane, Mr Wilson, Mr Morgan, Mr W. Skrimshire, jun., and Mr Singer. Mr Skrimshire in particular has examined a great number of bodies, and has published the results which he obtained in the 15th, 16th, and 19th volumes of Nicholson’s Journal. He placed the substance to be examined on a brass plate, fixed horizontally on the knob of the prime conductor, by a thick piece of wire, and he endeavoured to take the spark from it by means of the ball of the discharger. It was afterwards placed upon a wooden stand, and the shock of a Leyden phial first passed over it, about a quarter of an inch above its surface, by resting the points of the discharging rods at the distance of an inch or more from each other upon the stone to be tried. In all the experiments it is necessary to close the eyes till the explosion be heard. In this way Mr Skrimshire obtained the following results:

TABLE, containing Mr Skrimshire’s Experiments on the Phosphorescent Effects of Electricity upon different Bodies.

Calcereous Genus.

| Experiments of Mr Skrimshire.                      |
|-------------------------------------------------|--------------------------------------|
| Calcereous spar                                  | Rendered very luminous by the shock. |
| Common chalk                                     | Very luminous when the shock passed above it. When passed along its surface, a zigzag track of light continued several minutes. Part of the stone shattered, and its luminous grains dispersed in all directions. |
| Ketton stone                                     | Shines for a few seconds with a vivid greenish light. |
| Selenite                                         | Gave small sparks, which were red flame-coloured upon its surface. |
| Fresh nitrate of lime                            | More phosphorescent than the nitrate of lime. |
| Muriate of lime                                  | Gave no sparks, but the electric fluid passed in a purple stream with a whizzing noise. |
| Dark purple fluor spar                           | Gave very good sparks, while dark purple fluor spar gave none. |
| Yellowish fluor spar                              | The most luminous of any substance by the electric explosion. |
| Sulphuret of lime, or Canton’s phosphorus        | A minute red spark. It is inflammable by a very small shock. |
| Phosphate of lime                                | Are rendered beautifully luminous, and give the prismatic colours. |
| Calcined oyster shells                           | Give a durable and bright light, according to Mr Singer. |
| Ditto calcined with sulphur                      |                                                   |

Barytic Genus.

| Experiments of Mr Skrimshire.                      |
|-------------------------------------------------|--------------------------------------|
| Carbonate of Barytes                             | No spark, but very luminous when the shock was passed above it. |
| Sulphate of Barytes                              | Good sparks, but slightly luminous. According to Singer, it gives a bright green light, more bright than that of the carbonate. |
| Sulphuret of Barytes                             | Was slightly luminous by the electric explosion. |

Muriatic Genus.

| Experiments of Mr Skrimshire.                      |
|-------------------------------------------------|--------------------------------------|
| Magnesia, pure and carbonated                    | Were both transiently luminous by the electric explosion. |
| Sulphate of magnesia                             | Very luminous throughout its whole substance. |
| Sulphuret of magnesia                            | Not more luminous than the carbonate. |
| Chlorite                                         | Sparks branching off in minute party-coloured points. |
| Steatites, tale, and fibrous amianthus           | Gave sparks, and were slightly luminous by the explosion. |
| Asbestus                                        | Ramifications on its surface more variegated than in chlorite. |
| Mica                                           | Affords sparks, but is not luminous by the explosion. |
| Micaceous schistus                               | Sparks ramified as in chlorite, scarcely phosphorescent. |

Argillaceous Genus.

| Experiments of Mr Skrimshire.                      |
|-------------------------------------------------|--------------------------------------|
| Alum                                            | Spark purple, rather ramified, luminous through its whole surface. |
| Pipe clay                                       | Sparks, and luminous, but not luminous when made into pipes. |

* These results are given on the authority of Dr Henry and Mr Dalton.
ELECTRICITY.

Sparks, and luminous, but loses its absorbent power as it becomes bituminous. (Singer; all phosphoric, (Skrimshire).)

Light, first red, and then white; a pale stream instead of a spark. (Singer.)

Phosphoric, with a dull white light; a purple stream instead of a spark.

Small purple spark. Not so luminous as quartz.

Aids very good sparks, and is luminous by the shock.

Luminous by the explosion, and gave hissing purple sparks.

Hissing purple sparks, and luminous by the shock.

Similar hissing sparks. Oval pebbles more luminous than the sand.

{Good sparks from the arborescent parts, but only a hissing stream from the stone itself, which is slightly luminous by the shock.

Hissing stream in some parts, and good sparks in others, slightly luminous.

} Neither give a spark nor are luminous.

Ditto.

Native carbonate of strontites.

Only a hissing purple stream, but very luminous by the explosion.

Combustibles.

Gives no spark, and is scarcely luminous by the shock.

Are not phosphoric.

Infames both by the spark and shock.

Some kinds afford good sparks, and are phosphoric, and some not.

Gives sparks, beautifully variegated, in minute spangles, radiated upon their surface; but they are not phosphoric.

Gives a very good spark, but is scarcely luminous.

Gives no sparks, but the fluid spreads uniformly and silently over its whole surface like the electric light in an exhausted receiver; it is luminous by the shock.

Is also luminous by the shock.

Give the same phenomena as bitumen, but are not luminous by the explosion.

Gives no sparks, but is phosphorescent, particularly fat amber.

Gives good sparks, and is not phosphoric.

Mr. Skrimshire was not able to discover any phosphorescent appearances, either in the metallic ores or oxides, or in the metals themselves.

M. Cavallo found, that the colours of vermillion, carmine, verdigrise, white and red lead, were altered by the electric shock; but that opaline, gamboge, sap green, red ink, ultramarine, Prussian blue, and a few other compounds of the above, were not altered.

We have avoided in the present Section giving any account of the brilliant electro-chemical researches of Sir Humphry Davy, as we propose to give a full account of his splendid discoveries in our article GALVANISM.

Sect. III. On the Magnetic Effects of Electricity.

In enumerating the points of resemblance between lightning and electricity, Dr. Franklin remarks, that they have both the power not only of reversing the poles of magnets, but of destroying the magnetism altogether. By transmitting a shock of four large jars through a fine sewing needle, he gave it such a degree of polarity that it readily traversed when laid on the surface of water. If the needle lay east or west when it was struck, the end Franklin's which was entered by the electric shock pointed north, and if it lay north and south, the end which lay towards the north continued to point towards the north, whether the shock entered at that end or at the other. He likewise found that the communicated polarity was strongest when the needle was struck lying north and south, and weakest when it lay east and west. In these expe-

Experiments of Van Marum.

riments, the needle was sometimes finely blued, like the spring of a watch.

Becaria repeated the experiments of Franklin, and found that lightning always gave polarity to the magnetic needle, and to all bodies, such as bricks, &c. that have any iron in their composition; and by observing the way in which these poles lie, he was thus enabled to ascertain the direction in which they were struck by the lightning. Hence he has conjectured, that a regular and constant circulation of the whole mass of the electric fluid from north to south may be the cause of magnetism in general.

Mr Benjamin Robins having had occasion to compare two compasses of a different make, one of them having a bare needle, and the other a chart like mariners' compasses, he accidentally wiped off with his finger some dust which lay upon the glass of the former, and was surprised to observe that the needle was thrown into a disorderly motion, partly horizontal and partly dipping. This disturbance he found to be owing to the electrical excitation of the glass by the slight friction which it received from his finger. By rubbing the glass with his finger, or with a bit of muslin or paper, either end of the needle was attracted by the part thus excited, and when the needle had for some time adhered to the glass, and afterwards dropped loose, its vibrations were not bisected, as usual, by that point where the needle should have rested. At the end of 15 minutes the electricity was generally dissipated, and the needle obeyed the magnetic force. By moistening the surface of the glass, or putting a wet finger upon it, the electricity could, at any time, be removed.

On the 9th of January 1749, the ship Dover, Captain Waddel, bound from New York to London, was struck and considerably damaged by lightning, in 'West Long. 29° 15', and North Lat. 47° 30'. There were four compasses in the ship, one of them in a brass box, and three in wooden boxes, and all of them were in good order before the storm. After the ship was struck with the lightning, however, Captain Waddel observed that all the needles had lost their virtue. The hanging compass in the cabin was not so much injured as the rest. The needles were at first nearly reversed, but after a little while they moved about in every direction, and were of no use. Mr Gowne Knight examined the compass, and observed that the outward case was joined together by pieces of iron wire, 16 of which were found in the sides of the box, and 10 in the bottom. Mr Knight applied a small needle to each of these wires, and found that the lightning had made them strongly magnetic, particularly those that had joined the sides.

If a steel wire is placed in a perpendicular direction, and a strong charge of electricity sent through it, it will be magnetized, and the lower end will be the north pole; if this end is now placed uppermost, and another charge passed through it, it will either destroy its magnetism altogether, or reverse its poles. The polarity of a natural magnet may also be destroyed, by transmitting through it a powerful shock.

The most accurate experiments, however, on the magnetic effects of electricity, were made by M. Van Marum with a battery of 135 jars, containing 130 square feet of coated surface, and with watch spring needles from 3 to 6 inches long, and also with steel bars 9 inches in length, between $\frac{1}{2}$ and $\frac{3}{4}$ an inch in breadth, and nearly a line in thickness. When the needle or bar was placed horizontally in the plane of the magnetic meridian, the north end of the bar acquired north polarity, and the south end south polarity, in whatever way the shock was communicated. When the bars had some degree of polarity before the shock, it was either diminished or reversed after it. When the needle or bar received the shock in a vertical position, its lowest end became the north pole, whether it was magnetic or not before the experiment. In general, the degree of magnetism which was communicated, was as strong in a horizontal as in a vertical position.

When the needle or bar was laid in the magnetic equator, it never acquired any magnetism in whatever way it received the shock, excepting when it was given through its width, and then the needle became considerably magnetic, the end which lay towards the west being the north pole, and the opposite end the south pole.

When the shock was so powerful as to make the needle hot, no perceptible magnetism was acquired.

When a magnetic bar, or a natural magnet, received the electric shock, its power was always diminished in whatever direction it was given.

Sect. IV. On the Effects of Electricity upon Animal Bodies.

When the effects of the electric shock were first exhibited, the most sanguine hopes were entertained that electricity would become a powerful agent in the cure of diseases. A fluid, indeed, so powerful and penetrating, which could be sent at pleasure through any part of the human body, and in any given quantity, might well be supposed capable of restoring to action and vigour the disordered functions of the animal frame; and had this investigation been left in the hands of those eminent men who were engaged in advancing the progress of electricity, science would never have been degraded by those gross impositions which have been practised upon the credulous.

We have already seen, in our History of Electricity, that several respectable individuals were for a while misled, by a number of absurd experiments said to have been made at Venice and Bologna. A diligent and careful inquiry, however, proved them to be false; and since that time, it has only been among a number of wandering enquirers, or among a few ignorant practitioners, that the panaceal power of the electric fluid has been acknowledged.

In these general remarks, we must not be understood as censuring, in the smallest degree, the cautious application of electricity, in some particular cases of disease. It were unphilosophical to maintain, that cures cannot be performed by this powerful agent; but the skilful and prudent physician will only admit its efficacy when he has seen it established by a cautious and impartial induction of well authenticated facts.

So late as the year 1785, there appeared a work by the Abbé Bertholon; entitled, De l'Electricité du corps humain dans l'état de Santé et de Maladie, in 2 vols 8vo. This work was crowned by the Academy of Sciences at Lyons, and its respectable author, who has cultivated, with assiduity, several branches of physics, was professor...
of natural philosophy to the States-general of Languedoc. In this work, electricity seems to be regarded as a power which has a most extensive influence in the cure of disease; and there is scarcely a class of maladies in which the Abbé Bertholon has not represented it as having proved successful. He has even gone so far as to maintain, that the electricity of the atmosphere has a principal share in the number of deaths, and particularly sudden deaths, and that it has a decided influence on generation, conception, and parturition.

Mr Carpeaux, in his Introduction to Electricity and Galvanism, has treated this subject with more caution. He has collected a number of cases in which electricity has been employed, and he has given the cases in which it was unsuccessful, as well as those in which it succeeded. Mr Singer has likewise enumerated several cases, in which the application of electricity has been beneficial; but from a careful examination of these cases, we should be disposed merely to conclude, that in rigidity, sprains, relaxations, indolent tumors, and chronic rheumatisms, the patient may reasonably expect, that he will either be relieved or cured by the agency of electricity.

Various facts have been published respecting the effect of electrical shocks upon animals in a state of health. Mr Morgan informs us, that if the diaphragm be brought into the circuit of a coated surface of two square feet, fully charged, the lungs will make a sudden effort, which is followed by a loud shout; but that if the charge is small, it always produces a violent fit of laughter, even upon persons of grave and solemn habits. The effect of a strong charge on the diaphragm is often followed by involuntary sighs and tears, and sometimes by a fainting fit. When a shock is sent through the spine of a person standing, he will often drop on his knees, or fall prostrate on the ground.

The effect of electricity in quickening the pulse was long ago maintained by M. de Bozes; and M. Nollet concluded from experiment, that it increased the sensible perspiration both of men and animals. In order to ascertain these points Dr Van Marum made the following experiments. In determining the effects of electricity on the pulse, he selected eleven persons, and repeated the experiments four times on each, both with positive and negative electricity. In order to prevent any effect being produced by the imagination, the persons were placed in a different room, that they did not know when the machine was in motion, or when it was at rest. The result was, that in some single cases a few beats more were observed, but, on the whole, there was no increase of any importance. In general, however, the pulse was very irregular, both when the machine was in motion, and when it was at rest.

For the purpose of examining the insensible perspiration of persons electrified, Van Marum employed a very sensible balance, one of whose scales was insulated by a silk cord. He placed a boy eight years old upon this scale, and having connected him with the conductor, he brought the balance into equilibrium. He then found that the boy lost 280 grains in half an hour before he was electrified, and 295 grains when he was electrified; but on another occasion he lost 320 grains before he was electrified, and 310 when he was electrified. A girl seven years old lost 180 before she was electrified, and 165 when she was electrified. A boy eight and a half years old lost 423 grains when unelectrified, and 290 when electrified. A boy nine years old lost 170 grains when unelectrified, and 216 when electrified. As this boy was very quiet during the experiment, the increase was attributed to electricity. The experiment was therefore repeated, and it was found that he lost 550 grains when unelectrified, and 590, 530, 270, 550, and 420 when electrified; hence it follows, that in most of the experiments there was a decrease rather than an increase of insensible perspiration.

According to Mr Cavendish, the sensible shock depends more on the quantity of electricity than on its force; a double force, with half the quantity, always producing a shock rather less powerful. Volta observes, that only a little more electricity is required to produce an equal shock from a larger surface. He found that a surface 16 times as large required an elevation of the electro-meter to one-tenth of the number of degrees. According to Dr IIlison, a small charge from a large surface gives a less unpleasant shock than a large charge of a small one, and may therefore be better fitted for medical purposes. He found likewise that the spark taken from a long wire is sharper than when it is taken from a large body.

In order to ascertain the cause of death in those struck with lightning, Dr Van Marum made a number of experiments on eels, which are well known to retain signs of irritability even when they are cut into three, four, or six parts, and when deprived of their head. The eels which he employed were a foot and a half long, and when the shock was sent through their whole body, they were instantly killed, and never afterwards moved; they were then skinned, pinched, and prickled, and salts and sparks were applied in vain to discover if any irritability remained. When the charge was sent through individual parts, such as the head, those only lost their irritability, while the rest retained it, and when the head was not affected with the shock, the remaining parts only were injured. The same results were obtained from eels three and a half feet long. When the shock was sent through the upper and fore part of the head of large eels, the under jaw, as well as the muscles of the neck and belly, and even the lower part of the body, preserved their irritability, while it was totally destroyed in the parts through which the charge was transmitted. The same results were obtained when the shocks of smaller batteries were sent through warm-blooded animals, such as rabbits. Hence, as the circulation of the blood can no longer take place when such a derangement is produced, this circumstance is unquestionably the cause of the sudden death of those who are struck by lightning. If the large arteries are not affected by the shock, the animal may still recover, provided the cerebellum and spinal marrow are not injured.

Various experiments have been made on the effects of electricity upon different animals; but, as the results are in no respects interesting, we shall content ourselves with a reference to the works in which they will be found.

The effects of electricity on the corruption of dead animals, has been examined by M. Achard of Berlin. Having divided a piece of raw beef into three parts, he...
ELECTRICITY.

On the Effects of Electricity upon Vegetables.

We have already stated the results of the experiments made by M. Maimbray of Edinburgh and the Abbé Nollet, on the effects produced upon the growth of vegetables by electricity. Similar experiments upon vegetables were repeated, with the same results; and the effect of electricity in promoting vegetation was universally acknowledged, till a complete set of experiments was made by Dr. Ingenhousz, who could not discover any foundation for the general opinion.

M. Jalabert, M. Boze, the Abbé Menon, Dr. Carmoy, the Abbé Dornay, and the Abbé Bertholon have, without much success, endeavoured to establish the opinion of the Abbé Nollet. The Abbé Bertholon, indeed, has written a work solely on this subject; and we were not surprised to find, that an author, who seriously maintained the influence of atmospheric electricity upon the generation of the human species, should support the more sober opinion, that it has a powerful effect upon the germination of plants. By means of an instrument called an electro-vegetometer, which is nothing more than a thunder-rod for bringing down the electricity of the atmosphere to the earth, he has proposed to convey electricity to particular spots, for the purpose of fertilizing the soil, and invigorating the health of tender plants. And when this celestial nourishment cannot be drawn in sufficient quantities from the clouds, he proposes to supply its place by a shower of electrified water. In order that our readers may judge for themselves of the advantages which are likely to be derived from these processes, we shall lay before them the following general remarks of the Abbé Bertholon.

"By means of the electro-vegetometer just now described, one may be able to accumulate at pleasure this wonderful fluid, however diffused in the regions above, and conduct it to the surface of the earth, in those seasons when it is either scantily supplied, or its quantity is insufficient for vegetation, or, although it may be in some degree sufficient, yet it can never produce the effects of a multiplied and highly increased vegetation. So that by these means we shall have an excellent vegetable manure or nourishment, brought down, as it were, from heaven, and that, too, at an easy expense; for, after the construction of this instrument, it will cost nothing to maintain it: it will be, moreover, the most efficacious you can employ; no other substance being so active, penetrating, or conducive to the germination, growth, multiplication, or reproduction of vegetables. This heavenly manure is that which nature employs over the whole habitable earth, not excepting even those regions which are esteemed barren, but which, however, are often fecundated by those agents which nature knows so well to employ to the most useful purposes. Perhaps there was nothing wanting to bring to a completion the useful discoveries that have been made in electricity, but to shew this so advantageous an art of employing electricity as a manure. Consequently, that all the effects which we have already mentioned depend upon electricity alone; and, lastly, that all these effects, viz. acceleration in the germination, the growth, and production of leaves, flowers, fruit, and their multiplication, &c., will be produced even at a time when secondary causes are against it; and all this is brought about by the electric fluid, which we have the art of accumulating over certain portions of the earth, where we want to raise those plants that are most calculated for our use.

"By multiplying these instruments, which are provided at little expense, (since iron rods, of the thickness of one's finger, and even less, are sufficient for the purpose), we multiply their beneficial effects, and extend their use ad infinitum.

"This apparatus having been raised with care in the midst of a garden, the happiest effects were perceived, viz. different plants, herbs, and fruits, in greater forwardness than usual, more multiplied, and of better quality. These facts are analogous to an observation which I have often made, viz. that plants grow fast, and are most vigorous, near thunder-rods, where their situation favours their development. They likewise serve to explain why vegetation is so vigorous in lofty
ELECTRICITY.

The various subjects to which we shall have occasion to direct the attention of the reader in the present Part of the article, may be arranged under five different heads:

I. On Instruments for collecting Electricity;
II. On Instruments for accumulating and discharging Electricity;
III. On Instruments for indicating and measuring Electricity;
IV. On Instruments for condensing, doubling, and multiplying Electricity; and
V. On Instruments for general Purposes.

BOOK I.

On Instruments for Collecting Electricity.

The instruments which have been employed for collecting electricity, are of three kinds: 1. The electrifying machine, for collecting the electricity produced by the excitation of electric bodies; 2. The Electrophorus, for collecting the electricity produced by the contact of dissimilar bodies; and, 3. Electrical Kites, Thunder rods, and Conductors, for collecting and discharging the electricity which exists in the atmosphere.

CHAP. I.

On the Electrifying Machine.

The electrifying machine consists of several parts: Of the electric substance, which is excited by motion; of the rubber by which it is excited; of the amalgam interposed between the rubber and the electric for increasing the excitation; of the mechanism for producing the friction; and of the prime conductor, for receiving the electricity as it is generated by the excitation of the electric.
The electrics which have been generally employed in the construction of electifying machines, are glass, sulphur, resin, gum, lac, dried wood, pasteboard impregnated with amber varnish, cloth, and catskin. The most useful and generally employed of all these substances, is glass, which, independent of its other qualities, is superior to all others, both in durability and in elegance. It has been employed sometimes in a rough state, but almost always in a polished state; sometimes it has been fashioned into the shape of a globe, at other times into a cylindrical form, and sometimes into a flat circular plate. When the glass is used in the form of a globe or cylinder, it has sometimes been found advantageous to line the inside of it to the thickness of a sixpence with a resinous composition, consisting of four parts of Venice turpentine, one part of rosin, and one of bees wax. This must be introduced in sufficient quantity into the inside of the globe or cylinder, and when the glass is brought gradually to an equal degree of heat throughout, the melted substance is allowed to spread itself over the interior surface, by turning the globe or cylinder about its axis. A coating is almost never used in modern electifying machines, but it has been found of great use in improving bad ones.

The human hand was the only rubber which was employed by electricians, till a cushion was introduced by Professor Winkler of Leipsic. The rubber consists of three parts; the cushion, the flap, and the stand. The cushion is commonly made of soft leather, generally basil skin, stuffed with flannel or hair, so as to be as hard as the bottom of a chair, and sufficiently soft to accommodate itself without much pressure to the surface of the globe or cylinder to which it is applied. In order to effect this, a spring is formed either upon the stand which supports the rubber, as in Plate CCXLIV, Figs. 1, 2, 3, 4, 5; or a spring is placed within the rubber, as in Fig. 10, which represents the rubber contrived by Mr. Jones. A piece of flexible iron or brass cd, is placed within the rubber AB, and keeps the surface A of the rubber in a state of uniform contact with the contiguous surface of the glass. The length of the cushion should be about 8 or 10 inches, and its breadth between 1/2 to 1 inches wide. The flap, which was introduced by Dr. Nooth, is a piece of thin oiled silk, of the same breadth as the length of the cushion, and nearly equal in length to the semicircumference of the cylinder. It should be sewed on the surface of the cushion about a quarter of an inch from its upper edge, so that the junction of the silk with the cushion may form a straight line rising a little above its surface. The flap should reach to within an inch in a row of metallic points at the extremity of the prime conductor, which we shall afterwards describe. This flap is not used when a globe of glass is employed. The rubber should be insulated upon a stand of glass, or baked wood.

The amalgam, which was first recommended by Canton, consisted of tin and mercury. Dr. Higgins recommended an amalgam of four parts of mercury and one of zinc. The common amalgam, however, which was for a long time used in England and on the continent, consisted of five parts of mercury and one of zinc, reduced to the consistency of butter, either by fusion or triturating; and mixed with a little chalk, or Spanish white, perfectly dry. The amalgam invented by Baron Kienmayer, consisted of mercury two parts, purified zinc one part, and pure tin one part. When the tin and zinc are intimately mixed by fusion, the mercury is added before they are cold, and the whole is shaken together in a wooden box. It is then poured out on a table of marble, and reduced to a fine powder in a mortar. Kienmayer found, that with the common amalgam he could charge a Leyden phial having 1/2 square feet of coated surface only with 10 revolutions; whereas with the preceding amalgam he required only 6. A battery, consisting of 58 square feet of coated surface, required 250 revolutions with the common amalgam, whereas with the new amalgam it required only 50 revolutions of the machine. In laying the amalgam on the cushion, he mixed it with a little hog's lard. Never's amalgam consists of equal parts of tin and mercury. Cuthbertson employed mercury with tin filings and a little oil. Cavallo recommended for the tin amalgam two parts of mercury and one of tinfoil, with a little powdered chalk; and for the zinc amalgam, four or five parts of mercury and one of zinc. When the zinc is melted, the mercury, heated to above the temperature of boiling water, must be added to it, and shaken in a wooden box. It must then be triturated with a little tallow, and a very little powdered whitening; and one-fourth of the amalgam must be afterwards added. Mr. Singer melts together one ounce of tin and two ounces of zinc, and when they are fluid he adds six ounces of mercury, and agitates the mixture in an iron or thick wooden box till it is cold. It is then triturated in a mortar, and formed into a paste by hog's lard. Mr. Singer is of opinion, that when amalgams have a large proportion of mercury, their action is variable and transient.

The friction of the electric is produced by turning it about its axis either with a simple winch, as in Mechanism Fig. 1. Plate CCXLI. or by a multiplying wheel, as in Fig. 2. For this purpose, the ends of the cylinder must be cemented into two pieces of well-baked wood, which rest upon two vertical supports, and were also for the pivots round which the cylinder is turned. The axis of the pivots must coincide exactly with the axis of the cylinder, so that the pressure of the rubber against the cylinder or globe may be uniform. The most common way of putting the cylinder in motion is by a simple winch or handle, as in Fig. 1. When a multiplying wheel is used, as in Fig. 2, the string is always becoming loose; and, though more electricity is produced in a shorter time, the labour of the operator is increased. When a glass globe is used, it is fixed only at one end, and is supported on a single stand, as in Fig. 4. The best electrical cement for attaching the cylinder to its pivots, is made by mixing five pounds of rosin, one pound of bees' wax, one pound of red ochre, and two table spoonfuls of plaster of Paris. The ochre and plaster of Paris should be well dried, and then added to and alternately mixed with the other ingredients, when they are in a state of fusion. This cement is recommended by Mr. Singer.

The prime conductor, or the positive conductor as it is sometimes called, was first applied by Professor Boze of Wittenberg. It is a cylindrical tube of thin sheet brass, or copper, or tin, or of pasteboard covered with gold-leaf or tinfoil, terminating in both ends with hemispherical caps, which can be taken off at pleasure. The conductor may be made solid as well as hollow; but this is altogether unnecessary, as we have already seen from Coulomb's experiments, that the electricity is merely distributed over the surface of conductors, and never penetrates the solid mass. Conductors are often made of solid wood, covered with tinfoil. The greatest care must be taken in the formation of the conductor, that its surface be entirely free of all points and asperities; and the holes which are made in it, of
the size of a quill, for the purpose of attaching wires and balls, and other pieces of apparatus, must have their edges well rounded and smoothed off. To the side or end of the conductor, according as its side or end is presented to the cylinder, is fixed a row of metallic points, which receive the electricity from the globe or cylinder, and which are placed at the distance of one-eighth or one-tenth of an inch from its surface. These points are seen in Figs. 1, 2, and 5, as placed at the extremity of the conductor. The length of the conductor is, in general, a little greater than that of the glass cylinder, and its diameter about ¾ of that of the cylinder. It must be insulated upon a glass stand, having its non-conducting power increased by a coating of sealing wax dissolved in spirits of wine, or the glass pillar may be heated, and then rubbed over with the wax. As gum lac is a better conductor than sealing wax, it might be substituted in its place. On the back of the rubber, as represented in Fig. 3, there is often fixed another conductor, called a negative conductor, and supported, along with the rubber itself, upon a varnished pillar of glass.

A necessary part of the electrical apparatus, is an insulating stool, which is nothing more than a piece of mahogany, or any other wood, supported upon 4 glass feet. Sometimes it is made large enough to hold a common chair, but, in general, it has only that size and strength which will allow a person to stand upon it with safety.

When the electrifying machine is about to be used, the greatest care must be taken to free it from all particles of dust, and to dry it thoroughly, by rubbing every part of the apparatus with a piece of flannel or woolen cloth made excessively dry, by being toasted before a good fire. The amalgam must be laid upon the cushion, and spread uniformly with a piece of leather, so as just to reach the junction of the silk glass with the cushion. If the machine has already been in use, the old amalgam should be carefully taken off; the silk flap should be freed from any dust, or amalgam that may have lodged upon its surface, and from the black spots and lines which almost always accumulate upon the cylinder or plate of glass, particularly after a recent application of the amalgam. Mr. Wolff, of Hanover, recommends strongly that a piece of fine white paper should be placed above the amalgam, so as to be interposed between the rubber and the glass. Mr. Nicholson has deduced, from a variety of trials, the following general directions for producing the most powerful effects from electrical machines. His directions refer to that kind of rubber in which the silk flap is attached to the lower edge of the cushion, and returns back over its surface. After the cylinder is cleaned, and the silk well wiped, grease the cylinder by turning it against a piece of leather containing the grease from a tallow candle. Continue to turn the cylinder till the silk flap has wiped off as much of the grease as to render the glass semi-transparent. Some of Higgins’s amalgam must be spread upon a piece of leather till it is uniformly bright. The leather must then be held against the turning cylinder. The friction will immediately increase, and the leather must not be taken away until the friction has reached its maximum. When these directions are implicitly followed, Mr. Nicholson found that the effect was extremely powerful. With a cylinder 7 inches in diameter, and a cushion 8 inches long, three brushes of light escaped at once from a 3 inch ball. A 9 inch cylinder, and an 8 inch cushion occasioned frequent flashes from the round end of a conductor 4 inches in diameter. With a 12 inch cylinder, and a rubber of 7½ inches, a 5 inch ball gave frequent flashes upwards of 15 inches long, and sometimes flashes were emitted from a 6 inch ball. The 7 inch cylinder afforded a spark of 10½ inches at the best, and the 9 inch cylinder, which had not a sufficiently high support, sent flashes to the table which was 14 inches distant.

SECT. I. On Electrifying Machines made of Globes and Cylinders of Glass.

1. Description of the common Cylindrical Electrifying Machine, with a simple Handle.

The common electrifying machine, consisting of a glass cylinder, was first introduced by the Germans, and notwithstanding the changes which it has undergone, it is still the cheapest, the simplest, and the most perfect of all the electrifying machines formed of glass.

This machine is represented in Plate CCXLVII, Fig. 1, where AB is the cylinder of glass, supported upon the two pillars E, E, made either of glass or baked wood. These pillars are firmly fixed into a board or stand GH, which is screwed to a table by means of the two clamps shown at X and Z. The cylinder of glass receives its rotatory motion, by means of the simple winch or handle W. The rubber is represented at m, supported on a pillar R, fastened into the board GH. By means of the screw S, this pillar can be brought towards S, so as to make the rubber m apply with sufficient tightness to the cylinder. The silk flap, attached to the rubber, is shown at n. The prime conductor CD is placed upon an insulating stand, and receives the electricity from the cylinder, by means of the metallic points shown at p. The jar and discharger, attached to the conductor, will be afterwards described.

2. Description of the common Electrifying Machine, with a Multiplying Wheel.

This machine is represented in Fig. 2, and is almost exactly the same as the last, excepting in the mechanism for giving the cylinder a rotatory motion. Instead of doing this by the simple winch W, as in Fig. 1, a small wheel w is fixed on the axis of the cylinder, which projects beyond the pillar F. Below this, and fastened to the pillar F, is a large wheel W, which has a motion of rotation round the fixed axis x, by means of the handle seen above H. A string being passed over the wheel, as shewn in the Figure, the revolution of the large wheel W will give a rapid motion to the small wheel w, and thus produce more electricity in a given time. Grooves of different diameters are cut around the wheels W and w, in order to tighten the string when it becomes loose by frequent use. In this drawing, we have shewn a different construction of the rubber; instead of being pressed against the cylinder by a screw S, as in Fig. 1, the pillar R is fixed into a slider, which can be pulled out and in, and tightened in any position by the screw nut N. The other letters in this Figure refer to the same parts as those described in the preceding article.

This machine, which is both simple, compact, and powerful, and has been much used for medical pur-
ELECTRICITY.

Practical Electricity.

PLATE CCXLVII.

Fig.

poses, as represented in Fig. 3, where AB is the glass cylinder, about 12 inches long and 7 inches in diameter, supported by the glass pillars E, E, and moved by the simple winch W. This machine is provided with two conductors, one of which D is the positive conductor, and the other C, the negative conductor, attached to the back of the rubber, which is not visible in the Figure. Both these conductors are hollow, and admit their ends to be taken off, so as to introduce a coated Leyden phial, which we have represented in the Figure at P as lying within the positive conductor D. Each of the conductors has a brass knob k, and is supported upon glass pillars R, S. These pillars are fixed at right angles to sliding pieces of wood, which move in grooves formed in the stand GH, and are kept tight in any position by the screw nuts N, N. One of these screw nuts keeps the rubber in contact with the cylinder, while the other gives stability to the positive conductor. The flap o a is seen extending over the cylinder from the negative conductor.

4. Description of Dr Priestley's Electrifying Machine.

As the electrical machine invented and used by Dr Priestley, was for a long time in great repute, and as it affords an example of a machine with a glass globe, we have given a drawing of it in Fig. 4. The glass globe AB is fixed upon the extremity of an axis at A, which passes through the upper part of the vertical stand EF, and carries a small wheel w. The rubber m consists of a hollow piece of copper covered with brass skin, and filled with horse hair. It is supported by a socket, which receives the cylindrical axis of a circular plate of glass f, the other end of which is fixed into a spring R, which is made to press the rubber against the globe by tightening the screw S. The prime conductor is a pear-shaped hollow vessel made of polished copper, and supported by a pillar inserted in a firm stand of baked wood. It is perforated with several holes for receiving hooks and wires. It receives its electricity from the globe, by means of a long arched wire CD, terminating in an open ring on which several sharp pointed wires are hung, so as to play lightly upon the globe when it is revolving. The globe is put in motion by a multiplying wheel W, turned by the handle seen above W, which, by the intervention of the string W w, drives the small wheel w, and thus gives any degree of velocity to the globe. When Dr Priestley wished to have positive electricity, he connected the rubber with the table or floor by means of the chain m n, and when he wanted negative electricity, he connected the rubber by a chain with an insulated conductor, and the conductor C with the table or ground. In the machine, as originally constructed by Dr Priestley, he made provision for receiving globes of different diameters, and also for using several at the same time, as well as for employing those of such a large size that they required support at both ends of their axis. Mr Lane's electrometer, in its earliest state, is represented as annexed to the machine at L. See Priestley's History of Electricity, p. 531.

5. Description of Read's Electrifying Machine.

This machine, though assuming a very different appearance from any of those which we have described, does not exhibit any essential improvements. It is, however, a convenient and compact machine, and has been very generally used. The cylinder AB is placed vertically, and has the upper extremity of its axis moveable in the end of the bent iron support EF. The rubber m is attached to an iron spring R, and is pressed against the cylinder by a screw S, but it has the disadvantage of not admitting of insulation. The cylinder receives its motion from the multiplying wheel W, and small wheel w, by means of a string. The conductor CD has a very peculiar form. It is opened and bent downwards at one end, so as to present a series of points p, p for receiving the electricity from the cylinder; and it is screwed into the head of a Leyden jar J, coated as usual. When it is not required to give a shock, the coated jar J is removed, and an uncoated jar put in its place, so as to serve merely for an insulating support for the conductor. Lane's electrometer is represented at L, as connected with the machine. See Priestley's History of Electricity, p. 529.

This machine, of which it is completely unnecessary to give a drawing, is interesting principally from its having been employed in the experiments of Beccaria. It consists of a cylinder turning horizontally between two upright supports, by means of a large multiplying wheel. This machine was supported upon a clumsy rectangular frame of wood, which rested upon four glass feet. Each of these glass feet was placed in semicircular boxes of tin, put together so as to form a circular box; and when the machine was in use, these tin boxes were filled with warm ashes, in order to produce a more perfect insulation, by keeping off all moisture from the glass. The prime conductor, which was suspended by silk strings, consisted of a cylinder of tin 12 feet long, and a foot in diameter, and had a conical end towards the cylinder of glass, the opposite end having a hemispherical form. The whole machine being insulated; positive electricity was obtained, by making a communication with the ground by means of a chain; and when negative electricity was wanted, the whole machine became a negative conductor, by making the positive conductor communicate with the ground.

This machine is chiefly intended for medical purposes, and for administering electricity in cases of suspended animation. It consists of a cylinder 74 inches long, and four inches in diameter, turned by a simple winch. Instead of a conductor of the common kind, it has a small insulated collector, which is a piece of smooth wood, covered with tinfoil, and rounded at the ends. It is about six inches long, and one inch in diameter, and collects the electricity from the cylinder by means of about twelve fixed pins of brass. It is then connected by a chain with a plate of glass 9 inches by 74, cemented to the head on the four corners of the box, by electrical cement, and coated on both sides with tinfoil, as in plate CCXLIII. Fig. 7. This plate serves for a Leyden phial. See Nicholson's Journal, vol. i. p. 506.

Various other machines, formed with globes and cylinders, have been employed by different experimental philosophers; but as they differ from those which we have described only in the awkwardness of their construction, it would be an insult to our readers to offer any particular drawing or description of them.

The original electrical machine used by Otto Guericke, was merely a globe of sulphur, of the size of an infant's head, formed by melting sulphur in a glass globe, and afterwards breaking the glass. It was then placed upon an iron axis, after being perforated in two places.
Light bodies were placed in the box below it, and when put in motion, it was rubbed by the hand till the light bodies were attracted by it.

Mr. Hawkesbee's machine was a glass globe turned by a large multiplying wheel, which whirled it round with great velocity. It had no conductor. Dr. Priestley has given a drawing of it in his History of Electricity.

The machine employed by the Abbé Nollet, of which a drawing is given by Dr. Priestley, differs in nothing but its frame from that of Hawkesbee. It was furnished, however, with a conductor, which was merely a bar of iron, or a gun barrel, and sometimes a chain suspended by a silken string coming from the ceiling of the room.

Mr. Wilson's machine consisted of a cylinder, turned with a multiplying wheel. Two horizontal silk cords were supported upon four vertical pillars of wood, and the conductor, which was a bar of iron, rested in an insulated state upon the silk cords. See a drawing of it in Priestley's History of Electricity.

Dr. Watson's electrifying machine consisted of four globes, supported in a vertical frame, and whirled round by four different strings placed in four different grooves on the surface of a large multiplying wheel. His prime conductor was a bar of iron suspended from the roof of the room. A drawing of it may be seen in Priestley's History of Electricity.

SECTION II. On Electrifying Machines made with circular Discs of Plate Glass.

There is one obvious disadvantage attending the construction of electrifying machines made of globes or cylinders, namely, the difficulty of cleaning their interior surface, in case of any moisture that may have accidentally introduced. In order to avoid this inconvenience, large cylinders have sometimes been constructed, so that the hand could be introduced at one end, for the purpose of cleaning and drying the globe. In order to avoid this evil, as well as to render the electrifying machine more portable and less liable to injury, a circular disc of plate glass was substituted in place of the glass cylinder. The honour of this invention has been claimed for our countryman Mr. Ramsden, and also by Dr. Ingenhousz, physician to the Emperor of Germany. Some persons have endeavoured to settle these claims, by asserting that the idea was conceived by Ingenhousz, and executed by Ramsden, and there is every reason to believe that this was the case. Dr. Ingenhousz proposed the use of a circular disc of glass in 1703, and mentioned the idea to Dr. Franklin and several other persons; and among the additions at the end of the first edition of Dr. Priestley's History of Optics, published in 1767, we are informed that Mr. Ramsden had recently executed a plate glass machine, which turned vertically, and was rubbed by four cushions, each 1 1/2 inches long, and placed at the opposite ends of the vertical diameter. See Phil. Trans. 1779, p. 659.

1. Description of the Plate Glass Machine.

A small machine of this kind, chiefly intended for medical purposes, is represented in Fig. 6 where AB is a circular disc of plate glass supported upon a horizontal axis, the two extremities of which rest on two upright pillars E, F. The plate receives its rotary motion from the simple winch W. The rubber consists of two pair of cushions, fixed at the opposite ends of a diameter of the circle, to pieces of mahogany m, m, so thin as to be considerably elastic. These cushions are seen more distinctly in the section of the machine given in Fig. 8, where they are marked by the numbers 1, 2, 3, 4. The cushions are kept tight against the plate of glass by means of the screws s, s. In this machine the conductor CD has a particular form, for the purpose of conveying the electricity to a jar placed as near as possible to the pillar F, in order to make the machine very compact. When the machine is not used for medical purposes, the conductor has the form represented in Fig. 9, where AB is the plate of glass, W the handle that turns it, and CDE the archd conductor, insulated by a pillar of glass R, and carrying two sets of points p, p for receiving the electricity from the machine. To each pair of rubbers is attached a flap made of oiled silk, one of them ascending and the other descending to the points p, p. These flaps are shaded darker than the glass. A discharging electrometer by Lane, is represented in Fig. 6, as inserted in the top of the jar.

2. Cuthbertson's Plate Glass Machine, with an insulated stand.

Mr. Cuthbertson, to whom the science of electricity is under great obligations, not only for many valuable additions to, and improvements upon, electrical apparatus, but for several excellent experiments, has brought the electrical plate machine to a state of very great perfection. As it is extremely difficult to insulate the rubbers of the plate machine without giving it a clumsy appearance, negative electricity may be obtained with equal ease, by insulating the whole machine, as in Fig. 8, where it is supported by four glass pillars G, H, I, K. In this construction, it is necessary to insulate the winch W by a glass rod. Instead of making the whole stand of one piece, as in Fig. 8, the machine may be fastened with clamps to a glass stool, of the same size and shape as the stand of the machine. The conductor, insulated by a rod of glass r, is shown at CD.

The double plate machine, as constructed by Mr. Cuthbertson, differs from the preceding only in having a greater interval between the two upright pillars E, F, for receiving two circular plates instead of one. The two plates are fixed parallel to each other, on the same axis, and are turned by the same handle. Two branches of the conductor are introduced between the two plates, and have rows of points on each side for carrying off the electricity from the glass. Hence it is necessary to support the conductor by an insulated stand separate from the machine, instead of placing it in a dovetailed groove, as is done in Fig. 8. In the machine made upon this principle by Mr. Cuthbertson for the Teylerian museum at Haarlem, each of the circular plates was five feet five inches in diameter, their distance 7 1/2 inches, and the length of the rubbers 15 1/2 inches. In order to strengthen the plates, and to prevent any dissipation of electricity along the axis, the two circular plates were coated with a resinous substance to the distance of 16 1/2 inches from the centre. The prime conductor consisted of several pieces, and was sustained by three pillars of glass 57 inches high. It was by means of this machine, which is celebrated in the history of electricity, that Van Marum made his experiments on the fusion of metals, of which we have given a full account.

The most perfect machine, perhaps, that has ever been constructed, is that which was made under the direction of Van Marum, and of which we have given a perspective view and a section, in Figures 1, 2, 3, 4, and 5. of Plate CCXLVIII. Great ingenuity is displayed in the construction of this machine, not only in preserving all its parts from a dissipation of electricity, but also in the method of obtaining positive and negative electricity at pleasure. The plate of glass AB, 31 inches in diameter, with all its apparatus, is supported upon a single column E, at the upper end of which are two brass collars I, I, each of which is shown separately in Fig. 4. On these collars rests the axis MN, which carries a counterpoise of lead L, to prevent too much friction on the collar 1 nearest the handle or winch W. The rubbers are shown at m, n, Fig. 1, being invisible in the section in Fig. 2. Each pair is supported on a horizontal position upon the plane glass pillars f, f, and is attached to balls O, P. The whole of this apparatus is minutely and correctly shown in Fig. 3, where O, P are the balls, and m, n the rubbers, with the glass plate moving between them. Receiving conductors C, D, each of which is six inches long, and two and a half in diameter, are fixed at the ends of the semicircle CGD, which is attached to an axis g, that turns on the ball G, so that the conductor CGD can be turned round into any position. A copper tube h H, terminating in a ball h, moves like a radius upon the stem of a ball h 2 inches in diameter, which is motioned by the rotation round I, so that it can be turned like the conductor CD into any position. Hence by this apparatus, the receiving conductor CGD can be brought either directly opposite to the rubbers m, n, or placed at right angles to them; and the receiving conductor CGD can be brought into contact with the rubbers m, n, while the conductors C, D, have a vertical position. By this ingenious contrivance, positive and negative electricity can be produced at pleasure, without any trouble. In the position represented in Fig. 1, the conductor G will give positive electricity, because the rubbers m, n communicate with the ground by means of the semicircular wire c d, and the vertical rod KK (Fig. 2.). But when negative electricity is wanted, the arc c d is moved into a vertical position away from the cushions, while the conductor CGD is moved into a horizontal position, so as to leave the receiving conductors C, D, opposite to the rubbers m, n. In order to prevent all dissipation or loss of electricity along the surface of the glass supports, a mahogany cap T covers the metallic caps, into which the supports are cemented. The lower extremity of the supports is likewise guarded by a hollow ring of mahogany; covering the metallic socket into which the support is inserted.

Fig. 5. is a section of the moving part of the branch c d.

Fig. 3. shews the method of constructing the rubbers, which have at their extremities four pieces of gum lac a, b, c, b.

From this brief description, our readers will be enabled to form a correct idea of the excellence of this ingenious machine; but for a minute account of all its parts, we must refer to the Journal de Physique for vol. viii. part ii.

5. Description of Wolff’s Electrifying Machine.

The machine used by M. Wolff, of Hanover, is nearly the same as that of Van Marum, which we have just described, but it differs from it essentially in the construction of the rubbers. The rubbers, which are 5½ inches long, 1½ broad, and ⅕ of an inch thick, are made of dry walnut wood, soaked in amber varnish. They are covered with a piece of thick woolen, on which is a piece of fine neat’s leather. When the leather is fastened to the wood, it is wetted, and pressed between two boards till it is dry. It is then covered with another piece of leather a little broader, having its rough surface towards the glass. A piece of silk is next applied accurately to this leather, after the silk has been heated and besmeared with butter of cacao, and a great quantity of Kienmayer’s amalgam. The leather is next covered with amber varnish. Amalgam is spread over this, and when the varnish is dry it is smoothed with a burnisher. This operation is repeated several times. When the rubber is very dry, and has been brought by pressure to touch the glass in all points, the leather, after being coated with amalgam, is covered with a piece of white paper of the same length as the leather, and about half an inch broad, so as to cover the seam by which the silk is joined to the leather. The paper is then fastened to the wood, above and below, according as it is on the ascending or descending side of the plate. A more minute account of this construction, and of the advantages which its author supposes it to possess, will be found in Gilbert’s Annalen der Physick, 1802, and Nicholson’s Journal, vol. vii. p. 124.

6. Description of Musnier’s Electrifying Machine.

This electrifying machine consists of a plate of glass moving vertically, and differs only from those of the common form in having the four cushions insulated upon pillars of glass, and connected with the upper ends of these pillars by semicircular springs. A drawing and description of the machine will be found in the Mem. Acad. Par. 1772, p. 502; and in Bertholon, De l’Électricité du corps humain, vol. ii. p. 220.

7. Description of St Julien’s Machine.

This machine consists of three plates of glass put in motion by a winch driving three-toothed wheels. The winch is fixed on one end of the axis of the largest wheel, and at the other end of the axis is fixed the middle plate of glass. Above and below this wheel is another wheel, upon the axis of which is a plate of glass, so that by turning the winch all the three plates are put in motion. Each plate is rubbed by four rubbers fixed to the upright supports, between which the plates move. The conductor is supported upon two glass rods, and the extremity of it nearest the machine has three arms like a fork, the plane of which is vertical. From the upper prong proceeds two long pointed wires, which receive the electricity from the upper plate of glass. From the middle prong proceed other two similar wires, which draw the fluid from the middle plate, and from the lower prong proceeds other two wires, to take the electricity from the lower plate. Each of the plates of glass is 15 inches in diameter; and the machine is said to have been much more powerful than a single plate machine thirty inches in diameter.
ELECTRICITY.

3. Ingenhousz’s Portable Ribbon Machine.

This machine is nothing more than a varnished ribbon suspended upon a fixed pin or nail, and excited with a rubber of catskin. A small Lédon phial is held near the rubber, and collects negative electricity from the silk.

On account of the great expence of making a very powerful electrifying machine of plate glass, Dr Ingenhousz employed three pasteboard discs, four feet in diameter. Having soaked them in copal or amber varnish dissolved in linseed oil, he covered them with a thick coat of the same varnish, and dried them by the heat of a German stove. When the varnish had become very hard, he found that they were capable of a very powerful excitation by a rubber made of cat’s or hare skin. These discs were then placed in a frame, which was so constructed as to hold twelve of them. It consisted of two square pillars of wood, about five feet high and three inches broad, joined together above and below by a transverse piece of wood. In the middle of the two pillars was a hole about an inch and a half in diameter, made to receive a wooden axis. The pasteboard-discs were then put upon this axis, and between each two discs was placed a flat board, three inches broad, covered on both sides with flannel, and then with hare skin. The two square pillars were also covered with flannel and with hare skin. When the three discs were placed in the machine, Dr Ingenhousz received sparks about one and two feet long from the front surface of the first disc, by approaching his knuckle to it. He then applied a tin conductor, about six feet long, and six inches in diameter, divided into two branches, on the extremities of which was a thick silver lace fringe instead of points. Sparks, about four or five inches long, and extremely brilliant and strong, were received from this conductor. See Phil. Trans. 1779, vol. lxi. p. 659.

5. Electrifying Machines made of Wood.

M. P. Ammersin constructed electrifying machines made of a cylinder of wood, prepared by boiling it in linseed oil; and he obtained positive or negative electricity, according as he employed a rubber of silk or of wool. Professor Pickel at Wurtzburg, and Mr Kohlreif of St Petersburg, employed discs of well dried wood. Mr Kohlreif constructed a machine, in which he could substitute a plate of glass, or a plate of wood, according as he wished to have positive or negative electricity. The rubbers for the wooden plate were covered with fine fur from rats and mole.

6. Van Marum’s Machine consisting of Gum Lac and Mercury.

Van Marum constructed an electrifying machine that had a disc of gum lac, the inferior part of which was immersed in a vessel containing mercury, and was excited while in motion by the friction of the mercury. Van Marum found that the gum lac was much less affected than glass with the moisture of the atmosphere.

M. Lichtenberg constructed a machine which consisted principally of a drum or cylinder of wood covered with black woollen cloth. Above this cylinder he placed a cushion lined with catskin, which rubbed
against the woollen cylinder, and produced electricity in abundance. Beneath the drum he placed a pan containing burning charcoal, in order to keep the apparatus dry. Bohnenberger has constructed several machines upon this principle. Their principal recommendation is their cheapness and simplicity.

8. Dr Hamel's Electrifying Machine.

This machine, of which we have been favoured with an account by Dr Hamel of St Petersburg, is an improvement upon that of Lichtenberg. The cylinder of this machine is represented in section in Fig. 7; where A is its axis, and BC the cylinder, which is covered with wax taffetas. One end of the taffetas is fixed by silk strings, in two grooves on the circumference of the board B. The other end is lined with leather, along the edge of which are made a number of small holes, through which a silk string is conducted, and led round as many wooden pins, placed on the external surface of the board C, at some distance from the circumference. By this means the taffetas is stretched, and it is also forced into the grooves c, c, made upon the cylinder by means of a silk string tied round the periphery of the board C. When the taffetas becomes loose after long use, this string is taken off till the taffetas is again brought to a proper degree of tension. The cylinder, when mounted on its frame, and covered with a catskin, is shewn in Fig. 8. The catskin reaches from F to G, and has at F three silk strings, by which it is hooked on as many wooden hooks, H, H, H, fixed to the principal board of the machine. It is merely laid round the taffetas cylinder, and the attraction produced by the electricity, excited during the motion of the cylinder, is more than sufficient to keep it in every part perfectly close to the taffetas. This is an advantage which cannot be obtained in any machine, where the cylinder or plate presses against a fixed cushion. The contact between the rubber and the cylinder is thus rendered totally independent either of the form of the cushion, or the true centering of the cylinder. The hairy side of the catskin is placed in contact with the taffetas, and its other side may be covered with silk or any other stuff. In order to prevent the cylinder from turning in the wrong direction, a wooden ratchet wheel K is fixed to the axis, and its hook to the frame of the machine. The conductor M receives the electricity from the cylinder merely by one single point. As the catskin should always be very dry, it would be convenient to have two, one of which ought to be drying at the fire when the other is in use. Dr Hamel has observed that these machines always act most powerfully in a dry cold winter day, when the temperature of the external air was 80 or more degrees below the zero of Fahrenheit's scale, whatever was the temperature of the room in which the machine was placed.

CHAP. II.

Description of the Electrophorus of Volta.

As the electrophorus of Volta is obviously an electrifying machine of a particular form, the description of it belongs to the present Chapter. This ingenious instrument was invented by M. Volta, professor of natural philosophy at Como, and now at Padua, about the year 1774. It is represented in Plate CCXLVIII, Fig. 9, where A is a circular metallic plate, or a plate of wood covered with tinfoil, which has a glass handle screwed into a brass or wooden nut D. The edge of this plate must be pretty thick, and well smoothed and rounded off. The lower plate B consists of a resinous cake placed upon another metallic plate, and formed by pouring the resinous compound when fluid upon a metallic plate with a circular rim. This resinous plate is formed by melting together equal parts of shell lac, resin, and Venice turpentine; and if the plate is required to be formed separate from the lower conductor, this composition should be poured while hot upon a marble table, from which it can be readily separated when cold. The three plates which compose the electrophorus may be distinguished by the letters A, B, C, A being the upper conductor, B the resinous plate, and C the lower conductor. The leading phenomena exhibited by this instrument are given in the following experiments:

Exp. 1. If the resinous plate has been formed by being melted upon the lower conductor in a state of insolation, it will be found to possess negative electricity, and a spark may be drawn from any part of the compound plate BC, particularly from the lower conductor. This electricity, however, gradually dissipates.

Exp. 2. Rub the resinous plate with a piece of flannel, or fur, or, what is still better, whip it with a fox's tail, or a piece of catskin, and having placed the upper conductor A upon the resinous plate B, raise it again by its insulating handle, and the upper conductor will exhibit no signs, or very faint signs of electricity.

Exp. 3. Replace the upper conductor upon the resinous plate B, and touch it when in this situation with the finger, or with any other uninsulated conducting substance. Let it then be raised by the handle, and it will not only exhibit indications of positive electricity, but will afford a sharp spark. Let the plate A be again placed upon B, and again raised, and it will afford another spark, and this process may be repeated for a considerable time, till no spark is obtained. This exhaustion may be effected at once; for if we when we touch the raised plate A with the finger, we at the same time touch the lower conductor with the thumb, a sensible shock will be felt in the finger and thumb, and they will no longer exhibit any electricity.

Exp. 4. Let the upper conductor A be now placed upon the excited plate B, by means of its glass handle, and then bring the knob of a Leyden jar in contact with it. The leaves of an electrometer when touched with the knob of the jar, will then diverge with negative electricity. Let the upper conductor be now raised, and the knob of the jar again presented to it, and a spark will pass between them. If the knob of the jar is now brought into contact with the negatively electric electrometer, its divergence will be instantly destroyed. This effect is obviously produced by an equal quantity of positive electricity; for if the positive electricity had exceeded the negative electricity, the leaves would have again separated with the excess, and remained slightly positive; on the contrary, if the negative electricity had exceeded the positive, the divergence would not have been totally destroyed. This experiment is by Mr Singer.

Exp. 5. If the lower conductor C is now insulated, it will exhibit negative electricity, when the resinous plate B only is placed upon it, but when the upper conductor A is placed upon B, the electricity of the lower conductor C will change to positive. When the plate A is again raised, C will become negative. Hence the two conductors are always in opposite states of electricity.

When the electrophorus is well made, it may be em-
employed instead of an electrical machine. Mr Singer informs us, that about 20 sparks from the upper conductor, when raised, is sufficient to charge a Leyden phial of a moderate size.

Sometimes the resinous plate of the electrophorus is placed upon a plate of glass.

Dr Ingenhousz informs us, that the electricity produced by the electrophorus may be varied by transferring alternately the upper conductor from one resinous cake to another, and touching it after it is placed on the cakes. By this method, both cakes continually acquire more and more electricity, so that the upper conductor returns from either plate quite overcharged, and Leyden phials may be charged by it so very strongly that they may be broken by the charge. The conductor returns from one cake in a positive, and from the other in a negative state. This method of increasing the electricity, was communicated to Dr Ingenhousz by Dr Klincock of the University of Prague.

CHAP. III.

On Electrical Kites, Thunder Rods, and Conductors for collecting the Electricity of the Atmosphere.

We have already seen in our History of Electricity, and in the Section upon the Electricity of the Atmosphere, that lightning is identical with electricity, and that all the experiments made with a common electrifying machine may also be made with the electricity which is brought down from the atmosphere. The instruments which have been used for this purpose are electrical kites, for bringing it down from the higher regions of the atmosphere; thunder rods for collecting it from the lower strata; and conductors for carrying it off to the ground. The terms thunder rods and conductors are generally employed as synonymous; but in the present Chapter we have given the name of thunder rods to those instruments which are employed for collecting electricity for the purposes of experiment.

Sect. I. On Electrical Kites.

The electrical kite constructed by Dr Franklin consisted of two light stripes of cedar wood put together in the form of a cross, the arms being so long as to extend to the corners of a large thin silk handkerchief when properly stretched out; the corners of the handkerchief were then tied to the extremities of the cross, so as to form the body of the kite. It was then supplied with a tail, a loop, and a string, and was better able to withstand the resistance of a thunder storm than if it had been made of paper. To the top of the upright stick of the cross, Dr Franklin fixed a sharp pointed wire, which rose to more than a foot above the wood. To the lower end of the string made of twine, he tied a silk ribbon, and fastened a key at the junction of the silk and the twine. The kite is then raised during a thunder storm, and the person who holds the string stands within a door, or window, or under cover, so that the silk ribbon may not be wet, and so that the string does not touch the frame of the door or window. When the kite and the string are wetted by the rain, the electricity will stream out from the key when the knuckle is presented to it, and a Leyden jar or a battery may be readily charged.

In our account of the experiments made by M. Romas, we have already given a general description of the electrical kite which he employed. The twine string employed by Dr Franklin, was obviously unfit to conduct the electricity of the atmosphere until it had been wetted by the rain. In order to obviate this and other defects, M. Romas made the string of twine twisted round with a copper wire. Having formed a pretty stout thread of good hemp, he doubled it, and twisted the two threads and the metallic wire at the same time, so as to form only one string. In this manner, the string acquired a degree of strength, which rendered it capable of resisting the rough usage to which it must necessarily be subjected. In this state, he took another hempen cord, and twined it round the string, but at intervals of two feet he sewed it to the other threads, so that it should be broken by any accident, the continuity of the cord would not be broken for any considerable extent. Having received a severe shock from the lightning when he was raising the kite, M. Romas contrived to elevate it without touching the cord. This he effected by means of a small chariot, with which he could let out the string as rapidly or slowly as he chose.

Mr Cavallo, in his experiments on atmospheric electricity, generally used school-boys' kites, about 4 feet high, and 2 feet wide, the strings being formed, like that of Romas, of threads of common twine and copper wire, such as is used for trimming. In order to protect himself from danger, he usually hung a chain from the string, the end of which fell to the ground; and at other times he stood upon an insulating stool. When the kite was raised, he commonly brought the string through a window, and fastened it to a strong silk lace, the end of which was generally tied to a heavy chain in the room. By means of a small prime conductor standing upon a table, and connected with the string by a wire, he observed the character of the electricity which was brought down.

Mr Cuthbertson, in his Practical Electricity, has given a drawing of the apparatus which he employed in raising electrical kites, and which does not differ essentially from those which we have described. The string of the kite is coiled round a horizontal axis, supported upon three mahogany legs; and round a drum, on a thicker part of the same axis, is coiled a silk cord, the other end of which is again coiled round another axis or reel 20 or 25 feet distant, which is moved by a winch; by turning this winch, the string of the kite can be lengthened or shortened at pleasure without any danger.

Mr Cuthbertson sometimes used three kites all connected with one another; and on one occasion, when he could obtain no electricity with a kite having a string 500 feet long, he succeeded by adding other two, each of which had strings 500 feet in length. For further information on the construction of kites, see Franklin's Letters, p. 90, or Phil. Trans. 1751, p. 365; Romas, Mem. de Savanes Etrangers, tom. iv. page 514, &c.; Berthol, De l'Electricite des Meteores, tom. i. p. 51, 53; Cavallo, Phil. Trans. 1776, p. 407; Id. 1777, p. 48; and Cuthbertson's Practical Electricity, p. 237-244. Lond. 1807.
In our Section on the history of the atmosphere, we have already given an account of the simple thunder rods which were employed by Le Monnier, Mazeas, Becaria, Dalibard, and Delors. We shall, therefore, describe the present more complicated instruments constructed and used by Mr Read, Mr Cavallo, and Mr Ronalds.

The instrument employed by Mr Read, in the experiments of which he has already given a full account, is represented in Plate CCXLVIII. Fig. 10, where AA is a wooden rod 20 feet long, and 2 inches in diameter below, and 1 above. A solid glass pillar B covered with wax, 22 inches long, is cemented into the lower end of it, and along with the whole rod is supported upon a wooden pedestal C, at the end of an iron bracket driven into the wall. At the distance of 13 inches from D, a strong arm of wood E is fixed into the wall, holding a glass tube F, covered with sealing-wax. The rod AA passes through the tube, and thus stands at the distance of 12 inches from the wall. The tube F is lined with cork, so that when the rod is bent by the wind, it is thus prevented from touching or breaking the tube. At the upper end of the rod are several sharp pointed wires G, two of which are of copper, and about one-eighth of an inch thick, and one of them is twisted round the rod to the right, and the other to the left, so as to reach the brass collar at the top of the lower funnel H, to which they are soldered. The two funnels H, H, are intended to defend the glasses B, F, from the weather. A hole is bored through the wall at I, to receive a glass tube coated with sealing-wax, through which a strong brass wire is conveyed from the rod into the room. At the end of the glass tube it passes through a brass ball 2 inches in diameter; and proceeding a little farther, it keeps suspended at its extremity a pitch ball electrometer K, at the distance of about 12 inches from the wall. The outer end of the glass tube is kept dry, by a wooden box on the outside of the wall. A bell N, supported on a strong wire, is placed at the distance of 2 inches from the ball L, and the wire of the bell communicates by a metallic continuation with the moist ground. This bell is rung by a small brass ball three-tenths of an inch in diameter, suspended from a nail at O. A small table P is erected, for holding jars and other pieces of apparatus for making experiments. Mr Read afterwards brought all the insulated parts of this rod under the roof of his house, to preserve them from the moisture of the atmosphere.

When the insulation of his principal rod was so far injured by the moisture of the air that it exhibited no electrical indications, he made use of what he calls a hand exploring rod, which was about the length and thickness of a common fishing-rod, having plenty of small wires twisted round it from one end to another. In order to use this rod, he warmed the glass legs of an insulated stool, and having placed himself upon it, he raised with one hand the rod into a vertical position, where he kept it for a minute or two. With the finger of the other hand he touched a sensible electrometer, which pointed out the electricity of the atmosphere. When the electricity was too weak to produce any divergence in the pith balls, which did not often happen, he added to the rod a lighted torch, and placed it as far from his hand as the strength of the rod would permit; and by repeating the experiment, he always found the electricity sensible, being attracted more powerfully by the flame of the torch than by the extremity of the rod.

The atmospheric collector, with which Mr Cavallo made numerous experiments, is represented in Plate CCXLVIII. Fig. 11, where AB is a common jointed fishing-rod, which wants the last or smallest joint. A slender glass tube C is fixed at the extremity of this rod, and is covered with wax, having a cork D at its end, from which a pitch ball electrometer is suspended. A piece of cord HGI is fastened to the other extremity of the rod H, and is supported at G by a small piece of twine FG. A pin is fastened at the extremity I of the cord, and when it is pushed into the cork D, the pitch ball electrometer is in an uninsulated state. In order to observe the electricity of the atmosphere, he fixed the pin in the cork D, and taking the rod by the lower extremity H, he held it out of one of the highest windows in the house, and having raised it into a position inclined about 50° or 60° to the horizon, he kept it there for a few seconds; he disengaged the pin from the cork D, by pulling the twine at H; and the string dropping into the dotted position KL, left the electrometer insulated and electrified in a state opposite to that of the atmosphere. He then drew the instrument into the room, and examined the character of the electricity which it possessed.

In order to insulate a vertical atmospheric apparatus, Mr Singer has applied his new system of insulation, of which we shall give an account in our description of his electrometer. He proposes to employ a stick of glass 10 inches long, and one inch in diameter, coated with sealing-wax. The brass cap at each extremity, must have a screw to receive the lid of a cylindrical tin funnel. "There are to be two such funnels, one screwed at each end of the insulating pillar. They may be about 8 inches long, and one smaller than the other, in such proportion, that the circumference of the stick of glass, and the two funnels, may form a series of concentric circles, distant from each other about a quarter of an inch. The apparatus is represented by Fig. 12, the funnels being delineated by dotted lines. It is evident that in this apparatus, the vapour must first traverse the space between the outer and inner funnels, and then the interval between the inner funnel and the stick of glass, before the insulation can be destroyed; and this space may be lengthened to any extent, by increasing the number of concentric funnels. This arrangement is very simple and durable; and though the limit of its insulation is the distance of the funnels, that is, a quarter of an inch, this will be found sufficient for the most essential observations on the atmosphere; and the higher intensities may be obtained, if desired, by prolonging the insulator to some inches below the cap of the lower funnel, as shown in the figure, or by making this lower and internal funnel of a glass tube covered with sealing-wax.

If an apparatus of this description be used to insulate the horizontal wire, the open end of the larger funnel should have a circular tin plate of nearly twice its diameter, placed opposite to it, at a short distance, to prevent the intrusion of driving rain or snow. (Fig. 13.) Or, what might perhaps prove more effectual, it Fig. 13 may be placed within a sort of pigeon house, having a hole in its side for the wire to pass through."

Nearly upon the preceding plan of insulation, F. Ronalds, Esq. of Hammersmith, has erected an atmospheric apparatus, in a field near Highbury Terrace, Islington; but we have not yet seen an account of the observations which he has made with it. See Read,
Sect. III. On Conductors for the preservation of Buildings.

As soon as Dr Franklin established the identity of lightning and electricity, he applied this discovery to the great practical purpose of defending buildings from the effects of lightning. With this view he proposed to erect a metallic rod, pointed at each extremity, at the side of the building, so that it should rise to a considerable height above the highest part of it, and descend lower than its foundation, either into water, or the nearest conducting substance. Hence, if a thunder cloud is immediately above the building, its charge will be drawn off by the pointed conductor, and be transmitted silently to the earth; whereas, had it struck the unprotected building, the imperfect conducting bodies of which it is composed, would have exposed such a resistance to the passage of the lightning, that it would either have been considerably injured or destroyed.

When this instrument was first proposed, a dispute arose among the members of the Royal Society of London, respecting the propriety of making the conductors terminate in acute points. The subject was long and keenly agitated; but the party, headed by Mr Benjamin Wilson, who insisted upon the necessity of furnishing the extremities of the conductors with round balls, was ultimately baffled in the contest, and the use of pointed conductors now universally prevails. The advantages of conductors in the protection of buildings, have been generally illustrated by the experiments of the powder-house, the thunder-house, and the pyramid, of which we shall give a short explanation, for the sake of our young readers.

The thunder-house is represented in Fig. 14. of Plate CCXLVIII, where a thick piece of board A, representing the end of a house, is fastened into the base B. About 8 inches from A is fixed a glass pillar C, moveable about its axis, from the top of which proceeds a bent wire EF, having a spring socket F, through which a double knotted wire FG is moveable. In the piece of wood A is fixed a wire HL, with a knob H at its extremity, and another wire MN bent upwards at N, into a hole LMK, about 2 inch deep, and nearly one inch wide, is loosely fitted a square piece of wood, of the same shape, which can be taken out at pleasure. A diagonal wire IK is fastened to the piece of wood. Let a charged jar J be now placed near the apparatus, so that its inside coating communicates with the ball E by means of a chain, and its outside coating with the wire N by means of another chain. Having placed the balls G, H at a considerable distance, take out the piece of wood LMK, and put it in so that the wire IK lies in the direction ML, and forms a communication with the wires HL and MJ; then bring the balls G, H gradually nearer one another, and at a certain distance the jar will explode, and no particular effect will be produced: the explosion being carried off by the continuity of the conducting wires. Let the wire IK be now placed as in the figure, so that there is an interruption in the conducting wire HLMN, and let the jar be exploded as before. The piece of wood LMK will now be thrown out of its place to a considerable distance, as the electricity does not find a ready passage from L to M. In this experiment, the explosion of the jar may represent a thunder cloud above the chimney of the house A, which is saved when protected by a continuous conductor, but thrown down when the lightning does not find a ready passage.

The powder-house, as constructed by Mr Cuthbertson, is represented in Fig. 15. Plate CCXLVIII. The house is built of wood, A, which communicates with L by a brass wire; L Plate communicates with the ivory piece d by a brass chain; CXLVIII. and the ivory piece d communicates with the brass tube Fig. 15. c, standing in the brass dish e. This again communicates with the brass pipe k, which is connected with the hollow arm L. The tube c, and the ivory piece d, are then filled with loose gunpowder, and the brass pin is stuck into it within a quarter of an inch of the bottom. Alcohol is poured into the dish e; wetish gunpowder is put into k, and L is filled with gunpowder hard pressed. The house being then shut up, and its roof placed upon it, the outside of a Leyden phial is made to communicate with a hook below L; and as soon as the communication is complete, by making the inside of the jar communicate with the ball A, the explosion of the gunpowder in c and d will blow off the roof, and, inflaming the alcohol, will set part of the house on fire, and, after burning some time, it will kindle the gunpowder in the tube k, and when it is consumed, the powder in the arm L will be set on fire, and, after a loud explosion, the house will be blown up, and fall to pieces.

The pyramid consists of several pieces of wood placed one on another, the lowest piece forming a square base, and the pyramidal part resting upon this base by three small brass balls. A piece of wood is then loosely fitted into a square hole on one side of the base, and one of the brass balls is made to rest upon this piece of wood, so that the upper part of the pyramid will stand when this piece of wood is in its place, but will fall when it is thrown out. The piece of wood is so constructed that it can be made either to complete or to interrupt the communication between the upper and the lower wire, as in the thunder-house. When the interruption is completed, and an explosion takes place along the wires in the thunder-house, no effect will be produced; but, by interrupting the circuit, the piece of wood will be thrown out, and the pyramid will fall to pieces.

The effect of lightning upon ships may be shown by the following pretty experiment by Mr Cuthbertson. In Fig. 16. Plate CCXLVIII, where AB is a trough filled with water, C a ship swimming in it, so that the top of the mast may nearly reach the ball L. Place the ship as in the figure at the end of the trough, and, by means of a thread T attached to it, draw the ship under the ball L, connected with the two charged jars D, F, and the charge flying out of L will strike the mast, and break the ship in pieces. When the ship is repaired, unscrew the round piece of brass from the top of the spindle, and hang the chain q r upon it, having the star A screwed upon the top. Bring the ship, as formerly, with considerable rapidity under the ball L, and it will be struck by the shock, the fire being seen to pass along the chain, without touching the mast. But if the ship is drawn slowly forward, beneath the ball L, no discharge will be heard, as the electricity of the jar is drawn slowly off by the points of the star A.

Conductors for the preservation of buildings should be formed of a copper or iron rod, about 1/2 or 3/4 inch thick, made sharp at the point, and rising to the height of four or five feet above the highest part of the building.
ELECTRICITY.

BOOK II.

ON MACHINES FOR ACCUMULATING AND DISCHARGING ELECTRICITY.

SECTION I. ON THE CONSTRUCTION OF JARS AND COATED PLATES.

In our Section on the Accumulation of Electricity, we have already given a general account of the Leyden jar, and of electrical batteries, and shall therefore confine ourselves, at present, to some practical remarks on the construction and use of these instruments.

The best form of a jar is that of a cylinder, having its mouth sufficiently large to admit the hand, for the purpose of coating, cleaning, and repairing it. With this view, jars completely cylindrical were for some time employed, particularly by Mr Cuthbertson; but he afterwards found that it was better to have them a little contracted at the mouth. Dr Robison prefers bottles of a globular form, and he frequently used the balloons employed in distillation.

The glass of which the jars are made should have no more thickness than what is necessary to prevent them from being broken by a spontaneous discharge; for Mr Cavendish has found that the quantity of electricity necessary to charge different coated jars of the same extent, is inversely as the thickness of the jars.

The best method of coating jars, is to line them both on the outside and the inside with tinfoil, which may be made to adhere to the glass by gum water. When the jars, however, will not admit of being lined with tinfoil, or when tinfoil is not to be got, a coating of brass filings may be laid on with gum water, or a quantity of gold leaf or Dutch metal may be placed in the jar, so as not to rise higher than the external coating. When the jar has a globular form, it should be coated by cutting the tinfoil into groes or joints, in the same manner as terrestrial and celestial globes are covered. A coated jar is shewn in Plate CCXLIII. Fig. 5.

As jars are very often broken by the spontaneous discharge through the glass, Mr Brooke proposed, as the result of experiment, that the tinfoil should be first pasted upon common writing paper. When this precaution was taken, he very seldom had any of his jars broken.

For the purpose of preventing the charge of the jar from being dissipated, it is of great advantage to cover the uncoated part with melted sealing-wax or with varnish, to prevent the deposition of moisture from the atmosphere.

In order that the jar may retain its charge for a considerable time, it is constructed, as in Plate CCXLVII. Fig. 1, where it is shewn suspended at the end C of the conductor. After being coated in the usual manner, a glass tube abc, reaching to the bottom, is cemented into the cap. The inside of this tube is covered with tinfoil rather more than half its length from the bottom, and this lining communicates with the inner coating of the jar. A wire c, blunted at the lower end, and half the length of the tube, is placed loosely in a hole in the brass cap, so that when the jar has the position in the Figure, the wire c forms a communication between the brass cap and the inside coating; but when this wire is drawn up or taken out, there is no communication of the internal coating either with the brass cap or with the external air. The phial will consequently retain its charge, and may be carried about in the pocket till it is needed.

M. Cavallo has invented a curious instrument, which he calls a self-charging phial. It consists of a glass self-charging phial.

was then coated with tinfoil all but the neck. The tinfoil formed the inner coating and wire, and the tinfoil the outer coating, while the wax acted the part of glass in the common jar.

Sect. II. On Coated Plates.

We have already seen that electricity may be accumulated as well in a coated plate as in a coated jar, and we have represented a plate of this kind in Fig. 7 of Plate CCXLI. Mr Bevis was the first person who substituted coated plates of glass instead of jars, and Dr Franklin actually used a battery consisting of coated plates of crown glass. As the accumulation of the electric matter increases with the thickness of the glass, Muscovy tafle has been substituted in place of glass, and it has the additional advantage of being less liable to attract moisture from the atmosphere. Instead of glass, Beccaria employed a resinous plate consisting of equal quantities of pure colophony and powder of marble, and having previously stuck a piece of tinfoil within five inches of the edge of the table, he poured this composition, when melted, upon the table, and having spread it to the thickness of a 10th of an inch with a hot iron, he coated the upper side with tinfoil, and found that it had the power of accumulating a greater degree of electricity than an equal plate of glass, and was less liable to be broken by a spontaneous discharge.

Sect. III. On the Construction of Batteries.

The electrical battery was invented in the year 1746, by Gralath, a German. Dr Franklin constructed one of coated plates of glass. Dr Priestley employed one of 61 jars; but the largest that have ever been made are those which Mr Cuthbertson made for the Teylerian Museum of Haarlem.

The jars which compose a battery are formed and coated in exactly the same manner as a single Leyden phial. In Figs. 8 and 9, of Plate CCXLI, we have given a representation of two batteries, showing two different forms of the jar, and two different manners of uniting the separate effects of each.

The real measure of the power of batteries ought not to be estimated by the number of square feet of coated surface which they contain, but by the length of metallic wire which they are capable of igniting or exploding. In the year 1774, Mr Nairne constructed a battery, containing 50 square feet of coated surface, and he found that it was capable of igniting 45 inches of iron wire, of the 14th part of an inch in diameter, which corresponds to about 4ths of an inch of wire for each square foot. The first battery constructed by Mr Cuthbertson for the Teylerian Museum, contained 132 square feet of coated surface, and was capable of igniting about 180 inches of the same kind of wire, which is nearly one inch and 4ths of wire for each square foot, surpassing considerably the power of Nairne's battery. When this battery was increased to 225 square feet of coating, it ignited 300 inches of the same wire, which was also at the rate of one inch and 4ths for each square foot. The large battery of 100 jars, which Mr Cuthbertson afterwards completed for the same museum, contained 550 square feet, was capable of igniting 635 inches of the same wire, which was also at the rate of one inch and 4ths for every square foot. Mr Cuthbertson afterwards made a number of batteries of 15 jars each, and having about 17 square feet of coated surface. Calculating from Nairne's battery, these small ones ought to ignite 15½ inches of wire, and calculating from the Haarlem batteries, they ought to ignite 22 inches; but Mr Cuthbertson found them capable of igniting 60 inches of the same wire. This remarkable increase Mr Cuthbertson could not easily explain. The Haarlem batteries were made of Bohemian glass, and the small batteries mentioned above were made of flint glass; but Mr Cuthbertson does not think that the difference of power can be ascribed to this cause.

Mr Brooke had observed that a coated jar took a much higher charge when it was dirty than when it was clean; but he does not seem to have made any experiments to investigate this singular fact. In the year 1792, Mr Cuthbertson happened accidentally to observe, that a jar when it is a little damp in the inside, (which it always is when fresh coated,) took a higher charge than when it had been coated for some time and dry. He then tried the power of a jar when it was damp by breathing into it, and found that it was capable of igniting 12 inches of wire, whereas it ignited only 5 inches when well dried. In March 1796, in very dry weather, Mr Cuthbertson charged a battery of 13 jars, and 17 square feet of coated surface, and found that it ignited 18 inches of wire; but after breathing into each jar through a glass tube, and then charging the battery, he was astonished to find that it was then able to ignite 60 inches of the same wire. In order to examine this subject more accurately, Mr Cuthbertson constructed his compound electrometer, which will be described in the next Chapter, and instituted a set of experiments to determine in what degree the charging capacity of coated jars is increased by breathing into them. The result of these experiments was, that the force of batteries did not increase with the quantity of coated surface, but according to the law already given in page 499. Hence it resulted, that instead of the power of a battery being increased 4 times, as he at first supposed, by breathing into the jars, the increased effect was only two-thirds. This increase, however, is still sufficiently great to make us regard Mr Cuthbertson's discovery of the effects of dampness, as one of the most valuable additions which has for a long time been made to practical electricity.

An effect, similar to that of breathing into the jar, may be produced by placing a wet sponge within it, or by slightly oiling its surface; but as these methods are not permanent, it has been recently proposed to paste a slip of writing paper an inch broad on the interior surface of the jar, so as to rise about half an inch above the upper edge of the inner coating.

Sect. IV. On Instruments for discharging Jars and Batteries.

A description of the common discharging rod has already been given in a former Section. Discharging rods with only one branch, and having glass handles, are shewn in Plate CCXLIX, Fig. 2, and are of great service in many experiments, for completing the electrical circuit, by fastening a wire at the end a of the metallic branch ab. A jar may be discharged, as represented in Plate CCXLIX, Fig. 3, by connecting with the outside coating a bent arm be, attached to a ring de, and by suspending any conducting body c by a silk thread between the knobs a and b. The body c will oscillate between these balls till the jar is discharged. When the body c is shaped into the form of a spider, this experiment has been called the electrified spider.
1. Henley's Universal Discharge.

One of the most useful instruments for discharging would, was invented by Mr. Henley, and is represented in Plate CCXLIX, Fig. 4, where AB is a mahogany board 14 inches long and 4 wide; C, D two glass pillars cemented into the base AB, and having upon their upper extremities brass caps, and above them spring tubes m, n, which turn round joints at o and p, that have both a vertical and a horizontal motion. In these springing tubes, two wires are placed, having a ring of brass at one end and a knob at the other. The small table EF, about 5 inches in diameter, has a piece of ivory inlaid upon its surface, and may be raised or depressed by the screw nut s. The small mahogany case, represented in Fig. 5, is sometimes placed in the socket e instead of the table EF. It consists of two boards, which can be pressed together by the two nuts p, q. When this instrument is required to be used, the body through which the discharge is to be passed, must either be laid upon the table EF, or fixed in the press, Fig. 5. The balls of the sliding wires must then be brought in contact with the opposite sides of the body, and when one of the rings of the wires is connected with a jar or a battery, while the other ring is connected with the discharging rod, the charge will be sent through the body with the greatest accuracy. In many experiments, wires pointed at the extremities are used instead of those which have knobs.

2. Simple Discharging Electrometer.

This simple instrument, which is generally attached to plate glass machines, is nothing more than a brass ball at the end of a brass stem 14 inch long, movable in a hall and socket upon the top of a glass rod fixed into the base of the machine, so that the brass ball is about one inch distant from the brass ball of the conductor adjacent to the piece of wood on which the receiving points are fixed. The brass ball of this discharger can therefore be set at any distance, within certain limits, of the conductor, and hence it enables us to regulate the magnitude either of the sparks given by the conductor, or the shock of a jar connected with the conductor. When the ball of the electrometer, for example, is placed near the conductor, the electricity of the conductor or of the jar will always be carried off when it reaches a certain magnitude, proportional to the distance of the electrometer ball from the conductor.

3. Lane's Discharging Electrometer.

This instrument, which is universally used, is represented in Plate CCXLVII. Fig. 2, where fe is a piece of brass fixed into the end of the conductor D. This arm carries a bent piece of glass edc, having a brass cap at its extremity. Through a spring tube within this cap passes an arm of brass ab, having a ball a, b at each extremity. The arm ab is then connected with the ground by means of a chain, as shown in Fig. 1, where the electrometer has a different position upon the conductor. When the ball a is brought near the conductor D, the charge of the conductor will be carried off into the ground, by means of the chain when it has reached a certain magnitude. If the ball a is pushed to a greater distance from D, the conductor will require to have a higher charge before it passes to the ball. In this way, the distance of the ball a from the conductor becomes a measure of the electricity which it contains at the instant of the discharge. In Fig. 6, this instrument is represented as attached to a jar, but, in this case, the outer ball or ring must be connected with the external coating of the jar. This electrometer is represented under a different form at L, in Figs. 4 and 5.

CHAP. II.

On Instruments for Measuring Electricity.

Instruments for measuring electricity have received the name of Electrometers. An apparatus which has been given to those that indicate the presence of small quantities of electricity, as well as to those which afford an exact measure of its intensity.

SECT. I. On Instruments that indicate Small Quantities of Electricity.

1. The Abbé Nollet's Electrometer.

The electrometer used by the Abbé Nollet consisted of two silk threads, which indicated by their divergence in the presence of small quantities of electricity, and he even attempted to measure their magnitude by ascertaining the angle of divergence from the shadow of the threads upon a board. This electrometer was improved by Mr. Waitz, who suspended small weights to the silk threads.

2. Canton's Electrometer.

This instrument consisted of a pair of balls turned out of the dry pith of the elder. These balls were suspended by the finest linen threads. Mr. Canton kept them in a narrow box, with a sliding cover, and when he wanted to use them, he held the box by the end of the cover, and permitted the balls to hang freely from a pin to which they were suspended. This instrument is represented in Plate CCXLIII, Fig. 1, as placed upon an insulating stand. The balls are here shown in a state of divergence.

A perspective view of this instrument is shown in Plate CCXLIX. Fig. 6, and a section of it in Fig. 7. It consists of two strips of gold leaf m, n, suspended within a glass cylinder ABED. This cylinder has a brass cap AB, considerably broader than itself, in the centre of which is a hole a in the inside of the cap, which receives a small wedge of wood. On each side of this wedge two equal stripes of gold leaf, free of all raggedness at their edges, are fixed by a little varnish: these stripes are generally about two inches long, and about a quarter of an inch broad. The inside of the cap AB, and the upper part of the glass cylinder, are coated with sealing-wax. On the inside of the glass cylinder are pasted two stripes of tinfoil b, c, diametrically opposite to each other, and rising higher than the stripes of gold leaf. The lower ends of the tinfoil are in contact with the brass stand DEF, which supports the whole. In order to observe the electricity of the atmosphere, a pointed wire C is inserted in the brass cap AB. In order to use the electrometer, turn round the cap AB till the surfaces of the gold leaf are parallel to the surfaces of the pieces of tinfoil b, c, so that the two stripes of gold leaf may hang in contact in the middle of the cylinder. Then, if a body containing a small quantity of electricity be brought in contact with the cap AB, the gold leaves m, n will diverge, and their extremities will strike the
ELECTRICITY.

Mr Cavallo has proposed to improve this electrometer, by sticking two small pieces of gilt paper to the ends of the gold leaves.

Nicholson's Improvement on Bennet's Electrometer.

As the divergency of the gold leaves in the preceding instrument is increased by the stripes of tinfoil b, c, it might happen that the electricity was so weak that it could only be rendered sensible by having the stripes b, c brought very near to the gold leaves. With this view, Mr Nicholson constructed an apparatus, in which he substituted two flat radii of brass in room of the tinfoil, and, by means of a microtorn screw placed at the foot of the glass cylinder, he was able to open and shut the two radii of brass, so that their extremities could be brought within any distance of the gold leaves. The divergency of the brass radii afford a kind of measure of the intensity of the electricity. A drawing and description of this improved instrument may be seen in Nicholson's Journal, September 1797.

Cavallo's Electrometers.

The electrometers constructed and used by Mr Cavallo are represented in Plate CCXLIX. Figs. 8 and 9. Fig. 8, is his pocket electrometer, shown in its inner case at A, and in a state of action at B. The inner case or handle is made of glass, and is about three inches long, and 1/2 of an inch wide, half of it being covered with sealing wax. To the open end of the tube is fitted a cork which tapers at both ends, so that any end of it will suit the end of the tube. Two small cones of the pitch of elder are then suspended to two linen threads attached to one end of the cork. When the electrometer is to be used, the end of the cork opposite to the threads must be put into the tube, and the tube will form the insulated handle of the electrometer, as shown at B. The case of this electrometer, shown at C, contains a piece of amber at one end, for electrifying the electrometer negatively, and at the other end a piece of ivory insulated upon a piece of amber, for giving positive electricity when rubbed with woollen cloth.

Another electrometer of Cavallo's is represented in Fig. 9, at A, which does not differ very essentially from Bennet's, having small conical pieces of the pitch of elder, instead of gold leaves. These balls are suspended by two silver wires, which hang parallel to one another when the balls are at rest. The wires are shaped like rings at the top, and hang very loosely in holes, in a piece of ivory H. The cap of the electrometer has a particular construction, which will be seen at B.

Sauassure's Electrometer.

This electrometer is represented in Fig. 10, of Plate CCXLIX, and has a general resemblance to that of Cavallo's. The balls are round, and made of the pitch of elder. They are about half a line in diameter, and are suspended to the most delicate silver wires. The glass vessel ACB has a bell shape, and is so wide that the balls g, g, even at their greatest divergency, cannot reach the stripes of tinfoil h, h within the glass. In order that they may give out all their electricity, Sauassure used four stripes of tinfoil instead of two, each internal stripe having a corresponding one on the outside. The bottom BC is made of metal, and upon the edge of it is a divided scale, for measuring the divergency of the balls. This instrument of Sauassure's was extremely sensible; but

The following Table contains the electrical forces corresponding to the divergency of the balls, as determined by experiments.

This instrument consists of a needle of silver or brass, terminated by two globules, and movable upon a pivot, which forms the upper part of a stem of the same metal. The needle and stem are insulated, by being placed upon a cylindrical support of rosin. If a finger of the left hand is now placed upon the bottom of the metallic stem, while the right hand presents a piece of roughed sealing wax, during a second or two, at a small distance from the stem, then, if the finger is first withdrawn, and afterwards the stick of sealing wax, the needle will be negatively electrified, and will be ready for examining the poles of a mineral that is rendered electrical by heat. See Hus's Traité de Physique, tom. i. and Traité de Mineralogie, tom. i. and Plate VIII. Fig. 76, of that work.

8. Singer's Electrometer constructed upon a new principle of Insulation.

In order to produce a more perfect degree of insulation than had been before obtained, Mr Singer proposes to inclose the insulator within a narrow channel so that the moist air in contact with it may be limited in quantity, and little disposed to motion. In this way, the contact of the atmosphere with the insulators will be least free, and the transition of moisture to them necessarily retarded. In applying this principle to the perfection of the gold leaf electrometer, Mr Singer makes the insulation depend on a glass tube 4 inches long, and 1/2 of an inch internal diameter. It is coated on every side with sealing wax; and a brass wire, 1/4 or 1/2 of an inch thick, and 5 inches long, passes through its axis, so as not to touch any part of the tube, in the middle of which it is fixed by a plug of silk. This construction is shewn in Fig. 11, of Plate CCXLIX. Plate where A is a brass cap screwed upon the upper part of the tube B, the wire w, which keeps the atmosphere from having free contact with the outside of the tube B. The gold leaves are fastened at the end of the wire, and the glass
ELECTRICITY.

Sect. II. On Electrometers for Indicating and Measuring Electricity.

1. Henley's Quadrant Electrometer.

This instrument is represented in Plate CCXLVII. Fig. 11, where AB is a smooth round stem, about 7 inches long, surmounted by a ball A. Below this ball, and at one side of the stem, is fixed a semicircle of ivory C, having its lower quadrant divided into 90 degrees. A thin piece of cane mm, 4 inches long, with a ball n at its lower end, is suspended from a pin at m in the centre of the graduated arch, and turns freely round that pin as a center. When the instrument is electrified, the ball, which naturally hangs in a vertical direction, is repelled by the stem, and indicates the electrical force by its angular distance from the stem. This instrument may be either placed on a stand, like D, or it may be fixed at the end of a conductor, or upon the top of a Leyden jar. It is quite obvious, that equal spaces on the quadrant correspond to equal degrees of electricity. M. Aehard has shown, that the quadrant should be divided according to a scale of arcs, the tangents of which are in arithmetical progression.

2. Brooke's Steelyard Electrometer.

This ingenious, though complicated and expensive, instrument, is founded on the principle, that the charge of a jar or battery may be accurately determined by the weight in grains, which the repulsive force of the accumulated electricity is able to raise. This instrument, which is represented in Fig. 13, Plate CCXLIX. is supported upon a base AB, about 9¾ inches in diameter, and is completely insulated upon the glass pillar DD. The arms G and g, which may be hollow tubes of copper, have a motion round the brass wire H, so as to be turned as far away as possible from the jar or battery. The balls IK are made of hollow copper, so as to be as light as possible. The arm G is screwed to a solid piece within the ball F, and has a motion round an axis close to the surface of the ball F, in a vertical plane. The arm E has also a motion in a vertical plane round an axis concealed behind the dial plate R, and by means of a multiplying motion behind the dial plate, the index R performs one complete revolution, while the arm E moves through 90°, or from a vertical into a horizontal position. By means of the apparatus NPH, which we have not room to describe, the electrometer is connected with the conductor, or the jar, or the battery, and all the parts of it are electrified positively or negatively according as it gives positive electricity. The two balls I, K, will of course repel one another, and the arm G will rise in a vertical plane. In the same manner the ball L will repel the other ball C, and the arm EC will rise in a vertical plane. The angular motion of EC is indicated upon the outer edge of the dial plate, divided into 90° by the lower and longer arm of the index, and the force of repulsion by which the arm GI is raised, is marked in grains upon the inner circle; to which the shorter arm of the index points. In order to graduate the inner circle, a weight m is moved upon the arm GI, till it exactly counterbalances the weight in F at the other end of the lever. One end of the weight m will therefore be the zero, or commencement of the scale. Then having shifted the weight m nearly to the ball I, find, by a pair of scales, the weight of the ball I, or the weight produced in consequence of the motion of m towards I. Divide this space into the number of grains thus found, and subdivide the space, corresponding to each grain, into halves and quarters. These divisions may be readily transferred to the inner circle of the dial plate, by observing the position of the shorter index when m is standing at any number of grains in the arm GI. When this is done, Mr. Brooke even thinks that the arms G, g, and balls I, K, may be removed as unnecessary. This ingenious instrument, though never brought to perfection by its author, has given rise to several admirable electrometers founded upon the same principle, of which we shall give a particular description.

3. Hauch’s Improved Discharging Electrometer.

This instrument is an improvement upon the electrometer of Mr. Brooke, which M. Hauch has greatly simplified. It consists of two levers with unequal arms, supported on separate glass pillars, one of which is a little higher than the other. The end of the longest arm of the upper lever being raised by the repulsion of a ball with which it is in contact, acts upon the end of the shortest arm of the lower lever; and the end of the longest arm of the lower lever, by being thus raised, touches the apparatus of the upper lever, and discharges the jar or battery. Our limits will not permit us to give a more detailed account of this instrument; but a drawing and description of it will be seen in the Phil. Mag. vol. iv. p. 267, or in the Transactions of the Royal Society of Copenhagen.

4. Dr. Robison’s Compareable Electrometer.

This ingenious instrument, which is also an improvement upon Brooke’s electrometer, was employed by Dr. Robison in his experiments on the law of electrical action. It is represented in Plate CCXLIV. Figs. 5. and 6. and has been fully described in p. 440, 441.

5. Coulomb’s Torsion Balance Electrometers.

These ingenious instruments, three of which we have given representations of in Plate CCXLIV. Figs. 7—11. and Plate CCXLV. Figs. 1—3. have been already fully described in pages 441, 442, 450, 451, and are undoubtedly the most accurate instruments that have ever been made for measuring small quantities of electricity.

This instrument is represented in Plate CCXLIX. Fig. 14, where D, E are two glass pillars fixed in the base AB, 18 inches long and six inches broad. These supports terminate in brass balls D, E, under the last of which is a brass hook for connecting it with the outside of a jar: upon the top of a brass pillar DB is supported the metallic wire GH, terminating in two equal balls, and balanced like a scale-beam on a knife-edged centre, the ball b so constructed as to allow the arm GH to move in a vertical plane. A rectangular arm of brass FCD is fixed at D. The arm Gb is divided into 60 grains, and carries a slider g, which can be set at any number of grains. A common Henley’s quadrant electrometer is placed at k. If the balls G and F are electrified, and the slider g be set at 0, they will repel one another; G will ascend, and H will descend
BOOK IV.
ON INSTRUMENTS FOR CONDENSING, DOUBLING, AND MULTYPING ELECTRICITY.

The electrometers described in the preceding Book, though extremely delicate, are unable to indicate the presence of weak degrees of electricity. In order to remedy this defect, several ingenious instruments have been employed for condensing, doubling, and multiplying small degrees of electricity. The most important of these, we shall now proceed to describe.

CHAP. I.
INSTRUMENTS FOR CONDENSING ELECTRICITY.

Sect. I. Volta's Condenser.

This instrument is nothing more than an application of the electrophorus already described. Having constructed an electrophorus with a very thin resinous plate, and having its electricity completely extinguished, lay the upper conductor upon this resinous plate in full contact, taking care that it does not touch the lower conductor. A wire is now brought from the place where the weak electricity exists to the upper conductor above this. The apparatus being left a certain time in this situation, till the upper conductor has accumulated a sufficient quantity of electricity, remove the conducting wire, and raise the upper conductor from the resinous plate by the insulating handle, and it will be found to have condensed so much electricity as to affect the electrometer most powerfully, and even to give sparks. As the thin resinous cake may receive some electricity, Volta substituted in place of it an imperfectly conducting substance, such as a clean and dry marble slab, a plate of wood clean and dry or covered with a coat of varnish, or even a conducting body covered with a piece of dry taffy or other dry silk.

Volta's Condenser connected with an Electrometer.

This instrument, which Volta has employed for determining the effects of Galvanic electricity, is represented in Plate CCXLIX. Fig. 13. The electrometer consists of two slips of straw or, us, perfectly even and upright. These straws are suspended by means of two metallic wires terminating in hooks, which move freely in two small holes made in the lower end of a piece of metal, whose upper extremity is soldered beneath the stopple of the jar. Above this stopple is cemented the collecting plate or base of brass ed, from the lower surface of which proceeds a metallic wire tipp with a metallic globule g. Above this plate is another plate ab, with an insulating glass handle mn, and communicating with surrounding bodies by a slip of metal lg, bent in such a manner as not to come near the collecting plate. The lower surface of ab, and the upper surface of ed, are both varnished. A graduated scale tz is placed on the outside of the jar for estimating the angular distance of the straws when in a state of divergency. The electrified body is brought repeatedly in contact with a small globule g, and after a certain number of contacts, the upper plate ab is lifted up, and the straws immediately diverge.

Sect. II. Cavallo's improved Condenser.

It occurred to Mr. Cavallo, that if the condensing plate of the electrophorus indicated small degrees of electricity that could not otherwise be observed, another smaller plate, or small condensing apparatus, might be employed, to condense the weak electricity of the large plate. He therefore constructed a small plate about the size of a shilling, having a glass handle coated with sealing-wax, and when the large metal plate was scarcely able to affect an electrometer, he placed the small plate upon the inferior plane, and touched it with the edge of the large plate. He then removed the large plate, and upon presenting the small plate to the electrometer, the straws diverged to their utmost limits.

Sect. III. Cavallo's Condenser, or Collector of Electricity.

This instrument is represented in Plate CCXLIX. Fig. 16. where GHJKLX and NOPV, are two frames of wood, fastened to a wooden base by brass hinges, so that they can be either placed vertically, as in the Figure, or laid out in a horizontal position, so as to be supported on the table on which the instrument stands. The inner surfaces of these frames above their middle, are covered either with gilt paper, or with very flat tin plates. These two frames are kept in a vertical position, by means of two flat pieces of wood S and T, connected by a hook H. Between these two vertical frames there stands a flat tin plate, 15 inches long, and 8 inches broad, soldered to two tin tubes A, A, only one of which is seen in the Figure. These tin tubes, being supported by glass rods D, D, coated with sealing-wax, only one of which is seen. When the instrument is ready for use, as in the Figure, the surfaces of the gilt paper are parallel to the tin plate, but not in contact with it. An electrometer E is connected with one of the tin tubes A, A, while the other tin tube is connected by a wire with the body, whose electricity is to be condensed. When the tin plate apparatus has stood for a short time to accumulate the electricity, the hook H is loosened, and the wooden frames are thrown back into a horizontal position, and the electrometer will then diverge with the condensed electricity. The condensing power of this instrument increases with the proximity of the tin.
ELECTRICITY.

Sect. IV. Cuthbertson's Condenser.

A vertical section of this condenser is shown in Plate CCXLIX. Fig. 17, where a and b are two flat and round brass plates, about six inches in diameter, and screwed tightly into the brass balls c, d. The ball d is fixed to the top of a brass pillar e, which has a joint at its lower extremity. The ball c is placed upon a glass pillar firmly fixed into the wooden box. The plate b can therefore be thrown back into the dotted position shown in the Figure. The insulated receiving plate a, being connected with a wire to the body whose electricity is to be condensed, remains in this state for some time. The wire is then removed. The plate b is thrown back into the dotted position, and the plate a is presented to an electrometer, as formerly.

Sect. V. Condensing Electrometer.

This instrument, represented in Plate CCXLIX. Fig. 18, is nothing more than the preceding condenser applied to an electrometer, the plate a of the condenser being fixed to the cap of the electrometer instead of the insulating stand c. When the plate a has received the electricity from the electrified body, the plate B is then drawn back round the joint h, and the electrometer instantly indicates the condensed electricity.

In order to increase the effect, Cuthbertson's condenser is sometimes used along with this instrument, the fixed plate of the former being connected with the fixed plate of the latter by a small brass pin.

Sect. VI. Simple Condenser proposed by Mr. Singer.

Mr. Singer has proposed to construct a very simple condenser, by placing three small spots of sealing wax, so as to form a triangle on the lower surface of the upper conductor of the electrophorus. These spots of wax serve as short insulating legs, by which the plate may be supported at the distance of about the twelfth of an inch from the surface of a smooth and even table. The plate is then connected, as formerly, with the electrified body; and, after some time, the connecting wire is removed; and the plate, when raised from the table, will exhibit the condensed electricity.

Sect. VII. Read's Condenser.

In this instrument, the fixed plate is placed horizontally on a vertical insulated stand, and the moveable plate is separated from it by turning a screw nut, and allowing it to descend to the bottom of the stand.

Sect. VIII. Nicholson's Spinning Condenser.

A vertical section of this ingenious instrument is represented in Plate CCXLIX. Fig. 19, where A is a metallic vase, having a long steel axis, which passes through a hole in the stand H at K, and rests with its pointed end upon an adjustable socket at C. The two shaded plates D and F are circular, and are made of glass, being nearly 1/4 inch in diameter, and 1/25 of an inch thick. The plate D is fixed to the vase A, and revolves along with it, while the plate H is fixed to the stand. Two metallic hooks F, G, are cemented opposite to each other, into holes drilled in the edge of the plate F; and into the upper plate are cemented two small tails of the fine flattened wire used in making silver lace. These tails are bent down, as shown in the Figure, so as to strike the hooks F, G during the revolution, but so as to be free from the rest of the apparatus. By means of the screw at C, the distance between the glass plates D, E may be increased or diminished. The two contiguous faces of the glass plates are coated, as shown in Fig. 20. Each of the tails communicates with the tinfoil coating of the plate D, and the hook H with that of the plate E; but the other hook G is completely insulated, and is intended to communicate only with the electrified body. The instrument being thus constructed, the moveable part of it, viz. the plate D, and all above it and the steel axis, is set a spinning by the action of the finger and thumb upon the top T. One of the tails will strike the hook G, connected with the electrified body, and will receive and communicate to the coating of the plate D some of its electricity. At the end of half a revolution, the tail touches the hook F, and electrifies it along with the upper coating, and the lower coating on the side of E. The tail proceeds, collecting more electricity from the hook G, and again deposits it at F, till there is so much condensed as is requisite to produce a divergency in the pitch ball electrometer suspended at F. Mr. Nicholson constructed an instrument of this kind five inches high, and found it capable of condensing very small degrees of electricity. See Nicholson's Journal, April 1797.

CHAP. III.

On Instruments for Doubling Electricity.

The instruments called Doulors, are those which are constructed in such a manner, that very small quantities of electricity may be continually doubled, till it becomes perceptible by the common electrometer. The first instrument of this kind was invented by the Rev. Abraham Bennet.

Sect. I. Description of Bennet's Doubler.

This instrument consists of two brass plates, which Bennet's we shall call A and B. The plate A has an insulating handle fixed in its centre, while the plate B has a similar handle fixed in its circumference. Excepting the upper side of A, all the sides of these plates are varnished. The third plate C is a plate of brass varnished on its upper side, and laid upon Bennet's gold-leaf electrometer.

The body, whose electricity is to be doubled, is applied to the under side of the plate C, which lies upon the electrometer, while B is touched with a finger of the other hand, and then removing the communication with the electrified body, B is lifted up by its insulating handle; and if the electricity is not now sensible by the electrometer, A is placed, by means of its insulating handle, upon B, thus elevated; then touching A, by stretching a finger over the juncture of its insulating handle, and again withdrawing the finger, A is
ELECTRICITY.

Practical Electricity.

Nicholson's doubler.

526

is and represented sensibly fixed. These but lie. The plate B is then touched, by stretching a finger over the juncture of its insulating handle, and removing A, and then withdrawing the finger from B, and lifting it up from C, the electricity becomes doubled.

If the electricity is not sensible after duplication, Mr. Bennet proposes to repeat the operation 10 or 20 times, which, by doubling it every time, will render visible the smallest conceivable quantity of electricity, for at the end of the 20th operation it is augmented above 500,000 times. This operation, so often repeated, may appear tedious, yet when the art of performing it readily is acquired, it will not occupy 40 seconds. When it is required to elicit sparks, the plates must be placed upon amelectrometer, and the doubling repeated till the sparks are emitted.

In making the preceding experiments, great care must be taken not to excite any electricity by the friction of the finger upon the varnished side of the plate. In order to avoid this, Mr. Bennet joined to each of the plates a conducting handle of unbiased mahogany, by means of an insulating nut of baked wood, covered with sealing wax, so that he did not require to touch the sealing wax of the insulated nut, but occasionally to stretch a finger over it, to touch the plate, whilst the mahogany handle was held in the hand. Mr. Bennet likewise put thimbles on the ends of the touching fingers; but after every precaution, he still found that electricity was produced in the instrument without previous communication. See Phil. Trans. 1787, p. 288.

Sect. II. Darwin's Moveable Doubler.

In order to avoid the labour of the preceding operation, Dr. Darwin invented the moveable doubler, consisting of four metallic plates, which could be moved by a wheel worked into positions which required them to be touched by the hand, in order to produce the effect. This instrument was shown to Mr. Nicholson in December 1787, and it occurred to him that the whole of the operation might be performed by the rotation of a simple winch, and hence he was led to the construction of the following instrument.

This instrument is represented in Figs. 1 and 2 of Plate CCL. It is supported on a glass pillar 6½ inches long, and consists of two fixed plates of brass A, C, two inches in diameter, separately insulated, and placed in the same plane, so that a revolving plate B may pass near them without touching. A brass ball D, two inches in diameter, is fixed on the end of the axis that carries the plate B, and is loaded within at one side, to act as a counterpoise to the revolving plate B, so as to keep it at rest in any position. The axis PN is made of varnished glass, and so are the axes that join the three plates with the brass axis NO. The axis NO passes through the brass piece M, which supports the plates A and C. At one extremity of this axis is the ball D, and the other is connected with a rod of glass NP, upon which the handle L is fixed, and also the piece GH separately insulated. The pins E, F rise out of the back of the fixed plates A, C, at unequal distances from the axis. The piece K, is parallel to GI; and both of them have their ends armed with small pieces of harpsichord wire, that they may touch the pins F, E, in certain points of their revolution. In the piece M there is fixed a pin I, which intercepts a small wire proceeding from the revolving plate B. These wires are so adjusted by bending, that when the plate B is exactly opposite to D, the piece GI connects the two fixed plates, while the wire and pin at I form a connection between the ball D and the plate B. On the contrary, when the plate B is exactly opposite to the plate C, the ball D becomes connected with C, by the contact of F, with the wire at K, the plates A and B being then completely unconnected with any other part of the apparatus. In all other positions, the three plates and the ball will be perfectly unconnected with each other.

"When the plates A and B," says Mr. Nicholson, "are opposite to each other, the two fixed plates A and C may be considered as one mass; and the revolving plate B, together with the ball D, will constitute another mass. All the experiments yet made, concur to prove that these two masses will not possess the same electric state; but that, with respect to each other, their electricities will be plus and minus. These plates would be simple, and without any compensation, if the masses were remote from each other; but as that is not the case, a part of the redundant electricity will take the form of a charge in the opposed plates A and B. From other experiments, I find that the effect of the compensation on plates opposed to each other at the distance of one forty part of an inch, is such, that they require to produce a given intensity at least 100 times the quantity of electricity that would have produced it in either singly and apart. The redundant electricities in the masses under consideration, will therefore be unequally distributed: the plate A will have about 99 parts, and the plate C one; and, for the same reason, the revolving plate B will have 99 parts of the opposite electricity, and the ball D one. The rotation, by destroying the contacts, preserves this unequal distribution, and carries B from A to C, at the same time that the tail K connects the ball with the plate C. In this situation, the electricity in B acts upon that in C, and produces the contrary state, by virtue of the communication between C and the ball; which last must therefore acquire an electricity of the same kind with that of the revolving plate. But the rotation again destroys the contact, and restores B to its first situation opposite A. Here, if we attend to the effect of the whole revolution, we shall find that the electric states of the respective masses have been greatly increased; for the 99 parts in A and in B remain, and the one part of electricity in C has been increased so as nearly to compensate 99 parts of the opposite electricity in the revolving plate B, while the communication produced an equal mutation in the electricity of the ball. A second rotation will of course produce a proportional augmentation of these increased quantities, and a continuance of turning will soon bring the intensities to their maximum, which is limited by an explosion between the plates.

If one of the parts be connected with an electrometer, more especially that of Bennet, these effects will be very clearly seen. The spark is usually produced by a number of turns between 11 and 20; and the electrometer is sensibly acted upon by still fewer. When one of the parts is occasionally connected with the earth, or when the adjustment of the plates is altered, there are some variations in the effects not difficult to
be reduced to the general principles, but sufficiently curious to excite the meditations of persons the most experienced in this branch of natural philosophy.

If the ball be connected with the lower part of Ben- net's electrometer, and the plate A with the upper part, and any weak electricity be communicated to the electrometer, while the position of the apparatus is such that the cross piece GH touches the two pins, a very few turns will render it perceptible. But here, as well as in the common doubler, the effect is rendered uncertain, by the condition that the communicated electricity must be strong enough to destroy and predomi- nate over any other electricity the plates may possess. I scarcely need observe, that, if this difficulty should be hereafter removed, the instrument will have great advantages as a multiplier of electricity in the facility of its use, the very speedy manner of its operation, and the unequivocal nature of its results.” See Phil. Trans. 1788, p. 403.

Sect. IV. Bennet's Improvement upon his Doubler.

We have already seen, that Mr Bennet was aware, that electricity was produced in his doubler even when none had been previously communicated to it. In or- der to remedy this, he connected the plates A and C by a wire, having at its ends hooks, which went into two small knobs on the back of the plates, the pillar which supports the doubler being in contact with the middle of the same wire. Another wire connected the back of the plate B with the brass ball D. In this man- ner all the plates communicated with the ground, and by turning the winch, all its electricity could be dis- charged in every part of its revolution. Mr Bennet observed, that the spontaneous discharge of the doubler was always negative. With a phial positively charged he touched A and C, and turned the doubler till it pro- duced sparks for a long time together. He now hook- ed on the wires as formerly described, and made the plate B revolve about 100 times, which so completely deprived the doubler of its positive electricity, that, when the wires were taken off, it produced a negative charge at about the same number of revolutions which it formerly required. The phial positively charged was again applied, and the wires being again hooked upon the plates, B was made to revolve 50 times, which was found sufficient to deprive it of its positive charge. In many cases, five or six revolutions answered this purpose; but Mr Bennet generally allowed 40 or 50 turns of the handle.

Sect. V. Cavallo's Improvement upon Benne t's Doubler.

Mr Cavallo having found, that, after doubling 20 or 30 times, the doubler became strongly electrified although no electricity had been communicated to it, ima- gined that this electricity arose from some friction of the varnished plates. In order to avoid this source of electricity, he constructed three plates without the least varnish, and which stood within the eighth of an inch of each other. Each plate stood vertically, and was sup- ported by two glass sticks, which were coated with sealing-wax, and fixed on a wooden pedestal 7 1/2 inches long, 2 1/2 broad, and 1 1/2 thick. The vertical plate is about 8 inches in diameter, and is made of strong tin. The stand is so narrow, that it projects only a little be- yond the face of the tin plate, so as just to prevent the two faces from coming in contact when they are placed facing one another upon a table. The method of doubling with these plates is exactly the same as with Benet's doubler, only instead of placing the one upon the other, they are placed facing each other; and in performing the operations, they are held by the wooden stand, so that no friction can take place. Even with these precautions, however, Mr Cavallo candidly ac- knowledges that the plates still produced electricity from themselves, and that the instrument could not be depended upon. See Phil. Trans. 1788, vol. ixxxviii. page 1.

Sect. VI. Dr Robison's Improvement upon Bennet's Doubler.

Dr Robison was of opinion, that the instrument as originally constructed by Mr Bennet, might be freed from the error of producing electricity without communica- tions, by employing a plate of air as the intermedium between the three plates of the doubler. To effect this, he proposes to stick on one of the plates three small spherules, made from a capillary tube of glass, or from a fibre of melted sealing-wax. The other plate being made to rest on these three points, will be separated from the other by a plate of air, and will scarcely re- ceive any friction that will affect the results of the operation. Dr Robison was also of opinion, that if the fine wires, which form the connections in Nicholson's doubler, were tipped with little balls, the dissipation would be greatly prevented, and the instrument much improved. He likewise thinks, that an alternate motion like that of a pump handle might be advantageously used, as the plates would thus be permitted to approach each other face to face, and admit a greater multiplication, if it were thought necessary. See Robison's System of Mechanical Philosophy, vol. iv. now in the press.

fixed wire $N$, and of course renders the plate $B$ uninsulated. When the lever $KL$, however, begins to move towards $X$, the extremity $m$ of the wire $OM$ is withdrawn from $N$, and the plate $B$ remains insulated; and when the lever has reached the position $KX$ as far as it can go, the wire $m$ touches the plate $C$, so that the insulated plates $B$ and $C$ now communicate with each other.

When the plates $A$ and $B$ are together, as in the Figure, $A$ has its capacity for electricity increased by the presence of the uninsulated plate $B$, and therefore if any weakly electrified body is made to touch $A$, it will acquire a greater quantity of electricity from the contact than it would otherwise have done. Let us suppose that $A$ acquires a small quantity of positive electricity, then $B$ will acquire negative electricity.

On moving the lever $KL$, towards $X$, $B$ remains insulated and possessed of negative electricity. When $B$ touches $C$ by means of the wire $mO$, its negative electricity passes almost entirely to $C$, as the capacity of $C$ for electricity is greatly increased by the presence of the uninsulated plate $D$. If the plate $B$ is carried back to $A$, it will acquire a new quantity of negative electricity, which in a similar manner may be communicated to $C$. By a repetition of this process, the electricity will be multiplied or accumulated in $C$. The plate $D$ is drawn out from $C$ by means of the slider $FP$, and hence the capacity of $C$ for electricity will be much diminished. Consequently, if an electrometer be brought into contact with it, the negative electricity will be indicated by the divergency of the gold leaves. Mr Cavallo is of opinion, that the principal cause that renders this instrument certain in its effects, is, that all the residuum of electricity which can remain upon the plate $A$, after an experiment is performed, and after that plate is touched, is too inconsiderable to induce a contrary electricity in $B$, the electricity which is originally communicated to $A$ not being increased upon it in the course of the experiment. The drawing is about $\frac{1}{4}$ of the real size of the instrument. See Cavallo's Treatise on Electricity, 4th edit. vol. iii. p. 98, and his Elements of Natural Philosophy, vol. iii. p. 425-429.

BOOK V.

On Instruments for General Purposes.

Sect. I. On Kinnersley's Electrical Air Thermometer.

This instrument is represented in Plate CCL. Fig. 4, where $AB$ is a glass tube about 10 inches long and two inches in diameter, and made air tight at both ends by two brass caps. A small tube, $HA$, open at both ends, passes through a hole in the upper cap, and descends into some water at the bottom of the tube. The two hooked wires $FG, EI$, slide through the caps, so that the brass knobs $G, I$ can be set at any distance. This instrument is placed upon a wooden stand $CD$. If the knobs $G, I$ are brought into contact, and a charge sent through them, by connecting the hooks $E, F$ with the outside and inside of a Leyden jar, no effect will be produced; but if the knobs are separated, so that the charge is sent through the intervening mass of air, the air displaced and rarified will press upon the water at the bottom of the tube, and raise it almost to the top of the small tube $AH$; it will then sink a little, and will afterwards gradually subside into its first position.

Sect. II. Volta's Hydrogen Lamp.

The facility with which hydrogen gas is inflamed, Volta's hydrogen lamp. A quantity of hydrogen gas is put into a reservoir, and, by means of the pressure of a column of water, the gas is allowed to escape from a small aperture by turning a stop-cock. An electrophorus is placed in a box below this reservoir, and a wire passes through a glass tube from the upper part of the box to the small aperture. The cover of the electrophorus being connected by a silk cord with the handle of the stop-cock, is raised when the cock is opened, and the spark from this cover is conveyed by the insulated wire to the stream of gas, which instantly kindles, so that a candle may be immediately lighted. As only a small quantity of the gas is consumed, a light may be procured above a hundred times before all the gas in the reservoir is exhausted.

Sect. III. Volta's Electric Pistol.

This instrument consists of a brass vessel, of an oblong spheroidal form, pierced at its two vertices. Into one of these openings, a glass tube of the same diameter is introduced, which projects about four inches beyond the vessel, and is continued nearly to the middle of the cavity. A metallic stem passes through this tube, the outer end of which carries a brass ball, while the other end extends beyond the inner extremity of the tube. Through the other aperture in the spheroidal vessel, is introduced an equal mixture of inflammable gas and atmospheric air, and the aperture is then closed by a cork. The vessel is now taken in the hand, by the middle of its convexity, and a spark sent from the prime conductor to the metallic ball, will instantly inflame the gas, and drive out the cork with a smart explosion.

PART III. THEORETICAL ELECTRICITY.

CHAP. I.

On the Theories of Electricity before the time of Epinicus and Cavendish.

In our History of Electricity, we have already given a sufficiently full account of the crude hypotheses of Cabaneus, Descartes, and Boyle; of the more rational views of Dufay, Nollet, Symmers, and Ellicott; and of theories prior to those of Epinicus and Cavendish.
ELECTRICITY.

The admirable hypothesis of negative and positive electricity advanced by Dr Franklin, which afterwards formed the groundwork of the more perfect theories of Epininus and Cavendish.

To enter into any farther details upon these hypotheses, would be to waste the time without adding to the information of the reader.

The late Professor Russel, who filled the chair of Natural Philosophy in the University of Edinburgh with distinguished ability, endeavoured to explain the phenomena of electricity, by a substance which he called the electrical fluid, which was connected with bodies by attractive and repulsive forces, diminishing as the distance increases. He considered the electrical fluid as a compound fluid, containing elementary fire, and deriving from it a high degree of elasticity, or a mutual repulsion of its parts. This repulsive force, however, acts at a distance; and hence bodies containing more electric fluid than the spaces around them, repel each other. The principal ingredient of the compound fluid is electricity, which is united with the elastic fluid by chemical affinity or elective attraction. This attraction extends to all distances, but diminishes according to a law different from that of the mutual repulsion of the elastic fluid; and its general tendency is to repress these repulsions when the fluid exists in its compound state. Conducting bodies are attracted by the electricity at all distances, but it attracts electrics only at insensible distances, and at such distances its own particles attract each other. This complex theory, in which the forces are all accommodated to the phenomena, though proposed merely as a conjecture by its ingenious author, was received at the time with great satisfaction, and accorded pretty well with the common electrical phenomena.

A hypothesis somewhat similar to that of Professor Russel, was proposed by a celebrated and able naturalist, M. de Luc. Having had occasion to read Volta's theory of electric influences, De Luc was struck with the resemblance between the phenomena of the electrophorus, and the hygroscopic phenomena of the condensation and evaporation of moisture; and by a more extensive examination, he observed a striking analogy between all the other phenomena of electricity and hygroscopy. He was therefore led to refer all the phenomena of electricity to the operation of a compound expansive substance, called the electric fluid. This fluid he supposed to consist first of electric matter, which is the gravitating part of the compound, and of the electric deferent fluid, or carrying fluid, by which the electric matter was conveyed from one body to another. We cannot occupy the attention of the reader with any farther account of this theory. Those who think it worth their while to pursue it farther, will find it fully detailed in De Luc's Idées sur Meteorology, § 206; or a general view of it in Dr Robison's System of Mechanical Philosophy, vol. iv. where an account of Professor Russel's hypothesis will also be found. See also Nicholson's Journal, vol. xxviii. p. 3, for some recent observations of De Luc respecting his own theory.

SECTION I.

Cavendish's Hypothesis.

The electric fluid is a substance, the particles of which repel each other, and attract the particles of all other matter, with a force inversely as the square of the distance.

The particles of all other matter also repel each other, and attract those of the electric fluid, with a force varying according to the same law. Or, if we consider the electric fluid as matter different from all other matter, the particles of all matter, both those of the electric fluid, and of other matter, repel particles of the same kind, and attract those of a contrary kind, with a force inversely as the square of the distance. * Mr Cavendish never comprehends the electric fluid under the general term matter, but considers it only as another sort of matter. He regards it as indifferent whether all sorts of matter are supposed to possess in an equal degree the attraction and repulsion described in the hypothesis, or whether some sorts only are supposed to possess it in a greater degree than others. It is probable, however, that the electric fluid possesses this property in a much greater degree than any other matter; for its weight in any body probably bears a very small proportion to the weight of the matter in the body, but yet the force with which the electric fluid in any body attracts any particle of matter in that body, must be equal to the force with which the matter of the body repels that particle, otherwise the body would appear electrical, as will afterwards appear.

In order to explain this hypothesis more fully, Mr Cavendish supposes that one grain of electric fluid attracts a particle of matter at a given distance, with as much force as four grains, (or any other number,) of any matter, such as lead, for example, repel it; then one grain of electric fluid will repel a particle of electric fluid already been sufficiently detailed in our History of Electricity. The two theories, in which all the phenomena are explained by the agency of a single fluid, are essentially the same, and were framed without any communication between these two philosophers. Epininus, however, having published his theory about ten years before that of Cavendish appeared, has justly received the credit of the invention; and even in this country, his name has been alone associated with the theory which he formed. The justice of this decision we are neither disposed nor entitled to question; but the claims of Mr Cavendish, as a second inventor, have scarcely in his own country received due attention, while on the continent, his name is almost never mentioned by those illustrious men, who have cultivated and extended the science of electricity since the publication of his valuable researches.

We trust, therefore, that we are doing an act of justice to the memory of that distinguished philosopher, as well as a service to science, in giving, almost in his own words, a full account of his theory, which has never yet appeared in any work but the Philosophical Transactions, in which it was at first published. The hypothesis of Epininus has already been more than once published in our own language; and such of our readers as wish to see a full and able abridgment of it, are referred to the fourth volume of Dr Robison's System of Mechanical Philosophy.

SECTION II.

Theory of Epininus and Cavendish.

The circumstances under which the theories of Epininus and Cavendish were laid before the public, have al-

* In Mr Cavendish's own statement of his hypothesis, he characterises the electric force as a force varying, inversely, as some less power of the distance than the cube; but as the real law of action has been ascertained, (see page 410,) we have substituted it in the text.
ELECTRICITY.

The electric fluid, with as much force as four grains of lead attract it, and one grain of electric fluid will repel one grain of electric fluid, with as much force as four grains of lead will repel four grains of lead.

All bodies in their natural state, with regard to electricity, contain such a quantity of electric fluid, interspersed between their particles, that the attraction of the electric fluid, in any small part of the body, on a given particle of matter, shall be equal to the repulsion of the matter, in the same small part on the same particle. When a body is in this state, Mr. Cavendish calls it saturated with electric fluid; when the body contains more than this quantity of electric fluid, he calls it overcharged, and when it contains less, he calls it undercharged.

Lemma 1. Let \( EA \) (Plate CCL. Fig. 1.) represent a cone continued infinitely; let \( A \) be the vertex, and \( Bb \) and \( Dd \) planes parallel to the base; and let the cone be filled with uniform matter, whose particles repel each other with a force inversely as the \( n \) power of the distance. If \( n \) is greater than 3, the force with which a particle at \( A \) is repelled by \( E B b \), or all that part of the cone beyond \( Bb \) is as \( \frac{1}{AB^n} \). For supposing \( AB \) to flow, the fluxion of \( EB b \) is proportional to \(-AB \times AB^3 \), and the fluxion of its repulsion on \( A \) is proportional to \( \frac{AB}{AB^n} \); the flux of which is

\[
\frac{1}{n-3 \times AB^n-1};
\]

which when \( AB \) is infinite is equal to nothing; consequently the repulsion of \( EB b \) is proportional to

\[
\frac{1}{n-3 \times AB^n-1} \quad \text{or to} \quad \frac{AB^n}{1}.
\]

Corol. If \( AB \) is infinitely small, \( \frac{1}{AB^n} \) is infinitely great; therefore the repulsion of that part of the cone between \( A \) and \( Bb \), on \( A \), is infinitely greater than the repulsion of all that beyond it.

Lemma 2. By the same method of reasoning it appears, that if \( n \) is equal to 3, the repulsion of the matter between \( Bb \) and \( Dd \) on a particle at \( A \), is proportional to the logarithm of \( \frac{AD}{AB} \); consequently, the repulsion of that part is infinitely small in respect of that between \( A \) and \( Bb \), and also infinitely small in respect of that beyond \( Dd \).

Lemma 3. In like manner, if \( n \) is less than 3, the repulsion of the part between \( A \) and \( Bb \) on \( A \) is proportional to \( AB^{n-1} \); consequently, the repulsion of the matter between \( A \) and \( Bb \), on \( A \), is infinitely small in respect of that beyond \( Bb \).

Definition. If the electric fluid in any body is by any means confined in such a manner that it cannot move from one part of the body to the other, it is called immovable: if it is able to move readily from one part to another, it is called moveable.

Prop. 1. A body overcharged with electric fluid attracts or repels a particle of matter or fluid, and is attracted or repelled by it, with exactly the same force as it would, if the matter in it, together with so much of the fluid as is sufficient to saturate it, was taken away, or as if the body consisted only of the redundant fluid in it. In like manner an undercharged body attracts or repels with the same force, as if it consisted only of the redundant matter; the electric fluid, together with so much of the matter as is sufficient to saturate it, being taken away. This is evident from the definition of saturation.

Prop. II. Two over or under charged bodies attract or repel each other with just the same force that they would, if each body consisted only of the redundant fluid in it, if overcharged, or of the redundant matter in it, if undercharged. For, let the two bodies be called \( A \) and \( B \); by the last proposition, the redundant substance in \( B \) impels each particle of fluid and matter in \( A \), and consequently impels the whole body \( A \), with the same force that the whole body \( B \) impels it: for the same reason, the redundant substance in \( A \) impels the redundant substance in \( B \); with the same force that the whole body \( A \) impels it. It is shown, therefore, that the whole body \( B \) impels the whole body \( A \), with the same force that the redundant substance in \( B \) impels the whole body \( A \), or with which the whole body \( A \) impels the redundant substance in \( B \); and that the whole body \( A \) impels the redundant substance in \( B \) with the same force that the redundant substance in \( A \) impels the redundant substance in \( B \). Therefore the whole body \( B \) impels the whole body \( A \), with the same force with which the redundant substance in \( A \) impels the redundant substance in \( B \), or with which the redundant substance in \( B \) impels the redundant substance in \( A \).

Corol. Let the matter in all the rest of space, except in two given bodies, be saturated with immovable fluid; and let the fluid in those two bodies be also immovable. Then, if one of the bodies is saturated, and the other either over or under charged, they will not at all attract or repel each other. If the bodies are both overcharged, they will repel each other. If they are both undercharged, they will also repel each other. If one is overcharged and the other undercharged, they will attract each other.

\( N. B. \) In this corollary it is understood that a body overcharged is overcharged in all parts, or at least no where undercharged; in like manner, that a body undercharged is undercharged in all parts, or at least no where overcharged.

Prop. III. If all the bodies in the universe are saturated with electric fluid, it is plain that no part of the fluid can have any tendency to move.

Prop. IV. If the quantity of electric fluid in the universe is exactly sufficient to saturate the matter therein, but unequally dispersed, so that some bodies are overcharged and others undercharged; then, if the electric fluid is not confined, it will immediately move till all the bodies in the universe are saturated, for, supposing that any body is overcharged, and the bodies near it are not, a particle at the surface of that body will be repelled from it by the redundant fluid within; consequently some fluid will run out of that body; but if the body is undercharged, a particle at its surface will be attracted towards the body by the redundant matter within, so that some fluid will run into the body.

Lemma 4. Let \( BDE, bde, \) and \( \beta \delta \), (Fig. 2.) be concentric spherical surfaces, whose centre is \( C \); if the space \( B\delta \) is filled with uniform matter, whose particles Fig. 2. repel with a force inversely as the square of the distance; a particle placed any where within the space \( CB \), as at \( P \), will be repelled with as much force in one direction between the spherical surfaces \( BDE \) and \( bde \), or between \( BDE \) and

* By the space \( B\delta \) or \( \beta \delta \) is meant the space comprehended and \( \beta \delta \); by the space \( CB \) or \( C\delta \), is meant the spheres \( bde \) or \( \beta \delta \).
as another, or it will not be impelled in any direction.
This is demonstrated in Newt. Princip. lib. i. prop. 70.

Lemma 5. If the repulsion is inversely as the square of the distance, a particle placed anywhere without the sphere BDE, is repelled by that sphere, and also by the space Bb, with the same force that it would if all the matter therein was collected in the centre of the sphere; provided the density of the matter in it is everywhere the same at the same distance from the centre. This is easily deduced from Prop. 71. of the same book, and has been demonstrated by other authors.

Prop. V. Prob. 1. Let the sphere BDE be filled with uniform solid matter, overcharged with electric fluid; let the fluid in it be moveable, but unable to escape from it; let the fluid in the rest of infinite space be moveable, and sufficient to saturate the matter in it; and let the matter in the whole of infinite space, or at least in the space Bb, whose dimensions will be given below, be uniform and solid; and let the law of the electric attraction and repulsion be inversely as the square of the distance; it is required to determine in what manner the fluid will be disposed both within and without the globe.

Take the space Bb such that the interstices between the particles of matter in it shall be just sufficient to hold a quantity of electric fluid, whose particles are pressed close together, so as to touch each other, equal to the whole redundant fluid in the globe, besides the quantity requisite to saturate the matter in Bb; and take the space Bb such that the matter in it shall be just able to saturate the redundant fluid in the globe; then, in all parts of the space Bb, the fluid will be pressed close together, so that its particles shall touch each other; the space Bb will be entirely deprived of fluid; and in the space Cb, and all the rest of infinite space, the matter will be exactly saturated.

For, if the fluid is disposed in the above mentioned manner, a particle of fluid placed anywhere within the space Cb will not be impelled in any direction by the fluid in Bb, or the matter in Bb, and will therefore have no tendency to move. A particle placed anywhere without the space Bb will be attracted with just as much force by the matter in Bb, as it is repelled by the redundant fluid in Bb, and will therefore have no tendency to move. A particle placed anywhere within the space Bb, will indeed be repelled towards the surface, by all the redundant fluid in that space which is placed nearer the centre than itself; but as the fluid in that space is already pressed as close together as possible, it will not have any tendency to move; and in the space Bb there is no fluid to move, so that no part of the fluid can have any tendency to move.

Besides, it seems impossible for the fluid to be at rest, if it is disposed in any other form; for if the density of the fluid is not everywhere the same at the same distance from the centre, but is greater near b than near d, a particle placed anywhere between these two points will move from b towards d; but if the density is everywhere the same at the same distance from the centre, and the fluid in Bb is not pressed close together, the space Cb will be overcharged, and consequently a particle at a will be repelled from the centre, and cannot be at rest. In like manner, if there is any fluid in Bb, it cannot be at rest. And, by the same kind of reasoning, it might be shown, that, if the fluid is not spread uniformly within the space Cb, and without the sphere Bb, it cannot be at rest.

Corol. 1. If the globe BDE is undercharged, every thing else being the same as before, there will be a space Bb, in which the matter will be entirely deprived of fluid, and a space Bb, in which the fluid will be pressed close together; the matter in Bb being equal to the whole redundant matter in the globe, and the redundant fluid in Bb, being just sufficient to saturate the matter in Bb; and in all the rest of space the matter will be exactly saturated. The demonstration is exactly similar to the foregoing.

Corol. 2. The fluid in the globe BDE will be disposed in exactly the same manner, whether the fluid without is immovable, and disposed in such a manner that the matter shall be everywhere saturated, or whether it is disposed as above described; and the fluid without the globe will be disposed in just the same manner, whether the fluid within is disposed uniformly, or whether it is disposed as above described.

Lemma 6. Let the whole space comprehended between two parallel planes, infinitely extended each way, be filled with uniform matter, the repulsion of whose particles is inversely as the square of the distance; the plate of matter formed thereby will repel a particle of matter with exactly the same force, at whatever distance from it, it be placed.

For, suppose that there are two such plates, of equal thickness, placed parallel to each other, let A (Fig. 3.) be any point not placed in or between the two plates; let BCD represent any part of the nearest plate; draw the lines AB, AC, and AD, cutting the farthest plate in b, c, and d; for it is plain, that if they cut one plate, they must, if produced, cut the other; the triangle BCD is to the triangle bcd, as AB to AB; therefore, a particle of matter at A will be repelled with the same force by the matter in the triangle BCD, as by that in bcd. Whence it appears, that a particle at A will be repelled with as much force by the nearest plate, as by the more distant; and consequently will be impelled with the same force by either plate, at whatever distance from it, it be placed.

Prop. VI. Prob. 2. In Fig. 4, let the parallel lines AC, Bb, &c. represent parallel planes infinitely extended each way; let the spaces AD and EH be filled with uniform solid matter; let the electric fluid in each of those spaces be moveable and unable to escape; and let all the rest of the matter in the universe be saturated with immovable fluid; and let the electric attraction and repulsion be inversely as the square of the distance. It is required to determine in what manner the fluid will be disposed in the spaces AD and EH, according as one or both of them are over and under charged.

Let AD be that space which contains the greatest quantity of redundant fluid, if both spaces are overcharged, or which contains the least redundant matter, if both are undercharged; or, if one is overcharged, and the other undercharged, let AD be the overcharged one. Then, first, there will be two spaces, AB and GH, which will either be entirely deprived of fluid, or in which the particles will be pressed close together; namely, if the whole quantity of fluid in AD and EH together, is less than sufficient to saturate the matter therein, they will be entirely deprived of fluid, the quantity of redundant matter in each being half the whole redundant matter in AD and EH together; but if the fluid in AD and EH together is more than sufficient to saturate the matter, the fluid in AB and GH
The force with which it does so, is that with which the redundant fluid in CD is attracted by the matter in EF.

Corol. 3. If AD is overcharged, and EH undercharged, and the redundant fluid in AD is exactly sufficient to saturate the redundant matter in EH, all the redundant fluid in AD will be collected in the space CD, where it will be pressed close together: the space EF will be entirely deprived of fluid, the quantity of matter in it being just sufficient to saturate the redundant fluid in CD, and the spaces AC and EH will be every where saturated. Besides, if an opening is made in the planes AA or HH, the fluid within the spaces AD or EH will have no tendency to run out at it, nor will the fluid on the outside have any tendency to run in at it: a particle of fluid too placed any where on the outside of both spaces, as at F, will not be at all attracted or repelled by these spaces, any more than if they were both saturated; but a particle placed anywhere between these spaces, as at S, will be repelled from d towards c; and if a communication was made between the two spaces, by the canal de, the fluid would run out of AD into EH, till they were both saturated.

In the following propositions, the bodies are supposed to consist of solid matter, confined to the same spot, so as not to be able to alter its shape or situation by the attraction or repulsion of other bodies on it; the electric fluid in these bodies is supposed to be moveable, but unable to escape, unless when otherwise expressed. As for the matter in all the rest of the universe, it is supposed to be saturated with immovable fluid. The electric attraction and repulsion is supposed to be inversely as any power of the distance less than the cube, except when otherwise expressed.

By a canal, he means a slender thread of matter, of such kind that the electric fluid shall be able to move readily along it, but shall not be able to escape from it, except at the ends, where it communicates with other bodies. Thus when he says that two bodies communicate with each other by a canal, he means that the fluid shall be able to pass readily from one body to the other by that canal.

Prop. VIII. If any body, at a distance from any over or under charged body, be overcharged, the fluid within it will be lodged in greater quantity near the surface of the body than near the centre. For, if you suppose it to be spread uniformly all over the body, a particle of fluid in it, near the surface, will be repelled towards the surface by a greater quantity of fluid than that by which it is repelled from it; consequently the fluid will flow towards the surface, and make it denser there: moreover, the particles of fluid close to the surface will be pressed close together; for otherwise, a particle placed so near it, that the quantity of redundant fluid between it and the surface should be very small, would move towards it; as the small quantity of redundant fluid between it and the surface would be unable to balance the repulsion of that on the other side.

From the two problems, it seems likely, that almost all the redundant fluid in the body will be lodged close to the surface, and there pressed close together, and the rest of the body will be saturated.

Corol. If the body is undercharged, the deficiency of fluid will be greater near the surface than near the centre, and the matter near the surface will be entirely deprived of fluid. It is likely, too, that all parts, except near the surface, will be saturated.

Prop. VIII. Let the bodies A and D (Fig. 5.) communicate with each other by the canal EF; and let one
of them, as D, be overcharged; the other body A will be so also. For as the fluid in the canal is repelled by the redundant fluid in D, it is plain, that unless A was overcharged, so as to balance that repulsion, the fluid would run out of D into A. In like manner, if one is overcharged, the other must be so also, to compensate the repulsion of B; but as the leg Np in is nearer than the other, the repulsion of B on the fluid in it will be greater; consequently some fluid will run out of A into D, on the same principle that water is drawn out of a vessel through a syphon: but if the repulsion of B on the fluid in the canal is so great, as to drive all the fluid out of the space GPHp (so that the fluid in the leg MGpn does not join to that in N Ip, then it is plain that no fluid can run out of A into D, any more than water will run out of a vessel through a syphon, if the height of the bend of the syphon above the water in the vessel is greater than that to which water will rise in vacuo.

Corol. If B is made undercharged, some fluid will run out of D into A, and that the attraction of B on the fluid in the canal is ever so great.

Prop. XII. Let ABC (Fig. 8) be a body overcharged with immovable fluid uniformly spread; let the bodies near ABC on the outside be saturated with immovable fluid, and let D be a body inclosed within ABC, and communicating by the canal DG with other distant bodies saturated with fluid; and let the fluid in D, and the canal and those bodies be movable; then will the body D be rendered undercharged.

For let us first suppose that D and the canal are saturated, and that D is nearer to B than to the opposite part of the body C; then will all the fluid in the canal be repelled from C by the redundant fluid in ABC; but if D is nearer to C than to B, take the point F, such that a particle placed there would be repelled from C with as much force, as one at D is repelled towards C; the fluid in DF, taking the whole together, will be repelled with as much force in one way as the other, and the fluid in FG is all of it repelled from C; therefore, in both cases, the fluid in the canal, taking the whole together, is repelled from C; consequently some fluid will run out of D and the canal, till the attraction of the unsaturated matter there is sufficient to balance the repulsion of the redundant fluid in ABC.

Prop. XIII. If we now suppose that the fluid in the outside of ABC is movable, the matter adjacent to ABC on the outside will become undercharged. There is no reason, however, to think, that that will prevent the body D from being undercharged; but it is not easy to say exactly what effect it will have, except when ABC is spherical, and the repulsion is inversely as the square of the distance. In this case, it appears by the last proposition, that the fluid in the part DB of the canal will be repelled from C, with just as much force as in the last proposition; but the fluid in the part DG will not be repelled at all: consequently D will be undercharged, but not so much as in the last proposition.

Corol. If ABC is now supposed to be undercharged, it is certain that D will be overcharged, provided the matter near ABC on the outside is saturated with immovable fluid; and there is great reason to think that it will be so, though the fluid in that matter is movable.
joining to the plane AB, in which the fluid will be pressed close together; and the fluid in that space will press against the plane AB, and will endeavour to escape from it; and by Prop. 2. the two bodies will attract each other; then the force with which the fluid presses against the plane AB, is very nearly the same with which the two bodies attract each other in the direction EA, provided that no part of AEFB is undercharged.

Suppose so much of the fluid in each part of the cylinder, as is sufficient to saturate the matter in that part, to become solid, the remainder, or the redundant fluid, remaining fluid as before. In this case, the pressure against the plane AB must be exactly equal to that with which the two bodies attract each other in the direction EA; for the force with which D attracts that part of the fluid which we supposed to become solid, is exactly equal to that with which it repels the matter in the cylinder; and the redundant fluid in EabF is at liberty to move, if it had any tendency to do so, without moving the cylinder; so that the only thing which has any tendency to impel the cylinder in the direction EA, is the pressure of the redundant fluid in AabB against AB; and as the part near EF is saturated, there is no redundant fluid to press against the plane EF, and thus to counteract the pressure against AB. Suppose now all the electric fluid in the cylinder to become fluid, the force with which the two bodies attract each other will remain exactly the same; and the only alteration in the pressure against AB will be, that part of the fluid in AabB, which we at first supposed solid and unable to press against the plane, will now be at liberty to press against it; but as the density of the fluid, when its particles are pressed close together, may be supposed many times greater than when it is not denser than sufficient to saturate the matter in the cylinder, and consequently the quantity of redundant fluid in AabB many times greater than that which is required to saturate the matter in it, it follows that the pressure against AB will be very little more than on the first supposition.

N.B. If any part of the cylinder is undercharged, the pressure against AB is greater than the force with which the bodies attract. If the electric repulsion is inversely as the square or some higher power of the distance, it seems very unlikely that any part of the cylinder should be undercharged.

Lemma 7. Let AB (Fig. 10.) represent an infinitely thin flat circular plate, seen edgewise, so as to appear to the eye as a straight line; let C be the centre of the circle; and let DC, passing through C, be perpendicular to the plane of the plate; and let the plate be of uniform thickness, and consist of uniform matter, whose particles repel with a force inversely as the n power of the distance; n being greater than 1, and less than 3: the repulsion of the plate on a particle at D, is proportional to \( DC^{\frac{n-1}{n}} \times DA^{-1} \), provided the thickness of the plate and size of the particle D is given.

For if CA is supposed to flow, the corresponding fluxion of the quantity of matter in the plate, is proportional to \( CA \times CA \times \frac{DC}{DA} \times DA \); and the corresponding fluxion of the repulsion of the plate on the particle D, in the direction DC, is proportional to \( \frac{CA \times CA \times DC}{DA \times DA} = DA \times DA \); for \( DA \) is to \( CA : CA : DA \), the variable part of the fluent of which is \( DC^{\frac{n-1}{n}} \).

whence the repulsion of the plate on the particle D, is proportional to

\[
\frac{DC}{n-1 \times DA^{n-1}} \quad \text{or to} \quad \frac{DC}{DA^{n-1}}
\]

Corol. If \( DC^{-1} \) is very small in respect of \( CA^{n-1} \), the particle D is repelled with very nearly the same force as if the diameter of the plate was infinite.

Lemma 8. Let L and l represent the two legs of a right angled triangle, and \( h \) the hypothenuse; if the shorter leg \( l \) is so much less than the other, that \( 2l^2 \) is very small in respect of \( L^2 \), then \( h^2 - l^2 = h\cdot l \) will be very small in respect of \( L^2 \).

For \( h^2 - l^2 = (l^2 + l^2)^{\frac{1}{2}} = l^2 \times \left(1 + \frac{l^2}{2l^2}\right) = \frac{3n-1}{2l^2} - \frac{3n-1}{2l^2} \\
\therefore h^2 - l^2 = \frac{3n-1}{2l^2} - \frac{3n-1}{2l^2} \\
\therefore \frac{1}{2L^2} = \frac{3n-1}{2l^2} - \frac{3n-1}{2l^2} \\
\frac{1}{2L^2} = \frac{3n-1}{2l^2} - \frac{3n-1}{2l^2} \\
& c. which is very small in respect of \( L^2 \), as \( L^2 \) is by the supposition very small in respect of \( l^2 \).

Corol. If \( AC = \frac{1}{2} \), the point E be taken in DC, such that EC = \( \frac{1}{2} \), the repulsion of the plate on it is very nearly the same as if the column was infinitely continued. For, by lemma 8, \( AC = \frac{1}{2} + DC = \frac{1}{2} + DA = \frac{1}{2} \), supposing the thickness of the plate and base of the column to be given. For if DC is supposed to flow, the corresponding fluxion of the repulsion is proportional to \( \frac{DC \times DC \times DC}{DA \times DA \times DA} \); the fluent of which, \( \frac{3n-1}{2} \), vanishes when DC vanishes.

Corol. 1. If the length of the column is so great, that \( AC = \frac{1}{2} \), is very small in respect of \( DC = \frac{1}{2} \), the repulsion of the plate on it is very nearly the same as if the column was infinitely continued. For, by lemma 8, \( AC = \frac{1}{2} + DC = \frac{1}{2} + DA = \frac{1}{2} \), supposing the thickness of the plate and base of the column to be given. For if DC is supposed to flow, the corresponding fluxion of the repulsion is proportional to \( \frac{DC \times DC \times DC}{DA \times DA \times DA} \); the fluent of which, \( AC = \frac{1}{2} \), vanishes.

Corol. 2. If \( AC = \frac{1}{2} \), is very small in respect of \( DC = \frac{1}{2} \), and the point E be taken in DC, such that EC = \( \frac{1}{2} \), shall be very small in respect of \( AC = \frac{1}{2} \), the repulsion of the plate on the small part of the column EC, to its repulsion on the whole column DC, very nearly as \( EC = \frac{1}{2} \) to \( AC = \frac{1}{2} \).

Lemma 10. If we now suppose all the matter of the plate to be collected in the circumference of the circle, so as to form an infinitely slender uniform ring, its repulsion on the column DC will be less than when the matter is spread uniformly all over the plate in the ratio of \( \frac{3n-1}{2} \times AC \times \left(\frac{1}{AC^{n-1}} - \frac{1}{DA^{n-1}}\right) \) to \( DC = \frac{1}{2} - DA = \frac{1}{2} \).

For it was before said, that if the matter of the plate be spread uniformly, its repulsion on the column will be proportional to \( DC = \frac{1}{2} + AC = \frac{1}{2} + DA \), or may be expressed by it; let now \( AC \), the semidiameter of the plate, be increased by the infinitely small quantity \( AC \); the quantity of matter in the plate will be increased by a quantity, which is to the whole as \( 2AC \) to \( AC \); and the repulsion of the plate on the column will be increa-
ELECTRICITY.

Plate CCL. Fig. 10.

Theoretical Electricity.

By the fluid being disposed in a similar manner in both bodies, it is meant that the quantity of redundant or deficient fluid, in any small part of one body, is to that in the corresponding small part of the other, as the whole quantity of redundant or deficient fluid in one body, to that in the other. By the quantity of deficient fluid in a body, it is meant the quantity of fluid wanting to saturate it. This expression is used, in order to avoid confusion.

The fluxion of the fluid is equal to the fluxion of the fluid of the same quantity of matter collected in the point F, on the same column.

For the repulsion of the plate on the column in the direction CD, is the same whether the matter of it be collected in the whole circumference, or in the point A. Suppose it therefore to be collected in A, and let an equal quantity of matter be collected in F; take FG constantly equal to AD, and let AD and FG flow; the fluxion of CD is to the fluxion of FG, as AD to CD; and the repulsion of A on the point D, in the direction CD, is to the repulsion of F on G, as CD to AD; therefore the fluxion of the repulsion of A on the column CD, in the direction CD, is equal to the fluxion of the repulsion of F on CD; and when AD equals AC, the repulsion of both A and F on their respective columns vanishes; and therefore the repulsion of A on the whole column CD, equals that of F on CD; and when CD and CG are both infinitely extended, they may be considered as the same column.

Prop. XV. Let two similar bodies, of different sizes, and consisting of different sorts of matter, be both overcharged, or both undercharged, but in different degrees; and let the redundance or deficiency of fluid in each be very small, in respect of the whole quantity of fluid in them: it is impossible for the fluid to be disposed accurately in a similar manner in both of them; as it has been shown that there will be a space, close to the surface, which will either be as full of fluid as it can hold, or will be entirely deprived of fluid; but it will be disposed as nearly in a similar manner in both as is possible. To explain this, let BDE and bde, Fig. 12, be the two similar bodies; and let the space comprehended between the surfaces BDE and FGH (or the space BF as it may be called for shortness) be that part of BDE, which is either as full of fluid as it can hold, or entirely deprived of it: draw the surface sgh, such that the space sgh, shall be to the space BF, as the quantity of redundant or deficient fluid in bde, to that in BDE, and that the thickness of the space sgh shall everywhere bear the same proportion to the corresponding thickness of BF, then will the space sgh be either as full of fluid as it can hold, or entirely deprived of it; and the fluid within the space sgh will be disposed very nearly similarly to that in the space FGH.

For it is plain, that if the fluid could be disposed accurately in a similar manner in both bodies, the fluid would be in equilibrio in one body, if it was in the fluid; therefore draw the surface sgh such that the thickness of the space sgh shall be to every where proportional to the corresponding thickness of BF, as the diameter of bde to the diameter of BDE; and let the redundant fluid or matter in sgh be spread uniformly over the space sgh; then if the fluid in the space sgh is disposed exactly similarly to that in FGH, it will be in equilibrio; as the fluid will then be disposed exactly similarly in the spaces sgh and BDE; but as, by the supposition, the thickness of the space sgh is very small in respect of the diameter of bde, the fluid or matter in the space sgh will exert very nearly the same force on the rest of the fluid, whether it is spread over the space sgh, or whether it is collected in sgh.

Prop. XVI. Let two bodies, B and b, be connected to each other by a canal of any kind, and be either over or under charged: it is plain that the quantity of
be connected by the very slender cylindrical or prismatic canal \( \alpha \), filled with incompressible fluid, in the same manner as described in the preceding proposition: let the bodies be overcharged; but let the quantity of redundant fluid in each bear so small a proportion to the whole, that the fluid may be considered as disposed in a similar manner in both; let the bodies also be similarly situated in respect of the canal \( \alpha \); and let them be placed at an infinite distance from each other, or at so great a one, that the repulsion of either body on the fluid in the canal, shall not be sensibly less than if they were at an infinite distance; then, if the electric attraction and repulsion is inversely as the \( n \) power of the distance, \( n \) being greater than 1, and less than 3, the quantity of redundant fluid in the two bodies will be to each other, as the \( n-1 \) power of their corresponding diameters \( \alpha \) and \( \alpha \).

For if the quantity of redundant fluid in the two bodies is in this proportion, the repulsion of one body on the fluid in the canal, will be equal to that of the other body on it, in the contrary direction; and consequently the fluid will have no tendency to flow from one body to the other, as may thus be proved. Take the points \( D \) and \( E \) very near to each other; and take \( d \), \( a \) to \( D \), \( a \) to \( E \), as \( \alpha \) to \( \alpha \); the repulsion of the body \( B \) on a particle at \( D \), will be to the repulsion of \( B \) on a particle at \( d \), as \( \frac{1}{\alpha} \) to \( \frac{1}{\alpha} \); for, as the fluid is disposed similarly in both bodies, the quantity of fluid in any small part of \( B \), is to the quantity in the corresponding part of \( b \), as \( \frac{AF}{\alpha} \) to \( \frac{AF}{\alpha} \); and consequently the repulsion of that small part of \( B \), on \( D \), is to the repulsion of the corresponding part of \( b \) on \( d \), as \( \frac{AF}{\alpha^2} \), or \( \frac{1}{\alpha} \) to \( \frac{1}{\alpha} \). But the quantity of fluid in the small part \( DE \) of the canal, is to that in \( de \), as \( DE \) to \( de \), or as \( \alpha \) to \( \alpha \); therefore the repulsion of \( B \) on the fluid in \( DE \), is equal to that of \( b \) on the fluid in \( de \); therefore taking \( a \) to \( \alpha \), as \( \alpha \) to \( \alpha \), the repulsion of \( B \) on the fluid in \( ag \), is equal to that of \( B \) on the fluid in \( \alpha \); but the repulsion of \( b \) on \( ag \) may be considered as the same as its repulsion on \( \alpha \); for, by the supposition, the repulsion of \( B \) on \( \alpha \) may be considered as the same as if it was continued infinitely; and therefore the repulsion of \( B \) on \( ag \) may be considered as the same as if it was continued infinitely.

Corol. By just the same method of reasoning it appears, that if the bodies are undercharged, the quantity of deficient fluid in \( B \) will be to that in \( B \), as \( \alpha \) to \( \alpha \).

**Prop. XIX.** Let a thin flat plate be connected to any other body, as in the preceding proposition, by a canal of incompressible fluid, perpendicular to the plane of the plate; and let that body be overcharged; then the quantity of redundant fluid in the plate will bear very nearly the same proportion to that in the other body, whatever the thickness of the plate may be, provided its thickness is very small in proportion to its breadth, or smallest diameter. For there can be no doubt, but under that restriction, the fluid will be disposed very nearly in the same manner in the plate, whatever its thickness may be; and therefore its repulsion on the fluid in the canal will be very nearly the same, whatever its thickness may be.

**Prop. XX.** Let \( AB \) and \( DF \), Fig. 14, represent two equal and parallel circular plates, whose centres are \( C \) and \( E \); let the plates be placed so, that a right line joining their centres shall be perpendicular to the
plates; let the thickness of the plates be very small in respect of their distance CE; let the plate AB communicate with the body H, and the plate DF with the body L, by the canals CG and EM of incompressible fluid, such as are described in Prop. 17; let these canals meet their respective plates in their centres C and E, and be perpendicular to the plane of the plates; and let their length be so great, that the repulsion of the plates on the fluid in them may be considered as the same as if they were continued infinitely; let the body H be overcharged, and let L be saturated. It is plain, from Prop. 10, that DF will be undercharged, and AB will be more overcharged than it would otherwise be. Suppose now, that the redundant fluid in AB is disposed in the same manner as the deficient fluid in DF; let P be to 1, as the force with which the plate AB would repel the fluid in CE, if the canal ME was continued to C, is to the force with which it would repel the fluid in CM; and let the force with which AB repels the fluid in CG be to the force with which it would repel it, if the redundant fluid in it was spread uniformly, as π to 1; and let the force with which the body H repels the fluid in CG, be the same with which a quantity of redundant fluid, which we will call B, spread uniformly over AB, would repel it in the contrary direction. Then will the redundant fluid in AB be equal to \(\frac{B}{2}\pi r^2 - \frac{B}{\pi}r^2\); and therefore, if P is very small, will be very nearly equal to \(\frac{B}{2}\pi r^2\)

and the deficient fluid in DF will be to the redundant fluid in AB, as 1 - P to 1; and therefore, if P is very small, will be very nearly equal to the redundant fluid in AB.

For it is plain, that the force with which AB repels the fluid in EM, must be equal to that with which DF attracts it; for otherwise some fluid would run out of DF into L, or out of L into DF: for the same reason, the excess of the repulsion of AB on the fluid in CG, above the attraction of FD on it, must be equal to the force with which a quantity of redundant fluid equal to B, spread uniformly over AB, would repel it, or it must be equal to that with which a quantity equal to \(\frac{B}{\pi}\) spread in the manner in which the redundant fluid is actually spread in AB, would repel it. By the supposition, the force with which AB repels the fluid in EM, is to the force with which it would repel the fluid in CM, supposing EM to be continued to C, as 1 - P to 1; but the force with which any quantity of fluid in AB would repel the fluid in CM, is the same with which an equal quantity similarly disposed in DF, would repel the fluid in EM; therefore the force with which the redundant fluid in AB repels the fluid in EM, is to that with which an equal quantity similarly disposed in DF, would repel it, as 1 - P to 1; therefore, if the redundant fluid in AB be called A, the deficient fluid in DF must be \(A \times (1 - P)\); for the same reason, the force with which DF attracts the fluid in CG, is to that with which AB repels it, as \(A \times (1 - P)\) to \(A \times (1 - P)\); and therefore, the excess of the force with which AB repels CG, above that with which DF attracts it, is equal to that with which a quantity of redundant fluid equal to \(A \times (1 - P)\), or \(A \times (2P - P)\), spread over AB, in the manner in which the redundant fluid in it is actually spread, would repel it; therefore, \(A \times (2P - P)\) must be equal to \(\frac{B}{\pi}\) or \(A\) must be equal to \(\frac{B}{2\pi} - \frac{B}{\pi}\).

Vol. VIII. Part II.

**Corol. 1.** If the density of the redundant fluid near the middle of the plate AB is less than the mean density, or the density which it would every where be, if it was spread uniformly, in the ratio of 3 to 1; and if the distance of the two plates is so small, that \(EC = \frac{1}{2m}\) is very small in respect of \(AC = \frac{1}{n}\), and that \(EC = \frac{1}{2m}\) is very small in respect of \(AC = \frac{1}{n}\), the quantity of redundant fluid in AB will be greater than

\[
\frac{B}{2\pi} \left( \frac{AC}{EC} \right)^{1-n}, \text{ and less than } \frac{B}{2\pi} \left( \frac{AC}{EC} \right)^{1-n}.
\]

but will approach much nearer to the latter value than the former. For, in this case, \(P\) is, by lemma 10, coroll. 4; less than \(\frac{EC}{AC}\) and greater than \(\frac{EC}{AC} \times \frac{1}{2}\), but approaches much nearer to the latter value than the former; and if \(EC = \frac{1}{n}\) is very small in respect of \(AC = \frac{1}{n}\), \(P\) is very small.

**Remarks.** If DF was not undercharged, it is certain that AB would be considerably more overcharged near the circumference of the circle than near the centre; for if the fluid was spread uniformly, a particle placed any where at a distance from the centre, as at N, would be repelled with considerably more force towards the circumference, than it would towards the centre. If the plates are very near together, and consequently DF nearly as much undercharged as AB is overcharged, AB will still be more overcharged near the circumference than near the centre, but the difference will not be near so great as in the former case: for, let NR be many times greater than CE, and NS less than CE; and take ER and ES equal to CR and CS; there can be no doubt, he thinks, that the deficient fluid in DF will be lodged nearly in the same manner as the redundant fluid in AB; and therefore the repulsion of the redundant fluid at R, on a particle at N, will be very nearly balanced by the attraction of the redundant matter at r, for R is not much nearer to N than r is; but the repulsion of R will not be near balanced by that of r; for the distance of S from N is much less than that of s. Let now a small circle, whose diameter is ST, be drawn round the centre N, on the plane of the plate; as the density of the fluid is greater at T than at S, the repulsion of the redundant fluid within the small circle tends to impel the point N towards C; but as there is a much greater quantity of fluid between N and B than between N and A, the repulsion of the fluid without the small circle tends to balance that; but the effect of the fluid within the small circle is not much less than it would be, if DF was not undercharged; whereas much the greater part of the effect of that part of the plate on the outside of the circle, is taken off by the effect of the corresponding part of DF; consequently the difference of density between T and S will not be near so great, as if DF was not undercharged. Hence it is probable, that if the two plates are very nearly together, the density of the redundant fluid near the centre will not be much less than the mean density, or \(P\) will not be much less than \(\frac{1}{2}\); moreover, the less the distance of the plates, the nearer will \(P\) approach to 1.

**Corol. 2.** Let now the body H consist of a circular plate, of the same size as AB, placed so that the canal CG shall pass through its centre, and be perpendicular to its plate; by the supposition the force with which H repels the fluid in the canal CG, is the same with which a quantity of fluid, equal to B, spread uniformly over AB, would repel it in a contrary direction; therefore, if the fluid in the plate H was spread uniformly,

---

Theoretical Electricity.
the quantity of redundant fluid in it would be $B$; and
if it was all collected in the circumference, would be
$2B \times \frac{3}{\pi}$; and therefore the real quantity will be greater
than $B$, and less than $2B \times \frac{3}{\pi}$.

Corol. 3. Therefore, if we suppose $\vartheta$ to be equal to 1, the
quantity of redundant fluid in $AB$ will exceed that in
the plate $H$, in a greater ratio than that of
$\left(\frac{AC}{CE}\right)^{\frac{3}{4}} \times \frac{3}{\pi}$ to 1, and less than that of $2B \times \frac{3}{\pi}$: and from the preceding remarks it appears, that the real
quantity of redundant fluid in $AB$ can hardly be much
greater than it would be if $\vartheta$ was equal to 1.

Corol. 4. Hence the redundant fluid in $AB$, suppos-
ing $\vartheta$ to be equal to 1, will exceed that in the plate $H$,
in a greater ratio than that of $AC$ to $4CE$, and less than that of $AC$ to $2CE$.

Corol. 5. Let now the body $H$ consist of a globe
whose diameter equals $AB$; the globe being situated in
such a manner that the canal $CG$, if continued, would
pass through its centre; the quantity of redundant fluid in
the globe will be $2B$; for the fluid will be spread
uniformly over the surface of the globe, and its repul-
sion on the canal will be the same as if it was all collected
in the centre of the sphere, and will therefore be the
same with which an equal quantity, disposed in the
circumference of $AB$, would repel it in the contrary
direction, or with which half that quantity, or $B$, would
repel it, if spread uniformly over the plate.

Corol. 6. Therefore, if $\vartheta$ was equal to 1, the
redundant fluid in $AB$ would exceed that in the globe, in the
ratio of $AC$ to $4CE$; and therefore it will in reality ex-
ceed that in the globe, in a rather greater ratio than that
of $AC$ to $4CE$; but if the plates are very near together,
it will approach very near to that ratio, and the nearer
the plates are, the nearer it will approach to it.

Corol. 7. If the body $H$ is as much undercharged as
it was before overcharged, $AB$ will be as much under-
charged as it was before overcharged, and $DF$ as
much overcharged as it was before undercharged.

Corol. 8. If the size and distance of the plates be al-
terred, the quantity of redundant or deficient fluid in the
body $H$ remaining the same, it appears, by comparing
this proposition with the 18th and 19th propositions,
that the quantity of redundant and deficient fluid in
$AB$, will be as $AC^{-\vartheta} \times \left(\frac{AC}{EC}\right)^{\frac{3}{4}}$, or as $AC^{-\vartheta} \times \frac{AC^3}{EC^3}$: suppos-
ing the value of $\vartheta$ to remain the same.

Prop. XXI. If $AB$ and $DF$, Fig. 17, represent
the two plates, and $H$ and $L$ the bodies communi-
cating with them; let now $H$ be removed to $h$, and let
it communicate with $AB$, by the bent canal $gc$, the
quantity of fluid in the plates and bodies remaining
the same as before, and let us, for the sake of ease in the
demonstration, suppose the canal $gc$ to be every where
of the same thickness as the canal $CG$, though the pro-
position will evidently hold equally good whether it is
or not, then the fluid will still be in equilibrio. For let
us first suppose the canal $gc$ to be continued through
the substance of the plate $AB$ to $C$, along the line $crC$; the
part $crC$ being of the same thickness as the rest of the
canal, and the fluid in it of the same density: by the pre-
ceding proposition, the repulsion or attraction of each
particle of fluid or matter in the plates $AB$ and $DF$, on
the fluid in the whole canal $Creg$, in the direction of that
canal, is equal to its repulsion or attraction on the fluid in
the canal $CG$, in the direction $CG$; and therefore the
whole repulsion or attraction of the two plates on the
canal $Creg$ is equal to their repulsion or attraction on $CG$;
but as the fluid in the plate $AB$ is in equilibrio, each
particle of fluid in the part $Creg$ of the canal, is impelled
by the plates, with as much force in one direction as the
other, and consequently the plates impel the fluid in the
canal $cg$, with as much force as they do that in the
whole canal $Creg$, that is, with the same force that they
impel the fluid in $CG$. In like manner the body
$h$ impels the fluid in $cg$, with the same force that $H$ does
the fluid in $CG$, and consequently $h$ impels the fluid in
$cg$ one way in the direction of the canal, with the same
force that the two plates impel it the contrary way, and
therefore the fluid in $cg$ has no tendency to flow from
one body to the other.

Corol. By the same method of reasoning, with the
help of the corollary to the 21st proposition, it appears
that if $AB$ and $H$ each communicate with a third body,
y canals of incompressible fluid, and a communication
is made between $AB$ and $H$ by another canal of incom-
pressible fluid, the fluid will have no tendency to flow
from one to the other through this canal, supposing that
the fluid was in equilibrio before this communication was
made. In like manner, if $AB$ and $H$ communicate with
each other, or each communicate with a third body, by
canals of real fluid, instead of the imaginary canals of
incompressible fluid used in these propositions, and a communication is also made between them by a canal of incompressible fluid, the fluid can have no tendency to flow from one to the other. The truth of the latter part of this corollary will appear by supposing an imaginary canal of incompressible fluid to be continued through the whole length of the real one.

Prop. XXII. Let now a communication be made between the two plates AB and DF, by the canal NRS of incompressible fluid of any length, and let the body H and the plate AB be overcharged. It is plain that the fluid will flow through that canal from AB to DF. Now the whole force with which the fluid in the canal is impelled along it, by the joint action of the two plates, is the same with which the whole mass of fluid in the canal CG or CG is impelled by them, supposing the canal NRS to be every where of the same breadth and thickness as CG or CG. For suppose that the canal NRS, instead of communicating with the plate DF, is bent back just before it touches it, and continued infinitely along the line Ss; the force with which the fluid in the canal is impelled along it, by the joint action of the two plates, is the same with which they impel that in EL, supposing SS to be of the same breadth and thickness as ES, and is therefore nothing; therefore the force with which they impel the fluid in NRS, is the same with which they impel that in CG.

Prop. XXIV. Let now xys be a body of an infinite size, containing just fluid enough to saturate it; and let a communication be made between x and xys, by the canal hy of incompressible fluid, of the same breadth and thickness as gc or GC, the fluid will flow through it from x to xys; and the force with which the fluid in that canal is impelled along it, is equal to that with which the fluid in NRS is impelled by the two plates.

If the canal hy is of so great a length, that the repulsion of h on it is the same as if it was continued infinitely, then the thing is evident; but if it is not, let the canal hy, instead of communicating with xys, so that the fluid may flow out of the canal into xys, be continued infinitely through its substance, along the line yv: now, it must be observed, that a small part of the body xys, namely that which is turned towards x, will, by the action of h on it, be rendered undercharged, but all the rest of the body will be saturated; for the fluid driven out of the undercharged part will not make the remainder, which is supposed to be of an infinite size, sensibly overcharged: now the force with which the fluid in the infinite canal hyv, is impelled by the body h and the undercharged part of xys, is the same with which the fluid in gc is impelled by them; but as the fluid in yv cannot be impelled in any direction; and therefore the fluid in hy is impelled with as much force as that in hy, and therefore the fluid in hy is impelled with as much force as that in gc, and is therefore impelled with as much force as the fluid in NRS is impelled by the two plates.

It perhaps may be asked, whether this method of demonstration would not equally tend to prove that the fluid in hy was impelled with the same force as that in NRS, though xys did not contain just fluid enough to saturate it; but this is not the case, for this demonstration depends on the canal yv being continued, within the body xys, to an infinite distance beyond any over or under charged part, which could not be if xys contained either more or less fluid than that is.

Prop. XXV. Let two bodies B and b, Fig. 13, be joined by a cylindrical or prismatic canal Aa, filled with real fluid, and not by an imaginary canal of incompressible fluid, as in the 16th proposition, and let the fluid in it be in equilibrio, the force with which the whole or any given part of the fluid in the canal, is impelled in the direction of its axis, by the united repulsions and attractions of the redundant fluid or matter in the two bodies and the canal, must be nothing; or the force with which it is impelled one way in the direction of the axis of the canal, must be equal to that with which it is impelled the other way. For as the canal is supposed cylindrical or prismatic, no particle of fluid in it can be prevented from moving in the direction of its axis, by the sides of the canal; and therefore the force with which each particle is impelled either way in the direction of the axis, by the united attractions and repulsions of the two bodies and the canal, must be nothing, otherwise it could not be at rest; and therefore the force with which the whole, or any given part of the fluid in the canal, is impelled in the direction of the axis, must be nothing.

Corol. 1. If the fluid in the canal is disposed in such a manner, that the repulsion or attraction of the redundant fluid or matter in it, on the whole or any given part of the fluid in the canal, has no tendency to impel it either way in the direction of the axis; then the force with which that whole or given part is impelled by the two bodies, must be nothing; or the force with which it is impelled one way in the direction of the axis, by the body B, must be equal to that with which it is impelled in the contrary direction by the other body, but not if the fluid in the canal is disposed in a different manner.

Corol. 2. If the bodies, and consequently the canal, is overcharged; then, in whatever manner the fluid in the canal is disposed, the force with which the whole quantity of redundant fluid in the canal is repelled by the body B, in the direction B, must be equal to that with which it is repelled by b, in the contrary direction. For the force with which the redundant fluid is impelled in the direction B, by its own repulsion, is nothing; for the repulsion of the particles of any body on each other, have no tendency to make the whole body move in any direction.

Sect. II. Comparison of the preceding Hypothesis with Experiments.

1. It appears from experiment, that some bodies suffer the electric fluid to pass with great readiness between their pores, while others will not suffer it to do so without great difficulty, and some hardly suffer it to do so at all. The first sort of bodies are called conductors, the others non-conductors. It is evident that the electric fluid in non-conductors may be considered as moveable, or answering to the definition given of that term immediately before Prop. 1. As to the fluid contained in non-conducting substances, though it does not absolutely answer to the definition of immovable, as it is not absolutely confined from moving, but only does so with great difficulty; yet it may in most cases be considered as such without sensible error. Air does in some measure permit the electric fluid to pass through it; though, if it is dry, it lets it pass but very slowly, and not without difficulty, it is therefore to be called a non-conductor.

It appears that conductors would readily suffer the fluid to run in and out of them, were it not for the air which surrounds them; for if the end of a conductor is inserted into a vacuum, the fluid runs in and out of it with perfect readiness; but when it is surrounded on all sides with conducting matter, it is seen to be sensibly impeded. The reason of this is, that the fluid, in consequence of the action of the conducting matter, does not pass along the surface of the conductor, but is carried between the conducting matter and the conductor, which makes its way with some difficulty. This is the true reason why the electric fluid is carried between conducting matter, and not by the conducting matter directly, as in water, when it is carried between the spaces between the conducting matter. But the conducting matter is not fourteen times as heavy as water. For if we pour water into a vessel, and, while the water is pouring, we put in a conductor, it does not impede the water's passing in; but, if we put a conducting matter in the water while it is pouring, it will impede the water's passing in.
ELECTRICITY.

Theoretical Electricity.

Explanation of positive and negative electricity.

Electrified if understood, but overcharged is an
for small repulsion, as but and its body
be for which
lliey impossible it itself yet
If and very

Electrified, or other causes; yet the bulk of the
earth, and especially the interior parts, must be
saturated with electricity. Therefore assume any part of
the earth which is itself saturated, and is at a great
distance from any over or under charged part; any
body communicating with the ground, contains as much
electricity as it communicated with this part by a

canal of an incompressible fluid, and therefore is not at
all electrified.

If any body A, insulated, and saturated with
electricity, is placed at a great distance from any over
or under charged body, it is plain that it cannot be
electrified; but if an overcharged body is brought near it, it
will be positively electrified; for supposing A to com-
communicate with any body B, at an infinite distance, by
a canal of an incompressible fluid, it is plain that unless B
is overcharged, the fluid in the canal could not be in
equilibrium, but would run from A to B. For the same
reason, a body insulated and saturated with fluid,
will be negatively electrified if placed near an un-
dercharged body.

2. The phenomena of the attraction and repulsion
of electrified bodies seem to agree exactly with the the-
ory; as will appear by considering the following cases.

Case 1. Let two bodies, A and B, both conductors of
electricity, and both placed at a great distance from any
other electrified bodies, be brought near each other. Let A
be insulated, and contain just fluid enough to saturate
it; and let B be positively electrified. They will at-
tract each other; for as B is positively electrified, and
at a great distance from any other overcharged body, it
will be overcharged; therefore, on approaching A and B
to each other, some fluid will be driven from that part
of A which is nearest to B to the farther part: but
when the fluid in A was spread uniformly, the repul-
sion of B on the fluid in A was equal to its attraction on
the matter in it; therefore when some fluid is removed
from those parts where the repulsion of B is strongest,
to those where it is weaker, B will repel the fluid in A
with less force than it attracts the matter; and conse-
quently the bodies will attract each other.

Case 2. If we now suppose that the fluid is at li-
berty to escape out of A, if it has any disposition to
do so, the quantity of fluid in it before the approach of
B being still sufficient to saturate it; that is, if A is not
insulated and not electrified, B being still positively
electrified, they will attract with more force than be-
fore: for in this case, not only some fluid will be driven
from that part of A which is nearest to B to the
opposite part, but also some fluid will be driven out of
A. It must be observed, that if the repulsion of B on
a particle at E, Fig. 19, the farthest part of A, is very
small in respect of its repulsion on an equal particle
placed at D, the nearest part of A, the two bodies will
attract with very nearly the same force, whether A is
insulated or not; but if the repulsion of B, on a particle
at E, is very near as great as on one at D, they will
attract with very little force if A is insulated. For in-
stance, let a small overcharged ball be brought near
one end of a long conductor not electrified; they will
attract with very near the same force, whether the
conductor be insulated or not; but if the conductor
be overcharged, and brought near a small electrified
ball, they will not attract with near so much force, if
the ball is insulated, as if it is not.

Case 3. If we now suppose that A is negatively elec-
trified, and not insulated, it is plain that they will at-
tract with more force than in the last case; as A will be
still more undercharged in this case than in the last.

N. B. In these three cases, we have not as yet taken

PLATE CULL.

Fig. 19.
notice of the effect which the body A will have in altering the quantity and disposition of the fluid in B; but in reality this will make the bodies attract each other with more force than they would otherwise do; for in each of these cases the body A attracts the fluid in B; which will cause some fluid to flow from the farther parts of B to the nearer, and will also cause some fluid to flow into it, if it is not insulated, and will consequently cause B to act upon A with more force than it would otherwise do.

Case 4. Let us now suppose that B is negatively electrified; and let A be insulated, and contain just fluid enough to saturate it, they will attract each other; for B will be undercharged; it will therefore attract the fluid in A, and will cause some fluid to flow from the farthest part of A, where it is attracted with less force, to the nearest part, where it is attracted with more force; so that B will attract the fluid in A with more force than it repels the matter.

Case 5 and 6. If A is now supposed to be not insulated and not electrified, B being still negatively electrified; it is plain that they will attract with more force than in the last case: and if A is positively electrified, they will attract with still more force.

In these last three cases also, the effect which A has in altering the quantity and disposition of the fluid in B, tends to increase the force with which the two bodies attract.

Case 7. It is plain, that a non-conducting body saturated with fluid, is not at all attracted or repelled by an over or under charged body, until, by the action of the electrified body on it, it has either acquired some additional fluid from the air, or had some driven out of it, or till some fluid is driven from one part of the body to the other.

Case 8. Let us now suppose that the two bodies A and B are both positively electrified in the same degree. It is plain, that were it not for the action of one body on the other, they would both be overcharged, and would repel each other. But it may perhaps be said, that one of them, as A, may, by the action of the other on it, be either rendered undercharged on the whole, or at least may be rendered undercharged in that part nearest to B; and that the attraction of this undercharged part on a particle of the fluid in B, may be greater than the repulsion of the more distant overcharged part; so that on the whole the body A may attract a particle of fluid in B. If so, it must be affirmed, that the body B repels the fluid in A; for otherwise, that part of A which is nearest to B could not be rendered undercharged. Therefore, to obviate this objection, let the bodies be joined by the straight canal DC of incompressible fluid (Fig. 19.) The body B will repel the fluid in all parts of this canal; for as A is supposed to attract the fluid in B, B will not only be more overcharged than it would otherwise be, but it will also be more overcharged in that part nearest to A, than in the opposite part. Moreover, as the near undercharged part of A is supposed to attract a particle of fluid in B, with more force than the more distant overcharged part repels it; it must, a fortiori, attract a particle in the canal with more force than the other repels it; therefore the body A must attract the fluid in the canal; and consequently some fluid must flow from B to A, which is impossible; for as A and B are both electrified in the same degree, they cannot contain the same quantity of fluid as they both communicated with a third body at an infinite distance, by canals of incompressible fluid, and therefore by the cor. to Prop. 22, if a communication is made between them by a canal of incompressible fluid, the fluid would have no disposition to flow from one to the other.

Case 9. But if one of the bodies, as A, is positively electrified in a less degree than B, then it is possible for the bodies to attract each other; for in this case the force with which B repels the fluid in A may be so great, as to make the body A either entirely undercharged, or at least to make the nearest part of it so much undercharged, that A shall on the whole attract a particle of fluid in B. It may be worth remarking, with regard to this case, that when two bodies, both electrified positively but unequally, attract each other, you may, by removing them to a greater distance from each other, cause them to repel; for as the stronger electrified body repels the fluid in the weaker with less force when removed to a greater distance, it will not be able to drive so much fluid out of it, or from the nearer to the farther part, as when placed at a less distance.

Case 10 and 11. By the same reasoning it appears, that if the two bodies are both negatively electrified in the same degree, they must repel each other: but if they are both negatively electrified in different degrees, it is possible for them to attract each other.

All these cases are conformable to experiment.

Case 12. Let two cork balls be suspended by conducting threads, from the same positively electrified body, in such a manner, that if they did not repel, they would hang close together; they will both be equally electrified, and will repel each other: let now an overcharged body, more strongly electrified than them, be brought under them; they will become less overcharged, and will separate less than before: on bringing the body still nearer, they will become not at all overcharged, and will not separate at all: and on bringing the body still nearer, they will become undercharged, and will separate again.

Case 13. Let all the air of a room be overcharged; and let two cork balls be suspended close to each other by conducting threads communicating with the wall. By Prop. 13, it is highly probable that the balls will be undercharged, and therefore they should repel each other.

These last two cases are experiments of Mr. Canton's, and are described in Phil. trans. 1758, p. 350, where are other experiments of the same kind, all readily explicable by the preceding theory.

3. On the cases in which bodies receive electricity from or part with it to the air.

Lemma 1. Let the body A, Fig. 6, either stand near some over or under charged body, or at a distance from it. It seems highly probable, that if any part of its surface, as MN, is overcharged, the fluid will endeavour to run out through that part, provided the air adjacent to it is not overcharged.

For let G be any point in that surface, and P a point within the body, extremely near to it; it is plain that a particle of fluid at P must be repelled with as much force in one direction as another (otherwise it could not be at rest), unless all the fluid between P and G is pressed close together; in which case it may be repelled with more force towards G, than it is in the contrary direction: now, a particle at G is repelled in the direction PG, i.e. from P to G, by all the redundant fluid between P and G; and a particle at P is repelled by the same fluid in the contrary direction; so that, as the particle at P is repelled with not less force in the direction PG than in the contrary, Mr. C. does not see how a particle at G can help being repelled with more force in that direction than the contrary, unless the air on the outside of the surface MN was more overcharged than the space between P and G.

Lemma 2. On cases in which bodies receive electricity from or part with it to the air.
In like manner, if any part of the surface is undercharged, the fluid will have a tendency to run in at that part from the air. The truth of this is somewhat confirmed by the 2d problem; as in all the cases of that problem, the fluid was shown to have a tendency to run out of the spaces AD and EH, at any surface which was overcharged, and to run in at any which was undercharged.

Corol. 1. If any body at a distance from other over or under charged bodies, be positively electrified, the fluid will gradually run out of it from all parts of its surface into the adjoining air; as it is plain that all parts of the surface of that body will be overcharged, and if the body is negatively electrified, the fluid will gradually run into it at all parts of its surface from the adjoining air.

Corol. 2. Let the body A, Fig. 6, insulated, and containing just fluid enough to saturate it, be brought near the overcharged body B; that part of the surface of A which is turned towards B will, by Prop. 2, be rendered undercharged, and will therefore imbibe electricity from the air; and at the opposite surface RS, the fluid will run out of the body into the air.

Corol. 3. If we now suppose that A is not insulated, but communicates with the ground, and consequently that it contained just fluid enough to saturate it before the approach of B, it is plain that the surface MN will be rendered undercharged before; and therefore the fluid will run in there with more force than before; but it can hardly have any disposition to run out at the opposite surface RS; for if the canal by which A communicates with the ground is placed opposite to B, as in Fig. 5, then the fluid will run out through that canal, till it has no longer any tendency to run out at RS; and by the remarks at the end of Prop. 25, it seems probable that the fluid in A will be nearly in the same quantity, and disposed nearly in the same manner, into whatever part of A the canal is inserted, by which it communicates with the ground.

Corol. 4. If B is undercharged, the case will be reversed; that is, it will run out where it before ran in, and will run in where it before ran out.

These corollaries seem conformable to experiment: thus far is certain, that bodies at a distance from other electrified bodies receive electricity from the air, if negatively electrified, and part with some to it if positively electrified: and a body not electrified, and not insulated, receives electricity from the air if brought near an overcharged body, and loses some when brought near an undercharged body: and a body insulated and containing its natural quantity of fluid, in some cases receives, and in others loses electricity, when brought near an over or under charged body.

4. The well-known effects of points in causing a quick discharge of electricity, seem to agree very well with this theory.

It appears from the 18th Proposition, that if two similar bodies of different sizes are placed at a very great distance from each other, and connected by a slender canal, and overcharged, the force with which a particle of fluid, placed close to corresponding parts of their surface, is repelled from them, is inversely as the corresponding diameters of the bodies. If the distance of the two bodies is small, there is not so much difference in the force with which the particle is repelled by the two bodies; but still, if the diameters of the two bodies are very different, the particle will be repelled with much more force from the smaller body than from the larger. It is true, indeed, that a particle placed at a certain distance from the smaller body, will be repelled with less force than if it be placed at the same distance from the greater body; but this distance is, in most cases, very considerable; if the bodies are spherical, and the repulsion inversely as the square of the distance, a particle placed at any distance from the surface of the smaller body, less than a mean proportional between the radii of the two bodies, will be repelled from it with more force than if it be placed at the same distance from the larger body.

Hence, if two similar bodies are connected together by a slender channel, and are overcharged, the fluid must escape faster from a smaller body than from an equal surface of the larger; but as the surface of the larger body is greatest, it does not appear which body ought to lose most electricity in the same time; and indeed it seems impossible to determine positively from this theory which should, as it depends in great measure on the manner in which the air opposes the entrance of the electric fluid into it. Perhaps in some degrees of electrification the smaller body may lose most, and in others the larger.

Let now ACB, Fig. 18, be a conical point, standing on any body DAB, C being the vertex of the cone; and let DAB be overcharged: A particle of fluid placed close to the surface of the cone, any where between A and C, must be repelled with at least as much, if not more force, than it would, if the part A B of the cone was taken away, and the part a CB connected to DAB by a slender canal; and consequently, from what has been said before, it seems reasonable to suppose, that the waste of electricity from the end of the cone must be very great in proportion to its surface; though it does not appear from this reasoning, whether the waste of electricity from the whole cone, should be greater or less than from a cylinder of the same base and altitude. All that has been here said relating to the flowing out of electricity from overcharged bodies, holds equally true with regard to the flowing in of electricity into undercharged bodies.

But a circumstance which contributes as much as any thing to the quick discharge of electricity from points, is the swift current of air caused by them, and taken notice of by Mr Wilson and Dr Priestley, (see Priestley, p. 117 and 591); and which is produced in this manner. If a globular body ABD is overcharged, the air close to it, all round its surface, is rendered overcharged by the electric fluid, which flows into it from the body; it will therefore be repelled by the body; but as the air all round the body is repelled with the same force, it is in equilibrio, and has no tendency to fly off from it. If now the conical point ACB be made to stand out from the globe, as the fluid will escape much faster in proportion to the surface from the end of the point, than from the rest of the body, the air close to it will be much more overcharged than that close to the rest of the body; it will therefore be repelled with much more force; and consequently a current of air will flow along the sides of the cone from B towards C; by which means there is a continual supply of fresh air, not much overcharged, brought in contact with the point; whereas otherwise the air adjoining to it would be so much overcharged, that the electricity would have but little disposition to flow from the point into it.

The same current of air is produced in a less degree, without the help of the point, if the body, instead of being globular, is oblong or flat, or has knobs on it, or is otherwise formed in such a manner as to make the electricity escape faster from some parts of it than the rest.
In like manner, if the body ABD be undercharged, the air adjoining to it will also be undercharged, and will therefore be repelled by it; but as the air close to the end of the point will be more undercharged than that close to the rest of the body, it will be repelled with much more force; which will cause exactly the same current of air, flowing the same way, as if the body was overcharged; and consequently the velocity with which the electric fluid flows into the body, will be very much increased. Mr C. believes, indeed, that it may be laid down as a constant rule, that the faster the electric fluid escapes from any body when overcharged, the faster will it run into that body when undercharged.

Points are not the only bodies which cause a quick discharge of electricity; in particular, it escapes very fast from the ends of long slender cylinders; and a swift current of air is caused to flow from the middle of the cylinder towards the end: this will easily appear by considering, that the redundant fluid is collected in much greater quantity near the ends of the cylinders, than near the middle. The same thing may be said, but he believes in a less degree, of the edges of thin plates.

What has been just said concerning the current of air, serves to explain the reason of the revolving motion of Dr Hamilton's and Mr Kinnersley's bent pointed wires, (see Phil. Trans. vol. li. p. 905, and vol. liii. p. 86; also Priestley, p. 429, and 440 of this article): for the same reason which impels the air from the thick part of the wire towards the point, tends to impel the wire in the contrary direction.

It is well known, that if a body B is positively electrified, and another body A, communicating with the ground, be then brought near it, the electric fluid will escape faster from B, at that part of it which is turned towards A, than before. This is plainly conformable to theory; for as A is thus rendered undercharged, B will in its turn be made more overcharged, in that part of it which is turned towards A, than it was before. But it is also well known, that the fluid will escape faster from B, if A be pointed, than if it be blunt; though B will be less overcharged in this case than in the other; for the broader the surface of A, which is turned towards B, the more effect will it have in increasing the overcharge of B. The cause of this phenomenon is as follows:

If A is pointed, and the pointed end turned towards B, the air close to the point will be very much undercharged, and therefore will be strongly repelled by A, and attracted by B, which will cause a swift current of air to flow from it towards B, by which means a constant supply of undercharged air will be brought in contact with B, which will accelerate the discharge of electricity from it in a very great degree; and, moreover, the more pointed A is, the swifter will be this current. If, on the other hand, that end of A which is turned towards B is so blunt, that the electricity is not disposed to run into A faster than it is to run out of B, the air adjoining to B may be as much overcharged as that adjoining to A is undercharged; and therefore may, by the joint repulsion of B and attraction of A, be impelled from B to A, with as much or more force than the air adjoining to A is impelled in the contrary direction; so that what little current of air there is, may flow in the contrary direction.

It is easy to apply what has been here said to the case in which B is negatively electrified.

5. In the paper of Mr Canton's, quoted in the 5th section, and in a paper of Dr Franklin's (Phil. Trans. 1775, p. 800, and Franklin's Letters, p. 155) are some remarkable experiments, showing that when an overcharged body is brought near another body, some fluid is driven to the farther end of this body, and also some driven out of it, if it is not insulated. The experiments are all strictly conformable to the 9th, 10th, and 11th propositions; but it is needless to point out the agreement, as to the explanation given by the authors does it sufficiently.

6. On the Leyden Phial.—The shock produced by the Leyden phial seems owing only to the great quantity of redundant fluid collected on its positive side, and the great deficiency on its negative side; so that if any conductor was prepared of so great a size, as to be able to receive as much additional fluid by the same degree of electrification, as the positive side of a Leyden phial, and was positively electrified in the same degree as the phial, he does not doubt but what as great a shock would be produced by making a communication between this conductor and the ground, as between the two surfaces of the Leyden phial, supposing both communications to be made by canals of the same length and same kind.

It appears plainly from the experiments which have been made on this subject, that the electric fluid is not able to pass through the glass; but yet it seems as if it was able to penetrate, without much difficulty, to a certain small depth, perhaps he might say an imperceptible depth, within the glass; as Dr Franklin's analysis of the Leyden phial shows that its electricity is contained chiefly in the glass itself, and that the coating is not greatly over or under charged.

It is well known that glass is not the only substance which can be charged in the manner of the Leyden phial; but that the same effect may be produced by any other electric.

Hence* the phenomena of the phial seem easily explicable by means of the 20th proposition. For let CCLI. ACGM, Fig. 19, represent a flat plate of glass, or any other substance which will not suffer the electric fluid to pass through it, seen edgewise; and let BbDd, and EeFf, or Bd and Ef, as they may be called for shortness, be two plates of conducting matter of the same size, placed in contact with the glass opposite to each other; and let Bd be positively electrified; and let Ef communicate with the ground; and let the fluid be supposed either able to enter a little way into the glass, but not to pass through it, or unable to enter it at all; and if it is able to enter a little way into it, let b3d, or B3, as it may be called, represent that part of the glass into which the fluid can enter from the plate Bd, and cp that which the fluid from Ef can enter. By the above mentioned proposition, if bc, the thickness of the glass, is very small in respect of b, the diameter of the plates, the quantity of redundant fluid forced into the space Bd, or B3, that is, into the plate Bd, if the fluid is unable to penetrate at all into the glass, or into the plate Bd, and the space Bb3 together, if the fluid is able to penetrate into the glass, will be many times greater than what would be forced into it by the same degree of electrification, if it had been placed by itself; and the quantity of fluid driven out of Ef, will be nearly equal to the redundant fluid in Bb3.

*The following explanation is strictly applicable only to that sort of Leyden phial, which consists of a flat plate of glass or other matter. It is evident, however, that the result must be nearly of the same kind, though the glass is made into the shape of a bottle, as usual, or into any other form.
If a communication be now made between $B\beta$ and $E\phi$, by the canal $NRS$, the redundant fluid will pass from $B\beta$ to $E\phi$; and if in its way it passes through the body of any animal, it will, by the rapidity of its motion, produce in it that sensation called a shock.

It appears from the 2nd proposition, that if a body of any size were electrified in the same degree as the plate $B\beta$, and a communication was made between that body and the ground, by a canal of the same length, breadth, and thickness, as $NRS$; then the fluid in that canal would be impelled with the same force as that in $NRS$, supposing the fluid in both canals to be incompressible; and consequently, as the quantity of fluid to be moved, and the resistance to its motion, are the same in both canals, the fluid should move with the same rapidity in both; and there is no reason to think that the case will be different, if the communication is made by canals of real fluid.

Therefore what was said in the beginning of this Section, namely, that as great a shock would be produced by making a communication between the conductor and the ground, as between the two sides of the Leyden phial, by canals of the same length and same kind, seems a necessary consequence of this theory; as the quantity of fluid which passes through the canal is, by the supposition, the same in both; and there is the greatest reason to think, that the fluid with which it passes will be nearly, if not quite, the same in both.

It may be worth observing, that the longer the canal $NRS$ is, by which the communication is made, the less will be the rapidity with which the fluid moves along it; for the longer the canal is, the greater is the resistance to the motion of the fluid in it; whereas the force with which the whole quantity of fluid in it is impelled, is the same, whatever be the length of the canal. Accordingly, it is found in melting small wires, by directing a shock through them, that the longer the wire the greater charge it requires to melt it.

As the fluid in $B\beta$ is attracted with great force by the redundant matter in $E\phi$, it is plain that if the fluid is able to penetrate at all into the glass, great part of the redundant fluid will be lodged in $B\beta$; and in like manner there will be a great deficiency of fluid in $E\phi$. But in order to form some estimate of the proportion of the redundant fluid, which will be lodged in $B\beta$, let the communication between $E\phi$ and the ground be taken away, as well as that by which $Bd$ is electrified; and let so much fluid be taken from $B\beta$, as to make the redundant fluid in it equal to the deficient fluid in $E\phi$. If we suppose that all the redundant fluid is collected in $B\beta$, and all the deficient in $E\phi$, so as to leave $Bd$ and $E\phi$ saturated; then, if the electric reflexion is inversely as the square of the distance, a particle of fluid placed anywhere in the plane $bd$, except near the extremities $b$ and $d$, will be attracted with very near as much force by the redundant matter in $E\phi$, as it is repelled by the redundant fluid in $B\beta$. Hence it follows, that if the depth to which the fluid can penetrate, is very small in respect of the thickness of the glass, but yet is such that the quantity of fluid naturally contained in $B\beta$, or $E\phi$, is considerably more than the redundant fluid in $B\beta$; then almost all the redundant fluid will be collected in $B\beta$, leaving the plate $Bd$ not very much undercharged; and in like manner $E\phi$ will not be very much undercharged.

7. In the experiment of Wilke and Epinus, called electrifying a plate of air, (see page 528,) it does not appear whether the air contained between the two boards is very much overcharged on one side, and very much undercharged on the other, as is the case with the plate of glass in the Leyden phial; or whether the case is, that the redundant or deficient fluid is lodged only in the two boards, and that the air between them serves only to prevent the electricity from running from one board to the other; but whichever of these is the case, the experiment is equally conformable to the theory.

It must be observed, that a particle of fluid, placed between the two plates, is drawn towards the undercharged plate, with a force exceeding that with which it would be repelled from the overcharged plate, if it was electrified with the same force, the other plate being taken away, nearly in the ratio of twice the quantity of redundant fluid contained in the plate, to that which it would contain if electrified with the same force by itself; so that, unless the plate is very weakly electrified, or their distance very considerable, the fluid will fly from one to the other, in the form of sparks.

8. Whenever any conducting body, as $A$, communicating with the ground, is brought sufficiently near an overcharged body $B$, the electric fluid is apt to fly through the air from $B$ to $A$, in the form of a spark: the way by which this is brought about seems to be this. The fluid placed anywhere between the two bodies, is repelled from $B$ towards $A$ and consequently move slowly through the air from one to the other; now it seems as if this motion increased the elasticity of the air, and made it rarer; this will enable the fluid to flow in a swifter current, which will still further increase the elasticity of the air, till at last it is so much rarefied, as to form very little opposition to the motion of the electric fluid, on which it flies in an uninterrupted mass from one body to the other.

In the same manner may the electric fluid pass from one body to another, in the form of a spark, if the first body communicates with the ground, and the other is negatively electrified, or in any other case in which one body is strongly disposed to part with its electricity to the air, and the other to receive it.

In like manner, when the electric fluid is made to pass through water, in the form of a spark, as in Becaria's* and Lane's† experiments, the water, by the rapid motion of the electric fluid through it, is turned into an elastic fluid, and so much rarefied as to make very little opposition to its motion; and when stones are burst or thrown out from buildings struck by lightning, that effect is probably caused by the moisture in the stone, or some of the stone itself being turned into an elastic fluid.

It appears plainly, from the sudden rising of the water in Kinneries's electric air thermometer,‡ that when the electric fluid passes through the air in the form of a spark, the air in its passage is either very much rarefied, or entirely displaced; and the bursting of the glass vessels, in Becaria's and Lane's experiments, shows that the same thing happens with regard to the water, when the electric fluid passes through it in the form of a spark. Now there are no means by which the displacing of the air or water can be brought about, but by supposing its elasticity to be increased, by the motion of the electric fluid through it, unless we suppose it to be actually pushed aside, by the force with which the electric fluid endeavours to issue from the overcharged body; but he can by no means think, that the force with which the fluid endeavours to issue, in the ordinary cases in which electric sparks are pro-

---

† Phil. Trans. 1767, p. 451.
‡ Id. 1763, p. 84. Priestley, p. 216.
duced, is sufficient to overcome the pressure of the atmosphere, much less that it is sufficient to burst the glass vessels in Bectaria's and Lane's experiments. This is confirmed by Prop. 12. For, let an undercharged body be brought near to, and opposite to the end of a long cylin- drical body, communicating with the ground, the pressure of the electric fluid against the base of the cylinder is scarcely greater than the force with which the two bodies attract each other, provided that the part of the cylinder is undercharged; and consequently, if the spark was produced by the air being pushed aside, by the force with which the fluid endeavours to issue from the cylinder, no sparks should be produced, unless the electricity was so strong, that the force with which the bodies attracted each other was as great as the pressure of the atmosphere against the base of the cylinder; whereas it is well known, that a spark may be produced, when the force, with which the bodies attract, is very trifling in respect of that.

In discharging a Leyden phial, if the two knobs are brought together very slowly, a hissing noise will be perceived before the spark; which shows, that the fluid begins to flow from one knob to the other, before it passes in the form of a spark.

CHAP III.

On the Theory of two Fluids.

The theory of two fluids originated in the discovery made by M. Dufay of vitreous and resinous electricity; and was afterwards warmly supported by our countryman Mr Simmer, who thought that he discovered in the mechanical effects of the electric spark indubitable proofs of two opposite currents. For a long time, however, the question of one or two fluids scarcely occupied the attention of philosophers, who were more solicitous to discover new facts, than to connect together, by any general principles, the scattered phenomena of electricity.

In the theories of Epinon and Cavendish, the doctrine of a single fluid was adopted; but, in order to accommodate this hypothesis to the phenomena, they were obliged to assume, contrary to every physical analogy, that the particles of solid bodies repelled each other with the same force with which they attracted the particles of the electric fluid, or with which these particles mutually repelled each other. From this part of the hypothesis it will follow, that while all the particles of solid bodies are ended with a attractive force diminishing as the square of the distance increases; they are also ended with a repulsive force, following the same law, but infinitely greater in point of intensity, than the attractive force of gravity. This assumption we conceive to be most unphilosophical, as it ascribes to the particles of solid bodies, a new property almost the very reverse of that which they are known to possess; and whatever simplicity may appear in the doctrine of a single fluid, we consider it as merely nominal, and more than counterbalanced by the assumption which is necessary to its existence.

The doctrine of two fluids, which has never been adopted in this country since the time of Simmer, was supported by Coulomb, who has employed it in calculating the various phenomena which he observed.

In this hypothesis it is assumed, that there are two electric fluids, the vitreous and the resinous. The particles of the vitreous fluid repel one another with a force in the inverse ratio of the square of the distance, while they attract the particles of the resinous fluid with a force following the same law; and the particles of the

resinous fluid repel one another, while they attract those of the vitreous fluid according to the same law.

The fine experiments of Coulomb on the distribution of electricity over the surface of conductors, have afforded an excellent opportunity of comparing the theory with observation; and in so far as this has been done, the agreement is very surprising.

Coulomb has demonstrated, both by theory and experiment, that when electricity is communicated to any conducting body, it will be drawn from the interior of the body, and would diffuse itself indefinitely in space, if it were not arrested in its progress by the surrounding air, which, being a non-conductor, will oppose a resistance to its farther diffusion, and force it to distribute itself on the surface of the conducting body, in a thin envelope or coating, the thickness of which will vary in different parts with the form of the body. His demonstration, however, only applies to the case of a spherical body, in which the coating of fluid will be equally thick in every part of its surface.

This part of the theory has occupied the attention of the illustrious La Place, who has applied it to it, La Place, in a most elegant manner, the formula which he employed in determining the figure of the earth. He has shewn, by a method purely synthetical, that, in all ellipsoids of revolution, the electric fluid will distribute itself over their surface, and that the repulsive force of the fluid, or its tension at the pole of the ellipsoid, will be to that of the fluid at the equator, as the polar is to the equatorial axis.

These interesting results have been extended by M. of M. Biot to all spheroids differing but little from a sphere, whatever be the irregularity of their figure. This eminent mathematician has also examined analytically, the law which regulates the losses of fluid sustained by the two surfaces of a jar, or plate of coated glass, when discharged by successive contacts; and has shewn, that the losses of fluid form a geometrical progression. He has also found the same law to obtain in the discharge by successive contacts of a series of jars or plates in a state of mutual communication.

The analytical investigation of this subject has been carried to a very great length by M. Poisson of the Institute of France, a mathematician of the very first eminence, who had already distinguished himself by some improvements on the higher analysis, and by several fine discoveries on some of the most abstruse branches of physical astronomy. We expected, through the kindness of M. Poisson, to have had it in our power to present our readers with a very full account of his important researches; but we believe that the last memoir, which he has drawn up, have not yet been printed. We must therefore content ourselves with giving as copious an abstract as we can of his two recent memoirs on the distribution of electricity on the surface of conductors.

In order to determine in what manner electricity is distributed on the surface of a conducting body, M. Poisson has shewn, that the problem may be reduced to this, to find what ought to be the thickness of the coat of fluid on each point of the surface, in order that the action may be nothing in the interior of the electrified body. If the thickness of the coat of fluid is supposed to be very small, we shall have the distribution of electricity on the surface of a spheroid, differing very little from a perfect sphere. By the application of the formula for the attraction of spheroids, M. Poisson has calculated the attraction of the coating, for a point placed within or without the conductor; and he has found,
In determining the electrical densities of two unequal globes in contact, M. Poisson finds, that the ratio in which the electricity is divided between the two globes, is always less than that of the surfaces; so that, after separation, the mean thickness of the coat of fluid is always greatest on the smallest of the two globes. The ratio between these two thicknesses tends towards a constant limit, which is equal to the square of the ratio of the circumference to the diameter divided by six, which is very nearly as 5 to 3; that is, if a very small spherical conducting body is placed upon an electrified spherical conductor of considerable size, the electricity will be divided between the two bodies, in the ratio of about 5 times the surface of the small sphere to three times the surface of the great sphere.

The experiments of Coulomb, of which we have given a full account in page 452, enable us again to examine the theory by experiment. Coulomb found, that the ratio to which the electrical density constantly approached, was 2.0, which is the same as 6 to 3, while the theory gives the ratio of 1.67, or of 5 to 3. This difference is, at first sight, a little more than might not have been expected; but when we consider the difficulty of determining such a limit experimentally, we shall rather be surprised at the coincidence between the theory and experiment. It ought to be considered, too, that Coulomb always found the ratio below 2, or below 6 to 3; and the highest ratio which he appears, from his Table, to have found, is 1.65; which is almost exactly the same as that obtained by M. Poisson, and is, perhaps, not far from the limiting ratio.

M. Poisson proceeds to apply the analysis to a new case, where these two fluids occur at the same time on the surface of the same body. This takes place in the case of two spheres placed at a distance, which is great when compared to one of the two radii. If the smaller of the two spheres is not electrified directly, but merely from being within the atmosphere of the greater sphere, it will, of course, be possessed of an electricity opposite to that of the great sphere. This electricity accumulates towards the point that is least distant from the great sphere, while the electricity similar to that of the great sphere accumulates on the opposite point. The two opposite electivities on these two opposite points are almost equal; and the neutral line which separates them, almost coincides with the great circle which is perpendicular to the line joining the sectors of the globes, and divides the smaller globe into two equal parts. By means of very simple formulas, the electrical density, and the character of the electricity, may be determined for any part of the two surfaces. This result is confirmed by Coulomb's experiments, so far as they go. See Exp. 5. and 6. col. 2. p. 453.

In his second Memoir, M. Poisson has given the general integrals of the two equations of the problem, first under the form of a series, and then under a finite form, by means of definite integrals. By the nature of these equations, their integrals contain an arbitrary periodical function, which seems to indicate, that the problem is indeterminate, or that the distribution of the electric fluid, in a finite, may depend on these integrals, may take place in an infinite variety of ways. M. Poisson, however, has demonstrated, in a rigorous manner, that this function is foreign to the question, and that the term which contains it ought to be suppressed. After doing this, he obtains series which contain only determinate quantities, and which express the thickness of the coat of fluid, or what is the same thing, the electric density at any point on the two surfaces of the spheres. Except in the case where the two spheres are
very near to one another, these series are very convergent, and as they tend very rapidly to geometrical progressions, it is easy to obtain from them sufficiently accurate values. M. Poisson has calculated tables in the case of two spheres, whose radii are as one to three, and whose surfaces are separated by an interval equal to the smallest of the two radii. These tables contain the thickness of the coating of fluid to less than the 10,000th part, in nine different equidistant points upon each of the two spheres, viz. at the extreme points where the line joining the centres penetrates the surfaces of the spheres, and on other points of the great circles which pass through these extreme points. The simple inspection of these tables shews if the electricity increases or decreases upon one of the spheres, from the point nearest to the other sphere to the most remote point. They shew also whether the electricity is vitreous or resinous, and through what points passes the line of separation between the two fluids. On these different circumstances will depend the total quantities of electric fluid, whether vitreous or resinous, with which the two spheres are charged. We may make the electrical densities of the two spheres of any magnitude we wish, and make them either vitreous or resinous; and if we take one of these quantities equal to zero, we shall have the case where one of the two spheres is electrified solely by the influence of the other, and we shall obtain, at the same time, the reaction of this electrified sphere upon the sphere from which it derives its electricity. When the smallest of the two spheres is electrified by being placed within the atmosphere of the greater one, the latter presents a very remarkable circumstance. The electricity will diminish upon its surface from the point nearest the little sphere to a distance of 67° 30' from that point, and will then increase to the point 180° distant from the point of contact; so that the thickness of the coating of fluid, without changing its sign upon this surface, reaches its minimum about 67° 30'.

In making equal to one another the thicknesses of the coat of fluid which correspond to two different points upon the same sphere, and in determining by this equation the relation between the quantities of electricity with which the two spheres are charged, M. Poisson could produce at pleasure a similar minimum, which will fall somewhere between the two thicknesses which were made equal. By making equal to each other the two extreme thicknesses upon the small sphere, M. Poisson has given another example of this minimum. This particular case is remarkable, as the thickness of the coat is almost constant throughout the whole of the little sphere, and does not vary 1/7th above or below the mean thickness, so that it appears to have experienced no change from its proximity to the great sphere. In this case the electricity upon the surface of the great sphere, passes from positive to negative, and experiences considerable variations of intensity.

The memoirs of Coulomb do not furnish us with any experiments which could be compared with these results excepting experiments 3d and 4th, which we have given in p. 453, col. 2, and which agree with the results obtained by M. Poisson.

The series which represent the thicknesses of the coat of fluid cease to converge when the spheres are very near each other; and in order to apply the series in this case, it is necessary to give them another form, by expressing them in definite integrals. In this way, M. Poisson has transformed them into another series, which becomes more convergent as the distance between the two spheres diminishes. He has thus been able to explain what happens during the progressive approach of the two spheres before contact, and what happens when they are brought into contact, and then separated.

In the first case, the thickness of the coat of fluid at the nearest points upon the two surfaces, increases indefinitely, in proportion as the distance of the spheres diminishes. The same thing is true of the points at which the fluid exercises all the air intercepted between the two bodies; as this pressure is always proportional to the square of the thickness, it ought at last to overcome the resistance of the air, and the fluid in escaping, under the form of a spark, or otherwise, ought to pass, before contact takes place, from one surface to the other. The fluid thus accumulated before the spark, is of a different kind, and nearly equal in intensity upon both the spheres: If they are electrified, one vitreously and the other resinously, it is vitreous upon the first and resinous upon the second; but when they are similarly electrified, positively for example, the sphere, which contains less of the fluid than it ought to have at contact, becomes negative at the point where the spark is preparing itself, and, on the contrary, the sphere which contains more than it ought to have at contact, remains positive over all its surface.

When the two spheres are brought into contact, and then separated to a little distance, the ratio which exists between their total quantities of electricity, causes them to disappear, in the expression of the thickness, the term, which becomes infinitely great for an infinitely small distance. The electricity of the points nearest to each other upon the two surfaces, is then very weak for very small distances: it decreases with the distances, according to a law which M. Poisson has determined. Its intensity is nearly the same upon the two spheres; but when the spheres are unequal, this electricity is positive upon one, and negative upon the other; and it is always upon the smallest that it takes a sign contrary to that of the total electricity.

This result is quite conformable to the experiment of Coulomb formerly mentioned, (Exp. 4. p. 453, col. 2.); and M. Poisson considers it as furnishing an important confirmation of the theory of two fluids. When the two spheres are equal, the electricity during contact and after separation, distributes itself in the same manner upon both. Hence it is natural to think, that in this case the fluid is of the same kind over the whole of each surface, however small be the distance which separates the two spheres. This is in reality what is deduced from the formula, when the radii of the two spheres are supposed equal.

M. Poisson next considers what will take place, in the approach of the two spheres, at the most distant points upon their surfaces. The formula which expresses for very small distances the quantities of electricity relative to these points, shew that the thickness of the coat of fluid which corresponds to them, tends towards a constant limit, in proportion as the two spheres approach one another; and that this limit is the thickness which the coats would have had at the same points, at the instant of contact. These formulas also shew, that the quantity which they represent, converges very slowly to its limit, so that, for very small distances, the electricity of the most distant points upon the two surfaces, still differs much from what it will be in contact, or after the spark. Hence M. Poisson concludes, that the spark, when it takes place at a sensible distance, changes the distribution of the electric fluid over the whole extent of the two surfaces, and even to points diametrically opposite to those where it is produced. semitones, S, S, and $f$, (see Plate XXX, Vol. II.) and the octave is made up of $7S + 3S + 2S = V I L L I$. See the Philosophical Magazine, vol. xxxix. p. 414.

Concordant Elements, or elements of harmony, are the three smallest concords; the minor fourth, and major and minor third; 4th + 3rd + 2nd = V I I I. See Concord.

Diatonic of the septime, or system of seven notes; these are the tones major and minor, and the semitone major, T, t, and S in our notation; T, t, and H in Dr R. Smith’s; and G, L, and S in Mr Maxwell’s notation: here $3T + 2T + 2S = V I I I$. See Diatonic Elements.

Of Music, according to Chambers, are T, t, S, and $f$; yet these four elements seem incapable of being all combined together in one octave; but any three of them, except T, S, and $f$, may; and, in these cases,
ELEPHANT.

The Elephant has attracted the attention of mankind from the remotest ages, on account of his size, his strength, and his sagacity. He was considered by the ancients as a powerful engine of war, and is still regarded as a valuable part of the materiel of an eastern army, for the transportation of artillery and baggage, and he forms a necessary appendage to eastern magnificence. His form and manners have often been made the subject of description, and many curious particulars of his history have been detailed by enterprising travellers. Yet still we have cause to regret, that conjecture, in too many instances, has occupied the place of observation, so that qualities have been ascribed to the elephant which he does not possess, and habits to which he is a stranger; and that love of the marvellous has been gratified at the expense of truth, so that the gaudy description of Buffon must yield, in point of accuracy, to the simple narrative of Aristotle. In this article, we shall endeavour to lay before our readers the principal facts in the history of the animal, which appear deserving of notice; unfold the characters of the different species of which the genus Elephas is composed; and then describe the methods employed to obtain him from his native haunts, and to educate him for the service of man.

Sect. I. General Description.

The skin of the elephant is of a dusky black colour, with a few scattered hairs upon it, except on the crown of the head, where they are pretty thick, and are about the length of a hog's bristle. The skin is generally smooth and soft, and only becomes hard and callous, and sometimes knotty, from use or disease. The head is somewhat small in proportion to the size of the body. The forehead is remarkably prominent, and gives to the countenance an expression of dignity and intelligence. The eye is small, quick, and penetrating. The ears are large and pendulous; the back is considerably arched in the middle, and the tail is slender, with a tuft of long hair nearly reaching the ground; the legs are suited to the size of the animal, being thick, strong, and massive, and the foot which is not divided into toes, is furnished with five horny nails on the fore feet, and four on the hind feet.

Among individuals of the same species there appears to be a considerable difference in point of size, as they are known to vary from 7 to 12 feet in height. The dimensions of a full grown male elephant, as measured in India, were as follows:

- From foot to foot over the shoulders: 22. 10\(\frac{1}{4}\)
- From the top of the shoulder, perpendicular height: 10. 6
- From the top of the head, when set up as he ought to march in state: 12. 2
- From the front of the face to the insertion of the tail: 15. 1

The female elephant is always smaller than the male, and, in the Indian species, seldom exceeds eight feet in height. When either males or females are much below this size, they are not considered as of sufficient strength to sustain the requisite burdens. The standard of the Honourable the East India Company, for
The most remarkable organ which the elephant possesses, is its trunk or proboscis, formed by an elongation of the snout, and answering the purposes of a nose. It is sometimes eight feet in length, of a conical form, and composed of muscles entirely at the will of the animal; he can move or bend it, contract, lengthen, or twist it in any direction. The extremity of the trunk terminates in a small protuberance, which stretches out on the upper side, and possesses an astonishing degree of feeling and power. By means of this finger-like protuberance, he can seize, with the greatest facility, the smallest object, lift a piece of money from the ground, or untie the knots of ropes. By means of his snout and trunk, the elephant renders himself most serviceable to man. By his trunk he can raise a considerable weight, and by his snout he can move about pieces of ordnance, and roll away casks. In a wild state, this organ like any other serves the most important purposes. With it he gathers his food, and put it into his mouth, it draws up water to quench his thirst, or to sprinkle his body, and collects dust, which he throws over his skin to keep off the mosquitoes and flies that annoy him. On all occasions he is most careful of his trunk, and unless when tied and picketed he seldom uses it as a means of offence. The males use their tasks for this purpose, and the females endeavour, by falling upon the tiger, to crush him by their weight.

The elephant has no cutting teeth in either jaw in front; but he is furnished with most powerful grinders, that enable him to bruise the vegetables on which he feeds. These teeth, as in all herbivorous animals, have an uneven surface; but do not rise into points as in animals which feed on flesh. The structure of these grinders has excited much attention among anatomists, and led to many important conclusions, which it would be out of place here to enumerate. Each grinder is composed of a number of perpendicular laminae, which may be considered as so many teeth, each covered with a strong enamel, and joined to one another by a bony substance of the same quality as ivory. This last substance being much softer than the enamel, wears away faster by the mastication of the food, so that the enamel remains considerably higher, and, in this manner, the surface of each grinder acquires a ribbed appearance as if originally formed with ridges. From very accurate observations, which have been made on the Asiatic elephant, it appears, that the first set of grinders, or milk teeth, begin to cut the jaw eight or ten days after birth, and the grinders of the upper jaw appear before those of the lower one. These milk grinders are not shed, but are gradually worn away during the time the second set are coming forward, and as soon as the body of the grinder is nearly worn away, the fangs begin to be absorbed. From the end of the second to the beginning of the sixth year, the third set come gradually forward as the jaw lengthens, not only to fill up this additional space, but also to supply the place of the second set, which are, during the same period, gradually worn away, and have their fangs absorbed. From the beginning of the sixth to the end of the ninth year, the fourth set of grinders come forward, to supply the gradual waste of the third set. In this manner, to the end of life, the elephant obtains a set of new teeth as the old ones become unfit for the mastication of his food—a wise provision of nature, where the vast size of the carcass, to be maintained, must require increased exertions of the teeth in the preparation of food.

The milk grinders consist each of four teeth, or laminae; the second set of grinders of eight or nine laminae; the third set of 12 or 13; the fourth set of 15, and so on to the 7th or 8th set, when each grinder consists of 22 or 23; and it may be added that each succeeding grinder takes at least a year more than its predecessor to be completed.

The tusks of the elephant, which correspond with the canine teeth of other animals, are to him most powerful instruments of defence, as, by means of them, he can defend himself, or gore to death the objects of his rage. They are two in number, situated one on each side of the upper jaw. They vary in form and size, according to the age, the sex, or the variety of the individual. In the female the tusks are very small compared with those of the male. The tusks of the male elephant vary in form and appearance. Those called dauntelah, or elephants with large teeth, vary from the projecting horizontal, but rather elevated curve of the pulped or the perfect elephant, to the nearly straight tusks of the wooknah, which point directly downwards. Between these two there is a great variety in the form of the tusks. The largest teeth found in the male elephant are from 5 to 8 feet in length, and from 4 to 8 inches in diameter, and weigh from 20 to 80 lb. each tooth. The increase of the tusks arises from circular layers of ivory, which are supplied internally from the pulp on which they are formed. In some instances, balls have been found in the body of the tusk with which the animal has been shot when young, or, at least, the balls must have entered near the base of the tooth, as they are found imbedded in its hard substance. The temporary, or milk tusks, drop in twelve or sixteen months after birth, and are succeeded by the permanent tusks, which continue growing successively through life.

The elephant seems naturally of a social disposition, and is seldom to be met with alone. The herd, in general, consists of from ten to a hundred of young and old of both sexes. This herd is governed by an aged male and female, and seems to be completely under their direction.

These herds reside in the extensive forests, which they seldom leave, although the males sometimes make predatory excursions to the outskirts in search of more palatable food. Their haunts are seldom at a great distance from a spring of water, or from a river. They avoid the margins of muddy rivers with the greatest care, lest their unwieldy bodies should stick fast in the ooze; and over the large and deep rivers they swim with readiness, to the distance of one or two miles. Their bodies and even heads sink under the water; but, by means of their trunks, which they keep above the surface, they are able to respire, to direct their course, to avoid running foul of one another, and to know, by the smell, the approach of the opposite shore. In sultry weather they frequently spurt water over their bodies, by means of their trunks, and seem equally to avoid the extremes of heat and cold.

When we take into consideration the size of this animal, we need not be surprised at the quantity of food said to be required for his support. A full grown elephant is said to consume, each day, from 100 to 150 pounds weight of vegetables. In his wild state he feeds on grass, shrubs, the leaves and young branches of trees. When a herd of the animals approach the habitations of men, and enter the fields and vineyards in

Elephant.
search of rice, sugar canes, and plantain trees, de-
solation marks their steps. The portion which they
consume is small, when compared with the quantity
which they trample down and crush with their feet.
They appear to give a decided preference to sweet
fruits, and to plants which yield sugar.

The elephant, when young and healthy, lies down
to sleep in the same way as other herbivorous animals
do; but it is believed that, in an advanced period of
life, when the body becomes stiff, he usually takes
his repose in a standing posture, sometimes leaning
on a tree, or other support. When an elephant is first
taken, it is always considered as a good sign when he
lies down to sleep a few months after, as it shows
him to be of a good temper, not suspicious, but reconciled
to his fate; but some elephants have been known
to stand twelve months at their pickets, without lying
down to sleep, though occasionally they took a short
nap standing.

The cries of the elephant are of three kinds. By the
first, which is very shrill, and caused by his trunk, he
expresses his playful humour. The second is a low
note, produced by the mouth, and is expressive of want.
The third is heard when he is roaring, proceeding from the
throat, and indicates irritation or revenge.

It is impossible to ascertain the age to which ele-
phants arrive in a wild state. We may, however, form
some opinion of the term of their existence, by judging
from the circumstance, that, in a state of confinement,
they have been known to live a hundred and thirty
years; and we are probably within proper bounds,
when we fix the extent of the period at two hundred
years.

The sexual connection of the elephant has been the
subject of much discussion. As these animals rarely
copulate in a domestic state, several naturalists have at-
ttempted to account for the circumstance, by ascribing
to the elephant ideas of independence unknown even
to man, supposing them possessed of too much great-
ness of soul to propagate their species in bondage; and
beget a race of slaves; or of too much modesty to suf-
fer any human creature, or even any of their own kind,
to witness their union. But reasons have lately
been assigned why the males seldom show much in-
clination to have connection with the females in a do-

cestic state. When a male elephant is taken in the
prime of life, he is bold and ungovernable, and is not
easily tamed until he is much reduced in body; and
when thus brought low, it requires a considerable time,
the want of attention and experience, before he can
be brought into such high order as is necessary to in-
spire him with thoughts of the other sex. Further,
unless he is of a gentle disposition, and disposed to put
confidence in his keeper, and thus escape the influence
of fear and distrust, he will shew no inclination for
sexual intercourse. But this continent of the elephant,
in a domestic state, has been asserted without proof,
and in direct opposition to the testimony of the ancients.
The Romans collected elephants both from the east and
the south, to accompany their armies, and to add to the
parade of their courts; and they had an opportunity of
witnessing the fertility of these animals in a state of
confinement, as their historians have faithfully recorded.
Aelian says, "Cum Tiberi Caesaris nepos Germanicus,
gadiusque sexus elephanti Romae erat, e quibus aliis pleri-
que generati exitterunt: quorum artus interea dunt
committebatur, et confinabuntur, et membra infirma
conglutinabantur, peritus vir ad pertractandos corum
sensus animosimus mirabilis quodam disciplinae genere
eos erudiebat." Aelian (translation by Conrad Gesner)
de Animal. Nat. lib. ii. cap. 11. Columella more ex-
pressly affirms, "India perhibetur molibus ferum mi-
ribis, pari tum in hac terra (Italy) vastatibus bellus
proceri quis negat, cum interquies nostra natos ani-
madventarum elephantes" De Re Rustica, lib. iii. cap. 8.

These passages appear to have been overlooked by
succeeding observers, and every naturalist, in the ab-

cence of facts, was left to form his own opinion on the
subject. At last an experiment was instituted in India,
by Mr Corse, * whose opportunities were favourable,
and whose talents and habits of observation qualified him
for the task. This gentleman was then Resident at Tipperah,
a province of Bengal, situated at the eastern extremity
of the British dominions in Asia, where herds of ele-
phants are taken every season. He kept a young hard-
some male elephant, of a most docile disposition, and
a favourite female together, in a spacious shade erected
for purpose for their accommodation. In the day
they went out together to feed; they also brought home
a load of such succulent food as their drivers and attend-
ants could collect. After their return they stood to-
tgether, slept near each other, and every opportunity
was granted them to form a mutual attachment. In
the evening they had each ten or twelve pounds of rice
soaked in water, to which a little salt was added; and
from the middle of May until the latter end of June,
some warm stimulants, such as onions, garlic, turmeric,
and ginger, were added to their usual allowance of rice.
Long before this, however, a partiality had taken place,
as was evident from their mutual endearments, and ca-
ressing each other with their trunks, and this without
ceremony before a number of other elephants, as well as
their attendants. "Near the end of June 1793, (says Mr
Corse,) I was satisfied the male would not, even to re-
gain his freedom, quit the object of his regard; I there-
fore ordered the keepers to picket the female by one
of her forelegs only, in the house where they stood, but to
leave the male at full liberty. Fearful, however, of
hurting their supposed delicacy, and thinking the near-
ness and sight of the attendants might possibly give
derogation to their modesty, I desired them to remain
quiet in a little hut erected on the outside of the build-
ing appropriated to the elephants, where they could see
equally well as if nearer. On the evening of the 28th
of June 1793, the male was let loose from his pickets,
and soon after he covered the female, without any diffi-
culty, although before this she never could have re-
ceived the male, being taken when very young, about
five years and a half prior to this period. The male
was then led quietly to his stall; but early on the morn-
ing of the 29th he became so troublesome that the dri-
ers, as they said, in order to quiet him, but partly I
suspect to indulge their own curiosity, permitted him
to cover her a second time, which he readily did before
the usual attendants, as well as a number of other spec-
tators. After this the driver brought me a particular
account of the whole process. Though much pleased

* Now John Corse Scott, Esq. of Sinton, Selkirkshire, and Fellow of the Royal Society, whose excellent observations on the history of
the elephant, published in the Philosophical Transactions, have contributed a number of the most important facts in this article, and whose
subsequent observations in MS. have been kindly submitted to our inspection and use.
It would appear that in a wild state elephants have no particular seasons of love as other animals. The females taken in India, while in a state of pregnancy, produced their full grown young in different months of the year. The female is said to be disposed to receive the embraces of the male before she arrives at the age of fourteen.

Destined to feed on the vegetable productions of the earth, the elephant lives at peace with the other inhabitants of the forest. His gross size and strength renders him an object of terror; as with such power and such sagacity, neither the lion nor the tiger can contend with any prospect of success. Were he to exercise his vast powers in offensive operations, or were he prolific in proportion to his size, he would soon become the master of the wood. But man, even in his rudest state, appears destined to check his progress. Even when untutored by civilization, he kindles a fire, and the elephant retreats in terror; he poisons an arrow, and inflicts a wound which speedily ends in death; or he digs a pit, and the huge monster, unconscious of danger, is suddenly arrested.

The elephant is pursued for the sake of his flesh by the Hottentots of the Cape. When Sparman in his travels at the Cape baited at the Diep river, several Hottentots of the Boshiesman race, who were in the service of the farmer, had their huts, which were composed of straw, covered with large slips of elephant's flesh, cut out irregularly in strings of the thickness of two or three fingers breadth, and strung together to the length of several yards. Some of them were wound round the huts, while others were stretched from one hut to another, for the purpose of drying them. At that time, the men, women, and children in the place, had no other employment but to sleep, smoke, and gormandise upon elephant's flesh. The feet and the trunk are reckoned the most delicious pieces.

As the tusks of the elephant form the well-known article Ivory, a considerable temptation is held out to the huntsman to endeavour to kill these animals. Attempts of this sort appear to be attended with no small difficulty. From two farmers employed in a hunt of this kind, Sparman obtained the following interesting narrative. The evening on which they observed the wild elephant, they determined to pursue it on horseback, though they never before had seen one. Their horses, though equally unacustomed as their riders to the sight of this colossal-like animal, yet did not flinch in the least; nor indeed did the elephant appear to give himself any trouble about them till they came within sixty or seventy paces of him. At that moment, one of the party, agreeably to the usual manner of the Cape huntsmen, jumped from his horse, and fastening the bridle, fell upon one knee, and with his left hand sticking his ramrod into the ground, rested his gun upon it, took his aim, and fired at the elephant, which had then got about forty or fifty paces farther off; for in this country when they hunt the larger kinds of animals, they commonly choose to take the opportunity of firing at the distance of one hundred and fifty paces, both because they load their pieces in such a manner, that the ball, as they think, does most execution at that distance; and also they can in this way gain time to mount their horses again and ride off, before the wounded animal can make up to them to take his revenge. Our sportsman had scarcely got into the saddle, and turned round his horse's head, before he found that the elephant was at his heels. At that very instant, the animal set up a
shrikl piercing cry, which he imagined he felt pierce to the very narrow of his bones, and which occasioned his horse also, to make several hasty leaps, and then gallop off twice as fast as before. In the mean time, the sportsman had sufficient presence of mind to ride his horse up an ascent, well knowing that elephants, and such like heavy animals, are slow and unwieldy in going up a hill in proportion to their weight, and the contrary in descending a hill. He, by this means, not only more certainly distanced his antagonist, but his companion had the more time to advance on one side of the elephant, where he imagined he could most easily direct his shot at the heart and the larger arteries connected with the lungs of the animal. This shot did not, however, hit in any dangerous part, as the horse was rather unruly and pulled at the bridle, which the man had hanging over his right arm, at the instant that he had jumped off his horse and discharged his piece, in the same manner as the former. The elephant now turned upon this last antagonist, but was soon wearied of pursuing him, as the sportsman had an opportunity of riding away from him up a still steeper hill than his companion. The two hunters found that it would answer their purpose better to hold each other's horses, so that they should not get off, while each of the sportsmen fixed their pieces by turns. The elephant, even after the third ball, still threatened vengeance, but the fourth entirely cooled his courage; he did not move a foot, absolutely drop till he had received the eighth. None of the balls, of course, had taken effect in the directly vital parts.

In former times, when the elephant could be employed in battle, a sort of castle was erected on his back, from which missile weapons were thrown; and his sides were armed with sharp-edged instruments, to enable him to force his way through the opposing ranks. But since the invention of gunpowder, this animal has become useless in battle. The fire and the smoke terrify him. But he is still of great utility in transporting baggage of all sorts, and, as a beast of burden, exceeds all others in strength and intelligence. Were it not for the great quantity of food necessary to his subsistence, he would be found a very valuable addition to our western colonies, where land carriage is difficult and expensive.

With regard to the senses of the elephant, he clearly appears to possess, in great perfection, all the five generally enumerated. His eye is quick, and he sees at a considerable distance. His large ear, which he can move backwards and forwards at pleasure, give an additional acuteness to his organs of hearing. Although his skin seems hard, yet insects often annoy him; and the termination of his trunk possesses a delicacy of touch equal to that which belongs to the tips of the human fingers. The sense of smell is probably the most acute of all the other senses of the elephant. When hunting him, the sportsman must be careful to keep on the lee side, otherwise the elephant would soon discover his enemy, and make him suffer for his rashness. Thus Sparrman relates the adventure of one Dirk Marcus, who nearly suffered in the chase. "Once (says this adventurer) in my younger days, when from a hill covered with bushes near a wood, I was endeavouring to steal upon an elephant to the leeward of me, on a sudden, I heard from the lee side a frightful cry or noise; and although at that time I was one of the boldest elephant hunters in the whole country, I must confess that I was in a terrible quaking, insomuch that I believe the hairs on my head stood quite erect. At the same time, it appeared to me as though I had had several pails of water thrown over me; without my being able to stir from the spot, before I saw this huge creature so near me that the weight almost of laying hold of his trunk. At that instant, I fortunately had the presence of mind to take to my legs, and to my no small astonishment, found myself so swift, that I thought I hardly touched the ground. The beast, however, was in the mean time pretty close to my heels, but having at last got to the wood, and crept away from him under the trees, the elephant could not easily follow me. With respect to the place I was in at first, I am certain that the animal could not see me, and consequently that he first found me out by the scent."

In examining the intellectual qualities of the elephant, much caution is requisite in the admission of evidence, as there appears to be a strong desire to ascribe to this animal powers of mind, proportional to his physical strength. Thus he has been praised for uncommon modesty, in opposition to historical evidence, and without the testimony of a single fact. His lofty independence has been extolled, although he is, unquestionably, the most tameable and the most servile brute in the creation; and, in the Hindoo mythology, he is made the representative of the God of Wisdom. The vulgar are ever accustomed to attribute stupidity to animals which have long snouts, as cranes and woodcocks; but when some circumstances tend to elevate the facial line, without augmenting the capacity of the cranium, we fancy we see, in animals of that description, a peculiar air of intelligence. This last circumstance happens in the case of the elephant, where the frontal sinuses swell the cranium to such a degree, that they elevate the facial angle much beyond what the proportion of the brain would require. While the brain in man forms 4/5th part of his whole body, in the elephant it only forms 4/5th part.

It has been stated, that the sagacity of the elephant Memory, is so great, and his memory so retentive, that, when once he has received an injury, or been in bondage, and afterwards escapes, it is not possible, by any art, to entrap him. The following fact, to which Mr C. Scott was an eye witness, will shew how unfounded such speculations are, in which some pseudo-naturalists have indulged:

"In June 1787," (says Mr C. Scott), "Jattra Mugul, a male elephant taken the year before, was travelling in company with some other elephants, towards Chittigong, laden with a tent and some baggage, for our accommodation in the journey. Having come up on a tiger's track, which elephants discover readily by the smell, he took fright, and ran off to the woods, in spite of the efforts of his driver. On entering the wood, the driver saved himself by springing from the elephant and clinging to the branch of a tree, under which he was passing. When the elephant got rid of his driver, he soon contrived to shake off his load. As soon as he ran away; a trained female was dispatched after him, but could not get up in time to prevent his escape; she, however, brought back his driver, and the load he had thrown off, and we proceeded without any hope of ever seeing him again. Eighteen months after this, when a herd of elephants had been taken, and had remained several days in the inclosure, till they were enticed into the outlet, then tied and led out in the usual manner, one of the drivers, viewing a male elephant very attentively, declared he resembled the one which had run away. This excited the curiosity of every one to go and look at him; but when any per-
son came near, the animal struck at them with his trunk, and, in every respect, appeared as wild and outrageous as any of the other elephants. At length an old hunter, coming and examining him narrowly, declared he was the very elephant that had made his escape about eighteen months before. Confident of this, he boldly rode up to him, on a tame elephant, and ordered him to lie down, pulling by the ear at the same time. The animal seemed quite taken by surprise, and instantly obeyed the word of command, with such as much quickness as the ropes with which he was tied permitted; uttering, at the same time, a peculiar shrill squeak through his trunk, as he had formerly been known to do, by which he was immediately recognised by every person who had ever been acquainted with this peculiarity. Thus we see that this elephant, for the space of eight or ten days, during which he was in the enclosure, and even while he was lying in the outlet, appeared equally wild and fierce as the boldest elephant then taken, so that he was not even suspected of having been formerly taken, till he was conducted from the outlet. The moment, however, he was addressed in a commanding tone, the recollection of his former obedience seemed to rush upon him at once, and, without any difficulty, he permitted a driver to be seated on his neck, who, in a few days, made him as tractable as ever.

We shall conclude this account of the sagacity of the elephant, by quoting a few of those stories, which have been commonly related, as illustrative of the degree of intellect which he is supposed to possess, for the purpose of gratifying the general reader.

In India, elephants were once employed in launching of ships. One was directed to force a very large vessel into the water; the work proved superior to his strength; his master, with a sarcastic tone, bid the keeper take away this lazy beast, and bring another in his stead; the poor animal instantly increased his efforts, and, in doing so, fractured his scull on the spot.

In Delhi, an elephant passing along the streets, put his trunk into a tailor's shop, where several people were at work; one of them pricked the end of it with his needle. The beast passed on; but, in the next dirty puddle, filled his trunk with water, returned to the shop, and spurring every drop among the people who had offended him, spoiled their work.

An elephant, in Aden, which often passed through the bazar, or market, as he went by a certain herb woman, always received from her a mouthful of greens. At length he was seized with one of his periodic fits of rage, broke from his fetters, and, running through the market, put the crowd to flight; and among others this woman, who, in haste, forgot a little child she had brought with her. The animal, gratefully recollecting the spot where his benefactress was wont to sit, laid aside his fury, and taking up the infant gently in his trunk, placed it in safety on a stall before a neighbouring house.

Another in Dekan, not having received some arrack which had been promised by the Cornac, or governor, by way of revenge, killed him. The cornac's wife, who was an eye-witness to this, took her two children and flung them before the elephant, saying, "Now, you have destroyed their father, you may as well put an end to their lives and mine." He instantly stopped, relented, took the biggest of the children, placed him on his neck, adopted him for his cornac, and never afterwards would permit any body else to mount him.

A soldier at Pondicherry, who was accustomed, whenever he received his share of liquor, to carry a certain quantity of it to one of these animals, having one day drunk rather too freely, and, finding himself pursued by the guards who were going to take him to prison, took refuge under the elephant's body, and fell asleep. In vain did the guard try to force him from this asylum, as the elephant protected him with his trunk. The next morning, the soldier recovering from his drunken fit, shuddered with horror to find himself stretched under the belly of this huge animal. The elephant, which, without doubt, perceived the man's embarrassment, caressed him with his trunk, in order to inspire him with courage, and made him understand that he might now depart in safety.

A painter was desirous of drawing the elephant which was kept in the menagerie at Versailles, in an uncommon attitude, which was that of holding his trunk raised up in the air, with his mouth open. The painter's boy, in order to keep the animal in this posture, threw fruit into his mouth; but as he had frequently deceived him, and made an offer only of throwing him the fruit, he grew angry; and, as if he had known the painter's intention of drawing him was the cause of the affront that was offered him, instead of revenging himself on the lad, he turned his resentment on the master, and, taking up a quantity of water in his trunk, threw it on the paper on which the painter was drawing, and spoiled it.

Sect. II. Particular Description of the Species.

We come now to consider the situation of the elephant, in the system of nature, to examine the characters of the different species, and point out their physical distribution.

It is but recently that naturalists began to investigate the characters of the elephants of India and Africa, or to suppose that they constituted two distinct species. The ancients, who appear to have used in war animals from both countries, were aware, that the elephants of Africa were inferior both in size and courage to those of India. But the characters which constitute these distinct species, were never pointed out until Camper, from the form of the teeth, proved their title to rank as independent species. The observations of Camper have been still further elucidated by the investigations of Cuvier, who has, besides, added a third species to the genus.

By Linnaeus, the elephant is placed in the order Brute, in the class Mammalia, with the following generic character: "Dentes primores nulli utrinque, Laniatri superiores elongati, Proboscis longissimus, prehensilis, Corpus nudisculsum." By Cuvier the elephant is placed among the Pachydermata, or thick-skinned quadrupeds, in company with the sow, the river-horse, and the rhinoceros. Under this genus are now ranked the following species.

Scull rounded, processes of the enamel in the grinders
forming a series of lozenges touching each other in the
middle; ears large; toes four before and three behind.

The tusks of this species yield the best ivory, and are
the largest in point of size. The tusks of the female
differ but little in size from those of the male. The
ears are very large, and fall back and cover the shoulder.
The hide is of a deep brown colour. The ordinary
height is from eight to upwards of ten feet.
The native country of this species of elephant, is Africa. He inhabits the immense forests and dreary wastes of that extensive continent. In modern times few attempts have been made to bring this species into bondage, or to employ him for any useful purpose. Hence it is, that we know less of the manners of this species than of those of the following, which in the East has long been the slave of man.

Sp. 3. ELEPHAS Indicus. Asiatic elephant. Skull lengthened, forehead concave, enamel of the grinders disposed in the form of flattened ovals placed across the teeth; ears large; horny nails, five before and four behind.

La Menagerie du Museum National d'Histoire Naturelle, 1801, p. 1, tab. 1, 2.

The females of this species, and some varieties of the male, have small straight tusks. The ears are small, and often angular. The hide is grey speckled with brown, and sometimes white. The height from eight to twelve feet.

The elephants in Bengal are divided by the natives into two casts, which they term Koornareah or princely race, and the Merghee or hunting race. The Koornareah is a deep-bodied, strong, compact animal, with a large trunk (which is always esteemed a great beauty in an elephant,) legs short, but thick in proportion to the size of the animal. This variety is preferred, as it is of superior strength, can undergo greater fatigue, and carry heavier burdens than the following. An elephant of the Merghee race, when full grown, is generally taller than the former, but has not so compact a form, his legs are long, he travels fast, has a lighter body, and his trunk is both short and slender in proportion to his height. 'There appears no predilection in any of these elephants to have exclusive connection with his own particular cast, and hence the mixed breed is held in greater or less estimation, in proportion as it partakes of the qualities of the Koornareah or Merghee cast. In some elephants the tusks are large, as in the variety termed the Dauntelah, in which they generally project forwards, and curve upwards. In the variety termed the Mooknah, the tusks are very small and straight, and point almost directly downwards.

An elephant of this species is said to be perfect when his ears are large and rounded, not ragged or indented at the margin; his eyes of a dark hazle colour, free from specks; the roof of his mouth and his tongue without dark or black spots of any considerable size; his trunk large, and his tail long, with a tuft of hair reaching nearly to the ground. There must be five nails on each of his fore feet, and four on each of the hind ones, making eighteen in all; his head well set on, and carried rather high. The arch or curve of his back rising gradually from the shoulder to the middle, and thence descending to the insertion of the tail.

This species inhabits the continent of Asia, and is found on both sides of the Ganges, in China, and in the larger islands of the Indian Ocean. He has long been brought into a state of subjection to man. His manners are therefore very well known, and have been briefly detailed in the preceding general description.

Sp. 3. ELEPHAS Primigenius. Fossil Elephant or Mammoth. Skull lengthened, forehead concave, under jaw obtuse, grinders large, parallel processes of the enamel disposed in closely set ribbands, sockets of the tusks very long.

As many of our readers may be unequainted with this species, which it is highly probable no longer exists in a living state on the surface of the globe, we shall subjoin a few remarks illustrative of its history.

In various parts of Europe, from the shores of the frozen ocean to the Mediterranean Sea, bones and teeth of a large size have, at different times, been dug up. They have been found in alluvial strata of earth, gravel, or sand, generally in valleys, near the mouths of large rivers, and likewise in islands, as Iceland and Great Britain. These bones were at first considered as belonging to an extinct race of giants. But, in proportion, as the science of natural history was cultivated, such ridiculous fables disappeared, and these bones were considered as belonging to the elephant, at that time supposed to be the largest animal which had ever existed. This was an important step in the investigation of these fossil remains, and little else seemed wanting in their history but to account for the means by which they were brought to their present situation. Had they been found only in those countries, which had been conquered by the arms of the Macedonians, Carthaginians, or Romans, it might have been supposed that they had been brought by man to their present situation, since these nations carried along with them a powerful host of trained elephants. But the occurrence of these bones in Iceland, and at the mouths of the rivers of Siberia, clearly proved that these relics were not the remains of elephants slain in battle. The inhabitants of Russia invented a much more simple tale, to account for the occurrence of these fossil relics. They supposed them to belong to an animal, its manners resembling a mole, living under the surface of the earth, and unable to endure the light of day. To this subterraneous animal they gave the name of Mammoth.

Naturalists, finding these explanations merely acknowledgments of the difficulty, and still attaching to the idea of elephant a warm region, fancied that these fossil bones belonged to elephants formerly reared in Asia, and afterwards transported by some violent cause to their present situation. The Deluge was instantly resorted to, and the elephants browsing on the banks of the Ganges, were supposed to have been transported by the flood from their native haunts, and interred in the plains of Europe. But the high state of preservation of these bones, the situation of nearly entire skeletons in beds, formed at different though not remote intervals, and their general distribution over such extensive tracts, forbade the introduction of any torrent to bring them to their present position.

Had naturalists attended more to an examination of facts, the difficulty here complained of would soon have disappeared, and a rational explanation would have been obtained of so curious a phenomenon. It is to the labours of the illustrious Cuvier that we stand indebted for the first accurate observations on the subject. Some approaches to the truth had indeed been made by the labours of other anatomists, who had ascertained that the remains of the elephant found in a fossil state bear a closer resemblance to the bones of the Asiatic than to the bones of the African elephant. Hence some were disposed to believe, that these fossil bones had belonged to individuals of the Asiatic species. But Cuvier has now clearly proved, that the points of difference are so numerous, that the fossil elephant has a title to rank as a distinct species. In the fossil elephant, he ascertained that the teeth are larger in proportion than those belonging to the Asiatic species; that the processes of enamel on the surface of the grinders, are not only more numerous, but less festooned; that the tusks are larger, and more curved; and that the sockets of the tusks are much more produced.
This last circumstance must have influenced the form of the trunk, and given to its base a thickness and size widely different from those of the existing species. Its general height seems to have been little more than the Asiatic species sometimes attains, but its form must have been more rounded and thick.

Viewing all the circumstances in connection, it appears certain that the fossil bones belong to a species of elephant which formerly inhabited Europe in considerable numbers, but which has become extinct, in consequence of the revolutions which the earth has undergone. Nor has this extinction extended to the elephant alone: species of the genus Rhinoceros, Hippopotamus, and Tapir, besides many genera of fishes, shells, and corals, have shared the same fate. The crust of the earth appears to have been inhabited by very different races of beings, during the different periods of its formation and progress. Thus, during the period of the deposition of the flint rocks, the then existing animals appear to have been very different from those which we find in the subsequent formations of chalk and gypsum. And the organic remains which occur in the older alluvial strata, differ from the species which now exist, in form, habit, and geographical distribution.

It may surprise some, perhaps, to be told, that species of the elephant, rhinoceros, hippopotamus, and tapir, animals confined at present to the warmest regions, formerly ranged our forests, and lived on the continent of Europe. But why be deceived merely by the name? The European ox, and the Indian ass, our horse and the African zebra, are species of the same genus, yet they inhabit very different regions. It is not unreasonable therefore to conclude, that the elephants which formerly lived in Europe possessed a constitution and covering which fitted them to dwell on the shores of the Tanis, the Lina, the Rhine, and the Po.

It is fortunate that we are not left to conjecture on this subject. The rhinoceros found on the banks of the Lina, with its skin and part of its flesh preserved, had, according to the observation of Pallas, more hair on one of its feet than is to be found on the whole body of any of the existing species; thus indicating its aptitude to endure the cold of a northern climate. And the following curious discovery of a fossil elephant places beyond a doubt the fact, that it was adapted to live in high latitudes, and endure the rigours of a northern winter.

"In the year 1790, a Tungusian fisherman observed a strange shapeless mass projecting from an ice-bank near the mouth of a river in the north of Siberia, the nature of which he did not understand, and which was so high in the bank as to be beyond his reach. The next year, he observed the same object, which was then rather more disengaged from among the ice, but he was still unable to conceive what it was. Towards the end of the following summer, 1801, he could distinctly see that it was the frozen carcass of an enormous animal, the entire flank of which, and one of its tusks, had become disengaged from the ice. In consequence of the ice beginning to melt earlier, and to a greater degree than usual, in 1802, the fifth year of this discovery, the enormous carcass became entirely disengaged, and fell down from the ice-crag on a sand-bank forming part of the coast of the Arctic Ocean. In the month of March of that year, the Tungusian carried away the two tusks, which he sold for the value of 50 rubles; and at this time (says Cuvier, whose relation we quote) a drawing was made of the animal, of which I possess a copy. Two years afterwards, or in 1806, Mr Adams went to examine this animal, which still remained on the sand-bank where it had fallen from the ice; but its body was then greatly mutilated. The Tuckers of the neighbourhood had taken away considerable quantities of its flesh to feed their dogs; and the wild animals, particularly the white bears, had also feasted on the carcass: yet the skeleton remained quite entire, except that one of the fore legs was gone. The entire spine, the pelvis, one shoulder-blade, and three legs, were still held together by their ligaments and by some remains of the skin; and the other shoulder-blade was found at a short distance. The head remained covered by the dried skin, and the pupil of the eye was still distinguishable. The brain also remained within the skull, but a good deal shrunk and dried up, and one of the ears was in excellent preservation, still retaining a tuft of strong bristly hair. The upper lip was a good deal eaten away, and the under lip was entirely gone, so that the teeth were distinctly seen. The animal was a male, and had a long mane on its neck. The skin was extremely thick and heavy, and as much of it remained as required the exertions of ten men to carry away, which they did with considerable difficulty. More than thirty pounds weight of the hair and bristles of this animal were gathered from the wet sand-bank, having been trampled into the mud by the white bears while devouring the carcass. Some of the hair was presented to our Museum of Natural History, by M. Targe, censor in the Lyceum of Charlemagne. It consists of three distinct kinds. One of these is stiff black bristles, a foot or more in length; another is thinner bristles, or coarse flexible hair, of a reddish brown colour; and the third is a coarse reddish brown wool, which grew among the roots of the long hair. These afford an undeniable proof that this animal had belonged to a race of elephants inhabiting a cold region, with which we are now unacquainted, and by no means fitted to dwell in the torrid zone. It is also evident, that this enormous animal must have been frozen up by the ice at the moment of its death. Mr Adams, who bestowed the utmost care in collecting all the parts of the skeleton of this animal, proposes to publish an exact account of its osteology, which must be an exceedingly valuable present to the philosophical world. In the mean time, from the drawing (says Cuvier) which I have now before me, I have every reason to believe that the sockets of the teeth of this northern elephant have the same proportional lengths with those of other fossil elephants, of which the entire skulls have been found in other places."

The geographical distribution of this species, presents many curious and important facts. Its remains have been dug up in all the countries of Europe from the Mediterranean Sea to the Arctic Circle. In Asiatic Russia they occur in the greatest abundance. They have likewise been found in the European isles, as Iceland, and various parts of Great Britain and Ireland. Its bones have even been dug up in South and in North America, and in Hudson's Bay.

Sect. III. Method of Catching and Training the Wild Elephant.

The elephant has long been disturbed in his native haunts by the enterprising sportman. In Southern Africa, the ignorant Hottentot pursues him for the sake of his flesh, the equally ignorant boor prizes the ivory of his tusks, and the planter regards him as the enemy of his
fields and vineyards. Hence it is that various methods have been devised to gain possession of the unwieldy monster. The savage employs his poisoned arrow, and puts an end to the lingering torture by means of his lance. Where the use of gunpowder is known, the musket is usually made use of; but for this purpose the calibre must be of a considerable size, and, in order to inflict a mortal wound, the ball should strike him a little above the insertion of the trunk. But this kind of sport is attended with the greatest danger, as he is seldom brought dead to the ground, and when slightly wounded pursues with the greatest eagerness, and often with fatal certainty, the author of his pain. The most simple, and probably the most ancient method of catching the elephant, is one frequently employed by savage tribes. A round and deep hole is dug in the earth, near his ordinary haunts, which is carefully covered at the mouth with the branches of trees and grass, by which means the unwary animal is deceived, and falls headlong into the snare. But other methods are resorted to when the elephant is sought after as an animal capable of being trained and formed useful to man. In what manner the ancients recruited the vast hosts of elephants which were attached to their armies, we are at present ignorant. The practice followed at present in the different districts of Asia, and which has obtained for many generations, seems to be the result of an intimate knowledge of the habits of the animal, and appears to be both ingenious and effectual. We propose to lay before our readers a short account of this method, from the interesting paper of Mr. Corse Scott.

Previous to an elephant hunt, which is a work of great labour, a few of the more intelligent and active natives are sent into the forests, for the purpose of discovering the retreats of the animals. They endeavour to ascertain in what direction they range in the greatest numbers, and where they are accustomed to feed. When a herd is discovered, about 300 people are employed to surround it, who divide themselves into small parties, consisting generally of three men, each at the distance of twenty or thirty yards from each other, and form an irregular circle, in which the elephants are inclosed; each party lights a fire and clears a foot-path to the station that is next the herd, by which a regular communication is soon formed through the whole circumference from one to the other. By this path reinforcements can immediately be brought to any place where an alarm is given; and it is also necessary for the superintendents, who are always going round to see that the people are alert upon their posts. The first circle being thus formed, the remaining part of the day and night is spent in keeping watch by turns, or in cooking for themselves and companions. Early next morning, one man is detached from each station, to form another circle in that direction, where they wish the elephants to advance. When it is finished, the people, stationed nearest to the new circle, put out their fires, and file off to the right and left, to form the advanced party; thus leaving an opening for the herd to advance through, and, by this movement, both the old and new circle are joined, and form an oblong. The people from behind now begin shouting and making a noise with their rattles, drums, &c. to cause the elephants to advance; and as soon as they are got within the new circle, the people close up, take their proper stations, and pass the remaining part of the day and night as before. In the morning the same process is repeated, and in this manner the herd advances slowly in that direction, where they find themselves least incommode by the noise and clamour of the hunters, feeding, as they go along, upon branches of trees, &c. If they suspected any snare, they could easily break through the circle; but this inoffensive animal, going merely in quest of food, and not seeing any of the people who surround him, and who are concealed by the thick jungle, advances without suspicion, and appears only to avoid being pestered by their noise. As fire is the thing elephants seem most afraid of in their wild state, and will seldom venture near it, the hunters always have a number of fires lighted, and particularly at night, to prevent the elephants coming too near, as well as to cook their victuals and keep them warm. The sentinels supply these fires with fuel, especially green bamboos, which are generally at hand, and which, by the crackling and loud report they make, together with the noise of the watchmen, deter the elephants from coming near; so that the herd generally remains at a distance near the centre of the circle. Should they at any time advance, the alarm is given, and all the people immediately make a noise and use their rattles to make them keep at a greater distance. In this manner they are gradually brought to the Kedah, or place where they are to be secured. The Kedah is differently constructed in different places. At Tippera it usually consists of three enclosures, communicating with each other by means of narrow openings or gateways. The outer enclosure, or the one next to the place where the elephants are to enter, is the largest; the middle one is generally, though not always, the next in size, and the third or furthest is the smallest; and when in the third or last enclosure, the elephants are then only deemed secure; here they are kept six or eight days, and are regularly, though scantily, fed from a scaffold on the outside, close to the entrance of an outlet, which is about sixty feet long and very narrow, and through which the elephants are to be taken out by one. In many places this mode is not adopted; for, as soon as the herd has been surrounded by a strong palisade, Kaewnees are sent in with proper people, who tie them on the spot in the same manner as is done with the Goondahs, or male elephants that are taken singly. These enclosures are all pretty strong, but the third is the strongest, and has, like the other two, a pretty deep ditch on the inside; and, upon the bank of earth, that is thrown up from the excavation, a row of strong palisades of middle sized trees is planted, strengthened with cross bars, which are tied to them about the distance of fourteen inches from each other, and these are supported on the outside by strong posts like buttresses, having one end sunk in the earth, and the other pressing against the cross bars to which they are fastened. The greatest difficulty is to get the herd to enter the enclosure; for, notwithstanding the precautions taken to disguise the entry, as well as the palisade which surrounds this inclosure, the leader now appears to suspect some snare, from the difficulty and hesitation with which in general she passes into it; but, as soon as she enters, the whole herd implicitly follows. Immediately, when they are all passed the gateway, fires are lighted round the greatest part of the inclosure, and particularly at the entries, to prevent the elephants from returning. The hunters from without then make a terrible noise, by shouting, beating of drums, firing blunt cartridges, &c. to urge the herd on to the next inclosure. The elephants, finding themselves ensnared, scream and make a noise, but seeing no opening ex-
Elephant.

The Kadah or snare.

Except the entrance to the next inclosure, and which they at first generally avoid, they return to the place through which they lately passed, thinking, perhaps, to escape, but now find it strongly barriaded, and, as there is no ditch at this place, the hunters, to prevent their coming near and forcing their way, keep a line of fire constantly burning all along where the ditch is interrupted, and supply it with fuel from the top of the palisade, and the people from without make a noise, shouting and halloing to drive them away. Wherever they turn, they find themselves opposed by burning fires, or bunches of reeds and dried grass, which are thrust through the opening of the palisades, except towards the entrance of the second inclosure. After traversing the first enclosure, and finding no chance of escaping but through the gateway into the next inclosure, the leader enters, and the rest follow; the gate is instantly shut, by people who are stationed on a small scaffold immediately above it, and strongly barriaded, fires are lighted, and the same discordant din made and continued, till the herd has passed through another gateway into the last inclosure, the gate of which is secured in the same manner as the former was. The elephants being now completely surrounded on all sides, and perceiving no outlet through which they can escape, appear desperate, and in their fury advance frequently to the ditch, in order to break down the palisade, inflating their trunks, screaming louder and shriller than any trumpet, sometimes grumbling like the hollow murmur of distant thunder, but wherever they make an attack, they are opposed by lighted fires, and by the noise and triumphant shouts of the hunters. As they must remain some time in this inclosure, care is always taken to have part of the ditch filled with water, which is supplied by a small stream, either natural, or conducted through an artificial channel from some neighbouring reservoir. The elephants have recourse to this water to quench their thirst after their fatigues, by sucking the water into their trunks, and then squirting it over every part of their bodies. While they remain in this inclosure they continue sulky, and seem to meditate their escape; but the hunters build huts around them close to the palisade, watchmen are placed, and every precaution used to prevent their breaking through.

When the herd has continued a few days in the Kadah, the door of the outlet is opened, into which some one of the elephants is enticed to enter, by having food thrown first before, and then gradually further on into the passage, till the elephant has advanced far enough to admit of the gates being shut. Above this wicker gate, two men are stationed on a small scaffold, who throw down the food. When the elephant has passed beyond the door, they give the signal to a man, who, from without, shuts it by pulling a string, and they secure it by throwing two bars that stood perpendicular on each side, the one across the other thus X, and then two similar bars are thrown across each other, behind the door next to the Kadah, so that the door is in the centre. For farther security, horizontal bars are pushed across the outlet, through the openings of the palisades, both before and behind those crosses, to prevent the possibility of the doors being broken. The outlet is so narrow that a large elephant cannot turn in it, but as soon as he hears the noise that is made in shutting the gate, he retreats back wards, and endeavours to force it; being now secured in the manner already noticed, his efforts are availing. Finding his retreat thus cut off, he advances and exerts his utmost force to break down the bars, which were previously put across a little farther on in the outlet, by running against them, screaming and roaring and battering them like a ram by repeated blows of his head, retreating and advancing with the utmost fury. After he has fatigued himself in this confinement, strong ropes with running nooses are laid down, and as soon as he puts a foot within the noose it is immediately drawn tight, and fastened to the palisades. When all his feet have been made fast, two men place themselves behind some bars that run across the passage to prevent his kicking them, and with great caution to his hind legs together, by passing a cord alternately from the one to the other like the figure 8, and then fastening these turns in the middle. A strong rope is now put twice round his body close to his fore legs like a girth, and tied behind his shoulders, then the long end is carried back close to his rump, and there fastened, after a couple of turns more have been made round his body. Another cord is next fastened to the girth, and from whence carried under his tail like a crupper, and brought forward and fastened by a turn or two to each of the girths, by which the whole is connected, and each turn of these cords serves to keep the rest in their places. After this a strong rope is put round his buttocks, and made fast on each side to the girth and crupper, so as to confine the motion of his thighs, and prevent his taking a full step. These smaller ropes being properly adjusted, a couple of large cables with running nooses are put round his neck, and, after being drawn moderately tight, and the nooses secured from running closer, they are tied to the ropes on each side. This operation is represented in Plate CCL. Fig. 5, from an original drawing, communicated by Mr. Corse Scott. While these operations are going on, the other hunters stand before the gate of the passage, tickling his trunk, and diverting his attention with a pike or a bunch of cocoa-nut leaves, plantain leaves, or sugar canes, so that the cords are, in general, made fast without difficulty or opposition. Sometimes, however, he seizes the ropes with his trunk, and endeavours to break them, particularly those with which his feet are tied, or tries to bite them through with his grinders; but the hunters then goad him with sharpened bamboo, or light spears, so as to make him quit his hold. Those who are employed in putting the ropes round his body and over his head, stand above him on a small kind of platform, consisting of a few bars run across through the openings of the palisades, and as an elephant cannot see any thing that is above, and rather behind his head, they are very little incommode by him, although he appears to smell them, and endeavours to catch them with his trunk. When the whole of the apparatus is properly secured, the ends of the two cables, which were fastened round his neck, are brought forward to the outer end of the outlet, where two tamed elephants trained to the business are waiting, and to them these cables are made fast. When every thing is ready, the door at the end of the passage is opened, and the ropes that tied his legs to the palisades are loosened. When an elephant is not very formidable or unruly, it is sufficient to place him lengthwise between two large trees about forty feet distant from each other, there to bind his hind legs in contact together, and fasten them close to one of the trees with five or six turns of thick rope; likewise to bind one fore leg, to which greater liberty is given by the length and slackness of the cordage. The pair of tame elephants are then disengaged from the wild one, and conducted back to the toil to take charge of another captive. This is a most trying moment to the wild elephant. While guided by the tuition, and soothed by the society of his subjugated
brethren, he stands tranquil and quiet, appearing to forget his sorrows, and to gather fortitude under his sufferings; but the instant that his companionsMarch away, finding himself closely bound, a solitary and helpless prisoner, he is agitated with all the horrors of despair, breaks out into a roaring which makes all the forest tremble, and, in the fury of his extravagant grief, often falls a sacrifice to the exertions which he makes to regain liberty. At this moment, coconuts and plantain trees are brought to him for food. In the agony of distress, he tosses them contemptuously away, or tramples them with indignation under his feet. The cravings of hunger, however, at length induce him to eat, which he does at first with evident reluctance, but becomes gradually more resigned, and feeds plentifully at the end of a few hours.

In this manner whole herds of elephants are taken captive; but sometimes a small party of hunters endeavours to seize the males, which often sally forth from the forests alone in search of richer provision. In this object the hunters are frequently successful, by observing the following plan, which is very perspicuously related by Mr. C. Scott. As the hunters know the places where the elephants come out to feed, they advance towards them in the evening with four trained elephants. When the nights are dark, these stragglers are discovered by the noise they make in cleaning their food, by whisking and striking it against their fore legs, and by moonlight they can see them distinctly at some distance.

As soon as they have determined upon the particular elephant they mean to secure, three of the trained females are conducted silently and slowly by their drivers, at a moderate distance from each other, near to the place where he is feeding. These advance very cautiously, feeding as they go along, and appear like wild elephants that had strayed from the forest. When the male perceives them approaching, if he takes the alarm, and is viciously inclined, he beats the ground with his trunk, and makes a noise, showing evident marks of his displeasure, and that he will not allow them to approach near; and if they persist, he will immediately attack and gore them with his tusks; for which reason they take care to retreat in good time. But should he be amicably disposed, which is generally the case, he allows the females to approach, and sometimes even advances to meet them.

When from these appearances the hunters judge that he will become their prize, they conduct two of the females, one on each side, close to him, and make them advance backwards, and press gently with their posteriors against his neck and shoulders. The third female then comes up, and places herself directly across his tail. In this situation, so far from suspecting any design against his liberty, he begins to toy with the females, and caresses them with his trunk. When thus engaged, the fourth female is brought near with ropes and proper assistants, who immediately get under the belly of the third female, and put a slight cord round his hind legs. Should he move at this time it is easily broken, and if he takes no notice of this slight confinement, nor appears suspicious of what is going forward, the hunters then proceed to tie his legs with a strong cord, which is passed alternately, by means of a forked stick, and a kind of hook, from the one leg to the other, as we have before described. A strong cable, with a running noose sixty cubits long, is next put round each hind leg immediately above the cords. These cables are secured in their places by other cords tied round the legs above them. The putting on these ropes generally takes up about twenty minutes, during which the utmost silence is observed; and the hunters, who keep flat upon the necks of the females, are covered with dark coloured cloths, which serve to keep them warm, and at the same time do not attract the notice of the elephant. While the people are thus busily employed in tying his legs, he caresses sometimes one and sometimes another of the seducers, examining their hands with his trunk, and caressing with different parts, by which his desires are excited, and his attention diverted from the hunters, and in these amorous dalliances he is intrigued by the females. He is now generally so firmly secured by the pressure of the tamed elephants on each side, and by the one behind, that he can hardly turn himself, or see any of the people, who always keep snug under the belly of the third female that stands behind, and serves both to keep him steady, and to prevent his kicking any of the people who are employed in securing him; but in general he is so much taken up with his decays, as to attend very little to any thing else. In case of accidents, however, should he break loose, the people upon the first alarm can always mount on the back of the tamed elephants, by means of a rope that hangs ready for the purpose, and thus get out of his reach.

When his hind legs are properly secured, they leave him to himself, and retire to a small distance; but as soon as the females go away he attempts to follow them, but finding his legs tied, he is obliged to a protracted silence, and retreat towards the forest. The hunters now follow at a moderate distance on the females, accompanied by a number of people who had been previously sent for, and who, as soon as the wild elephant passes near a stout tree, make a few turns of the long cables that are trailing behind him around its trunk. His progress being thus stopt he becomes furious, and exerts his utmost force to disengage himself; nor will he then allow any of the females to come near him, but is outrageous for some time, falling down, and gorin the earth with his tusks. If by these exertions the cables are once broken, which sometimes is effectual, and he escapes into the forest, the hunters dare not advance for fear of the other wild elephants, and are therefore obliged to leave him to his fate; and, in this hampered situation, it is said he is even ungenerously attacked by the other wild elephants. As the cables are very strong, and seldom give way, such accidents rarely occur. When he has exhausted himself by his exertions, the trained elephants are again brought near, and take their former positions. After getting him nearer the tree, the people carry the ends of the long cables round his legs, then back and about the trunk of the tree, making if they can two or three turns, so as to prevent even the possibility of his escape. For still further security, as well as to confine him from moving to either side, his fore legs are tied exactly in the same manner as the hind legs were. He is now harnessed with all the expedition possible in the same manner as those already described, and conducted to his proper station.

As soon as each elephant is thus secured, he is left in charge to a keeper, who is appointed to attend and instruct him, and four or five inferior servants, in order to assist and supply food and water, till he becomes so tractable as to bring the former himself. The first object of the keeper is to gain his confidence, and, for this purpose, he constantly supplies him with food, and soothes and caresses him by a variety of little arts. Sometimes, however, the keeper threatens, and even goads him with a long stick pointed with iron, but more
generally coaxes and flatters him, scratching his head and trunk with a long bamboo, split at one end into many pieces, and driving away the flies from any sores occasioned by the hurts and bruises he got by his efforts to escape. The keeper likewise keeps him cool, by squirting water over his body. In a few days he advances cautiously to his side, and strokes and pats him with his hand, speaking to him all the while in a soothing tone of voice, and in a little time he begins to know his keeper, and to obey his commands. By degrees the keeper becomes familiar to him, and at length gets upon his back from one of the tame elephants, and, as the animal becomes more tractable, he advances gradually forward, till at last, he is permitted to seat himself on his neck, from which place he afterwards regulates all his motions. The iron hook with which they direct him is pretty heavy, about sixteen inches long, with a straight spoke advancing a little beyond the curve of the hook. When they wish to turn them, they catch one of their ears with this instrument, and, by pressing it into their skin, make them move in any direction that is required.

While they are training in this manner, the tame elephants lead out the others in turn for the sake of exercise, and likewise to ease their legs from the cords with which they are tied, and which are apt to galls them severely, unless they are regularly slackened and shifted. In the course of five or six weeks, the elephant becomes obedient to his keeper, his fetters are taken off by degrees, and generally in about five or six months he suffers himself to be conducted by his keeper from one place to another. Care, however, is always taken not to let him approach his former haunts, lest a recollection of his freedom once more enjoyed should induce him again to recover his liberty. This obedience to his conductor seems to proceed partly from a sense of gratitude, as it is in some measure voluntary; for, whenever an elephant takes fright, or is determined to run away, all the exertions of the keeper cannot prevent him, even by beating or digging the pointed iron hook into his head with which he directs him. On such an occasion, the animal totally disregards the feeble efforts, otherwise he could shake or pull him off with his trunk, and dash him to pieces. Accidents of this kind happen almost every year, especially to those keepers who attend the large males, and are in general owing to their own carelessness and neglect. It is necessary to treat the males with much greater severity than the females, to keep them in awe; but it is too common a practice among the keepers, either to be negligent in using proper means to render their elephants tractable, or to trust too much to their good nature, because they are thoroughly acquainted with their dispositions.

For further information concerning the history of the elephant, we refer our readers to the following works: Cuvier's papers Sur les Elephants vivans et fossiles, in the Annuels du Musum d'Histoire Naturelle, vol. viii. and to his work on the fossil bones of quadrupeds; La Menagerie du Musum National d'Histoire Naturelle, 1801; Corse Scott's Observations on different Species of the Asiatic Elephants, in the Philosophical Transactions for 1799, Part ii. and to An Account of the Method of catching wild Elephants, by the same gentleman, in the third volume of Extracts from the Asiatic Researches; Cordier's History of Ceylon; the Travels of Sparrman, Vaillant, and Barrow. (1. v.)

ELEPHANTA, a small mountain isle, with a double top, wooded to the summit. It is situated about 5½ miles in an easterly direction from Bombay, and is not more than 3 miles in circumference. Its proper name is Gali Pour; but Europeans call it Elephanta, from the figure of an elephant, as large as life, conspicuous in black stone near the shore, and apparently cut from the rock on which it stands. A neat village near the landing place contains all the inhabitants of the island. They are under British protection, and pay L. 56 annually to the Bombay government.

But the spot is only deserving of notice, from its exhibiting, with the exception of the caves of Ellora, perhaps unrivalled monuments of labour and superstitious zeal. The cave of Elephanta, as it is commonly called, has furnished ample materials for the curiosity and research of the student of eastern antiquities. The mythological symbols and sculpture have been traced to be of Hindoo origin and execution; but their date is lost in fable and obscurity. Whatever mixture of Egyptian or Ethiopian extraction may have been engraven on the stock of Hindoo mythology, undoubtedly the Brahmins can claim a large portion of their system of theology to be of no foreign offshoot, but the result of their own subtility and invention. How vain must it be, at a remote period of time, to attempt to account for the origin and variety of the symbols of worship of a nation sunk in idolatry, since the dreams of enthusiasm, the fictions of poetry, the caprice of princes, the craft of priests, and the boundless powers of human imagination, all conspire to raise and embellish the shrines of superstition, and to propagate delusion and absurdity! We shall give our readers such account of the monuments at Elephanta, as are drawn from the most authentic sources, and relations of travellers who have repaired to the spot.

The cave, about three quarters of a mile from the beach, is approached by an ascent through romantic passes of the mountain, and bursts unexpectedly upon the eye. A spacious excavation in the solid rock of 135 feet in length, by an equal breadth, presents a magnificent spectacle of elaborate sculpture and mythological embellishment. The roof is supported by pillars of the rock left standing; their order is uncommon, but effect agreeable. The reader is referred to the article of CLI. VII. ARCHITECTURE in this work, for a Plate illustrative of part of the interior of the cave. The figures which decorate the walls are in relief so prominent, that they are attached to the rock only by the back. Gigantic forms are observed, some with aspects of benignity, others with looks of terror. Neither in design or execution can the sculpture be compared to the monuments of Grecian art; but it much surpasses in elegance, the Egyptian models, and the bas reliefs from the ruins of Persepolis. The upper extremity of the cave is chiefly distinguished by the profusion of figures. Here the most striking is a bust 13 feet high, of a figure with three heads, expressive of that being of whom the Hindoos had the most sublime conceptions. The middle head represents Brahma, or the creative attribute; the head on the left, Vishnou, or the preserver; and on the right, Seva the destroying, or changing. Brahma's face is represented full, with a look of dignity and composure; his head and neck profusely covered with ornaments. The face of Vishnou is in profile, with, likewise, a complacent regard, and a richly decorated head. One hand bears a lotus flower, the other a fruit resembling a pomegranate; on one of his wrists is seen a ring, as worn by the Hindoos at present. Seva, on the contrary, frowns with a terrific countenance in profile, with projecting forehead, and glaring eyes. Snakes supply the place of hair; and
the representation of a human skull is conspicuous on the covering of the head. One hand grasps a monstrous Cobra di Capella, the other a smaller one; the whole calculated to strike terror and admiration; the length, from the crown of the head to the chin, is 6 feet exclusive of the cap, which is 3 feet more.

The bust, or trimurti as it is called, is entire with the exception of Brahma's two hands, which are quite destroyed. On each side of the bust is seen a gigantic figure leaning on a dwarf, all much defaced. On the right is a large square compartment, loaded with a variety of figures; the largest of which, 16 feet high, is the consort of Seva, represented with one breast. The figure has four arms, the foremost right hand leaning on the bull Nandi, the other grasps a Cobra di Capella, while the inner left hand bears a circular shield. The head is richly decorated. A male, bearing an instrument resembling a trident, appears on the right hand; on the left a female holding a mace or sceptre. Brahna is seen with four heads, sitting on a lotus, while, as it is supposed, Indra and Indrane are represented on an elephant near him. Here Vishnoo with four arms, appears mounted on the shoulders of Garuda. Above this assemblage are seen small figures, in different attitudes, supported by clouds. Corresponding with this niche, is another on the left of the bust. Here two figures are conspicuous, the one a male 14 feet high, said to represent Seva; the other a female 10 feet, who is Parvati his wife. The circular rings, worn by the Hindoo women at present, are seen on the legs and wrists of the female; the mode of braiding the hair the same; and the countenance expressive of gentleness. Vishnoo and Garuda are here portrayed as on the other niche, while the heads of most of the attendant small figures have a whimsical appearance of covering, exactly resembling our wigs. Niebuhr, one of the most intelligent travellers who have visited Elephants, not possessed of that knowledge of Eastern antiquities, requisite to illustrate and explain the sculptures, from his own observation, has drawn conclusions, rather fanciful than just. Of the figure, represented with one breast, he remarks, that it thence appears, that the story of the Amazons was not unknown to the Indians; but this, beyond Niebuhr, we have no reason to support the case. It has been more reasonably deduced, by those acquainted with Indian mythology, that it is intended in this figure, considered as male and female, to represent the active power of Seva, as Bawani or Courage, and as Isani or the goddess of nature. The above ingenious person appears to us not more happy in his conclusion of wigs being of Indian invention. This peculiarity of feature in the symbols, we conceive to be of foreign extraction, and that the sculptor, in merely designing to represent curly and bushy hair, has given them the grotesque appearance of a wig. But these conjectures cannot detract from Niebuhr's general merit as a traveller, who must be regarded as a person of singular intelligence and erudition. But we shall pursue our description of the remaining most remarkable figures.

On each side of the above described groups, is a dark room, or recess, formerly inaccessible to all, perhaps, but the Brahmins; but now in undisputed possession of bats, serpents, and snakes, instigated by clouds. On the left is another group, of which the most remarkable figure is a male, leading a female towards a majestic person seated in the corner of the niche, his head covered like our judges on the bench. The countenance and attitude of the female are expressive of timidity and reluctance. A male urges her forward. Here several small figures are introduced. All the females have ornaments similar to those worn by the Hindoo women at present, round the wrists and legs; the male's ornaments, bearing the same correspondence, round the wrists alone. This resemblance, however, assists us but little in ascertaining the date of the sculptures; the same customs and dress have been in immemorial use among the natives of India, as at this day.

The attention is forcibly arrested by a figure on a niche of equal dimensions with the last, opposite to it, and 50 feet nearer the entrance of the cave. It is a gigantic half length of Seva, or the destroyer, in action, represented with eight arms, and a belt of human skulls around his neck. A right hand grasps a sword uplifted to sever a victim. A Cobra di Capella rises under one arm; a human skull is conspicuous on the head. Small attendant figures are portrayed in distress and pain. Many of the figures are mutilated, as is the principal, whose aspect indicates unrelenting fierceness.

On the other side of the cave, near one of the small rooms above mentioned, are seen Seva and his consort, represented sitting in the manner of the country at this day. A bull reclines at the feet of Seva; in each corner of the niche stands a gigantic guard. On each side of the entrance, is a niche loaded with figures, all much defaced and mutilated. In an apartment, half way up the cave, is inclosed the lingum. The space is entered on the four sides, where are placed eight colossal statues differently decorated. Compartments on both sides of the great cave, separated from it by large fragments of rock, which perhaps formerly composed the roof, present several pieces of sculpture; the most remarkable is Ganesa, or the Hindoo God of Wisdom, with a human body and an elephant's head, such as he is represented in the temples throughout India.

The cave and its decorations appear evidently to be dedicated to Seva the destroyer. A conviction of the harmony of the proportions of these gigantic figures, reconciles the mind to view them with complacency. Many of them were measured by a scale of proportions, allowed to be the most correct; and were found not to deviate more from the standard, than the disproportions which the configuration of the human body deeply presents. Other excavations are in the vicinity, but being still unexplored, they are probably of comparative insignificance.

The islanders, who are said to have fled hither from the opposite island of Salsette, to avoid the persecution of the Portuguese, and who now live in tranquillity under their Banyan tree, say the cave was formed by the gods; nor has a much more satisfactory account yet been traced, than what these simple people give, at least with respect to the date of its construction. Marks of dilapidation and ruin are evident throughout the whole structure. This mutilation is said to have been the effect of the Portuguese cannon, dragged to the spot for the purpose of desolating the shrines of idolatry. How often is the page of the history of nations stained by fanaticism assuming the features of the most sanguinary superstition, while, in the pursuit of the objects of its vengeance, it erases the fairest monuments of art, and abandons itself up to every species of outrage and licentiousness! However characteristic persecution and the sword may be, of the spirit of Mahometanism, they find no sanction from the mild and benevolent doctrines of Christianity.
The cave of Elephantus, like the excavations near Ellora, is the work of a people among whom the arts have attained a high state of perfection. There, labour and skill are displayed in a degree much superior to the theory to construct the pyramids. The one exhibits the toil of barbarous slavery, the other the genius of a civilized and scientific nation. Asiatic literature having been followed through its thousand streams, at this moment, the gods of India stand revealed in their various attributes, almost as clearly as the deities of Greece and Rome; yet has the research failed to deduce science from its parent source, and to reflect much light on the dark page of the history of that splendid era, when Asia eclipsed all nations in works of magnificence and art. Egyptian priests are believed to have come from the Nile to the Ganges, and it may be inferred from the innumerable prejudices and self-sufficiency of the Brahmins, not as their preceptors, but rather to be instructed than to instruct. We know Egypt to have been the fountain of knowledge for the western, and India for the eastern regions of the globe; but which of the two nations can boast of priority of claim to the arts and sciences, remains a doubt. We are ignorant of what the learned of Memphis wrote concerning India, and the sages of Benares give but obscure accounts of Egypt. Indeed, Hindoo testimony, from its preposterous claims to antiquity, is entitled to little belief. We are abundantly warranted in supposing that a connection subsisted between the ancient isolatrons nations, and that Egyptians, Indians, Greeks, and Italians emanated from one central point, from thence scattering their different arts and knowledge, along with themselves, over the world. See Asiatic Researches, vol. iv.; Niebuhr's Travels; and M. Graham's Journal of a Residence in India. (w. t.)

ELGIn, a royal burgh of Scotland, and the county town of Morayshire, lies upon the banks of the Lossie, about seven miles from where that river falls into the Moray Firth. It is supposed to have derived its name from Helgy, a Norwegian general, who, in the beginning of the 10th century, when Siward, Earl of the Orkneys, spread his conquests over the northern parts of Scotland, is said to have built a town southward of Duffeyrus. This description corresponds with the site of Elgin; and the supposition is farther confirmed by the inscription on the common seal of the town, Sigillum commune civitatis de Helgy. This town consists of one street above a mile in length, intersected by seven smaller streets or lanes; and the houses which front the principal street are generally of three stories. Near the centre of the town, and in the middle of the street, which here widens very much, are huddled together the town-house, the sheriff-court-house, and the county jail; and near to these is the parish church, a low irregular building, all of which both deform and encumber the street. At the west end of the town, on a green mount called Lady Hill, are the ruins of a royal fort. The area within the wall which surrounds the summit of the hill is 85 yards in length by 45 in breadth; and from the remains of the interior buildings, it would seem, that they once formed a square. This fort was destroyed by Robert de Bruce, when he surprised the English garrison which then held it, on his unexpected return from the Hebrides.

Elgin was at an early period erected into an Episcopal see, and was adorned with the palaces of ecclesiastics, and the endowments of monks. The chapel of the monastery of the Grey Friars, is still almost entire, but the monastery itself has been long occupied as the habitation of a private family. The Bishop's palace, now the property of the Duke of Gordon, is but a mean building, and can scarcely be distinguished from the ordinary dwellings. The ruins of the cathedral stand at the east end of the town, and display both magnificence and elegance. This pile is in the form of a cross, 264 feet long, and 36 broad, of Gothic architecture, and stands due east and west. It had five towers; two on the corners of the west end, 84 feet high, exclusive of the steeples; two on the east, 60 feet; and one in the middle, 158 feet. The grand entrance is by the west, through an arched gateway 24 feet high, and 24 feet broad at the base. Above this gate was a window in the form of an acute angled arch, 27 feet high, and 19 wide; and on the east gable was a parallel range of five windows, each ten by two feet; above these, five more, each seven feet high; and over all, a circular window about 10 feet in diameter. On both sides of the church, eastward from the transept, were aisles 15 feet broad outside the walls, having each a large window, and above these a range of windows six feet in height. The whole is richly ornamented with carved devices and embellishments. But the most beautiful part of the building is the chapter-house, which communicates with the choir by a vaulted vestry. It has the form of an octagon 34 feet high, and 27 in its greatest breadth. Its vaulted roof is supported by a clustered pillar nine feet in circumference, from the top of which ribs stretch along the roof to each angle of the octagon. Except where it joins the choir, there is a window on each side; and in the north wall are five stalls in niches for the bishop and dignified clergy. The middle stall intended for the bishop or dean is larger, and raised a step higher than the rest. This cathedral was built by Bishop Andrew de Moray in 1224. In 1590 it was burnt down, together with the town of Elgin, by Alexander, (son of Robert II.) called the "Wolf of Badenoch," in resentment against Bishop Barr. It was soon after, however, restored to its former magnificence, and Bishop Innes laid the foundation of the great tower, and made some other additions to the building. In 1506, the great tower fell, and although Bishop Foreman began to rebuild it in the following year, it was not completed till about 32 years after. The whole cathedral remained entire till 1608, when the council at Edinburgh ordered the lead to be taken from the cathedral churches of Aberdeen and Elgin, and sold for the maintenance of the Regent Murray's soldiers. Being thus uncovered and exposed to the weather, it soon after began to decay, and the great tower fell down in 1711. The remains of a high stone wall still exists, which inclosed the cathedral and burying ground, with houses and small gardens for 22 canons and dignitaries of the see.

Among the buildings of this town, it may be proper to include an intended hospital for the sick poor of the town and county. The funds, now amounting to nearly £40,000, which are to be appropriated to this purpose, were left by Dr Alexander Gray, a native of Elgin, who died some years ago in India. The trustees have already fixed upon a very elegant plan for the
ELICHrysium, a genus of plants of the class Syngenesia, and order Polygama Superfus. See Botany, p. 299.

ELK. This is one of the larger animals inhabiting the globe, belonging to the genus Cervus, and order Pecora of Linnaeus. The history of the elk is involved in considerable confusion, from which we shall find it difficult to lay down its specific characters, as those who have had the most favourable opportunities for observation are scarcely agreed concerning them.

This animal dwells in the north-eastern parts of Europe, in Asia, and North America, chiefly frequenting the colder climates. In the latter country it is called the moose deer, or wapooose by the natives. It is said to consist of two kinds, the red elk or moose deer, which is larger than the tallow horse, and has been seen eight or ten feet high, of a dark grey colour, sometimes black, but much paler on the legs and beneath the tail; the hair is long and coarse, ten or twelve inches in length on the back, and forming a kind of mane on the upper part of the neck. There is a sort of barbule on the excrecence pendent from the throat of some; but it is not ascertained whether this is a general characteristic of the animal, or belongs only to the male. The tail is short, the eyes and ears are large and erect, and the hoofs broad. But the elk is chiefly distinguished by two wide spreading palmed horns of great size, proceeding from the forehead, between two and three feet long, or even between four and five in those of the greatest size; and they have undoubtedly been seen in recent instances, though not so large, yet of such dimensions as to enable us to determine the probability of the fact. The other species is said to be smaller, and of a light grey colour, to herd in flocks of 20 or 30, and to bear more resemblance to the fallow deer; whereas the moose is either solitary, or not to be found with above four or five in company. The motion of the elk is unlike that of the deer; it does not spring on being surprised, it advances with a shuffling gait, while the hoofs make a loud clattering, and runs with great speed. Its food is the herbage of the ground or the foliage of young trees. It dwells on hills or in woody countries, sometimes clustering open pastures in summer, and re- treating to thickets and the banks of lakes or rivers in winter. From the shortness of its neck and length of the legs, declivities are principally frequented, for the ease of reaching the ground. In winter, it prefers willows and some aquatic plants. These animals breed about the month of April, and generally produce two at a time. The males are said to cast their horns annually in November, and to renew them in spring: the females have none, and are besides very different from the males, in being much inferior in size, of a brownish sandy colour, the hair white at the root, and nearly so in some parts of the surface.

The elk is of a quiet, tractable, and docile nature. In summer it is harmless and inoffensive, and it is very easily tamed. When pursuing two crossing rivers and lakes it makes no resistance, and boys or women can easily destroy it. Mr Hearne relates, that he repeatedly saw many as tame as sheep at the settlement in Hudson's bay, and that they would follow their keepers, or come to meet them, in the same manner as the most domestic animal would have done. At New York they have been broke to harness, and apparently not without success. The disposition of the animal renders it particularly favourable for such experiments, and it is not unlikely that it might be naturalized and domesticated in this island.

Of late years a description has been given by Dr Smith of an animal of this genus, which he characterises as the real and genuine elk, and he deduces its characteristics from four individuals, which were exhibited to him in America. The colour, he observes, is reddish in spring; it then changes to greyish dun, afterwards to grey in autumn, and continues so during winter. The rump for six or seven inches from the tail is pale yellow, and separated by a blackish semicircular line from the rest of the body. The fore part of the legs and the nose are black, as also the under lip on each side. A mane about six inches longer than the hair of the rest of the body, and a beard on the throat and breast, are seen on the male in winter. He is provided with horns, which, according to Dr Smith, are not palmed, but consist of three principal divisions, and are cast, all except a pith or core, several inches long, in May. In about eight weeks they begin to grow, and according to the age of the animal a prong successively vegetates from the inside of each alternately. Under the lower angle of each eye is a large external oblique slit, nearly an inch in length, by means of which a whistling noise is produced. Two of the animals were males, and two females; the former had a small vesicle on the external part of each hind leg, containing an unctionous matter, which they can open and anoint the sprouting horns; this was done regularly at four in the morning and at ten at night. These creatures are ordinary vegetables, and readily received tobacco; but as all were domesticated, no inferences could be drawn with regard to their food. At the same time it is said, that in the natural state they feed on the wild plant. All being young, at least not full grown, the extreme limits of their size could not be ascertained; a male, two years old, was 7 feet 3 inches in length; a female, three years old, 7 feet 9 inches long, and 4 feet 7 inches in height; the ear nine inches long, the tail only three. The whole were taken in Upper Canada.

From the preceding description, it appears there is a sensible difference between the real elk of naturalists and those of Dr Smith. The Cervus Pygargus of Pallas, which dwells in Russia, beyond the Volga, seems to bear some resemblance to the latter, in having the muzzle and upper lip black; the tail is only a cutaneous elongation, and the horns are trifurcated. But in other places he speaks of the elk in contradistinction to this animal.
There is a striking peculiarity in the nature of the elk, which has given birth to various conjectures. When sprung by the huntsman, it sometimes suddenly falls down as if in a fit, and then as suddenly recovering itself, sets off at great speed. An opinion has hence prevailed, that it is subject to epilepsy: and a part of the animal’s hoof has been worn as an amulet or charm against that distemper. Horses, it is said, have been seen with the same peculiarity; and we know there are among the smaller tribes of animals, some which counterfeit death on being alarmed.

The elk is hunted in various ways, for the sake of its flesh and skin, and as the fur of wild animals is richer in winter, that season is commonly selected for its capture. The Indians near Hudson’s Bay can easily run it down, for although endowed with sufficient speed, the elk is tender-footed and short winded, so that a good runner will generally tire it in less than a day, and frequently in six or eight hours. However, the huntsman has been known to continue the pursuit two days, before coming up with the game. On occasion the Indians go lightly clothed and loaded, in order to preserve them from fatigue. When the elk can advance no farther, it stands and keeps the pursuer at bay with its head and fore feet; by means of the latter it can kill a dog or even a wolf, and people who suddenly rush upon it, are in danger of serious injury; therefore the Indians who want fire arms, or bows and arrows, stab the animal with a knife fixed to the end of a long stick. This kind of pursuit is much facilitated by the state of the snow; for a heavy animal like the elk sinks deep at every step, when a thaw begins, while the huntsman is kept up by snow shoes on the surface. Snare are also set for the elk; its approach to lakes and rivers is watched, when it is shot with guns or arrows: dogs are likewise used in the chase, and there are various other modes of capture.

The flesh of the elk is good and nutritious, and the skin is converted to various useful purposes. It serves for covering the tent of the Indian, for his shoes, belts, and clothes; in drying, while ladies are bastings of the horns. The skin, when properly dressed, is peculiarly soft and even; but not being prepared with oil, it is said to become hard after having been wet, unless precautions are taken to rub it while drying.

It is probable that some species of these animals are extinct, unless they remain in the recesses of those forests as yet unexplored by the modern races of men. But we know from undoubted evidence, that they once dwelt in countries, even in these islands which we now inhabit, where they no longer exist, nor does any tradition of them now remain. Horns of enormous size are frequently discovered near the surface of the earth, or far below it, which the present elk, though its neck be of great strength, would almost seem incapable of supporting. Nor is it less singular, that such remains are often associated with those of other animals so different in nature, as to render it doubtful whether the living race of both could survive together.

These enormous horns are probably more common in Ireland than elsewhere, and have certainly belonged to a species nearly analogous to that which dwells in the northern regions of the world. Of this description is a pair which Dr Molyneux long ago described in the Philosophical Transactions, measuring 10 feet 10 inches, from tip to tip; each horn 5 feet 2 inches in length, and 11 inches in circumference at the root. Yet the head bore no proportion to these immoderate dimensions, for it was only two feet long, by one in breadth, or just about the size of that of the largest of the elk described by Dr Smith. But these horns do not seem of the largest size, as Mr Parkinson more recently speaks of one 12 inches in circumference at the root. The place of their deposit is usually among alluvial remains. Duvier, a celebrated anatomist, has objected to the fossil horns belonging to the same species as the present elk, because, although palmed like them, the palms are higher from the head, and somewhat of a different figure. But if we are entitled to judge from analogy, the distinctions are not very remote; nay, on strictly attending to the dimensions of the heads which are discovered, inferences might be drawn that the ancient elk of the world was little different from the recent elk in size. See Hearne’s Journey from Hudson’s Bay, Kulin’s Travels in North America. Philosophical Magazine, vol. vi. Philosophical Transactions, vol. xxiv. p. 51. Parkinson’s Organic Remains, vol. iii. Pallay Voyages, tom. i. p. 8. (c)

ELLESMORE, a market town of England, in Shropshire, lies 16 miles north-north-west from Shrewsbury, and 176 north-west from London, and is situated on the margin of a beautiful lake, from which it takes its name. It is a very ancient town, and was formerly very strongly fortified. During the frequent contentions between the English and Welsh in the early period of our history, the castle of Ellesmere became a post of considerable importance, and was held alternately by both nations. The site of the castle, from whence there is a delightful prospect, and a distinct view of nine different counties, is now converted into one of the finest bowling greens in the kingdom. No vestige of the building remains, except three walls and fosses, by which it is still surrounded. It is a neat clean town, but has nothing to boast of except its situation. It contains four well-built streets, a spacious church of an irregular cruciform construction, in the centre of which is a handsome square tower with pinnacles; and the ceiling of the chapel is highly enriched with Gothic fret work. The principal trade of this town consists in malting and tanning, and it has of late derived considerable advantages from the Ellesmere canal, which forms a communication between the river Dee at Chester, and the Severn at Shrewsbury. The lake covers 116 acres; it is well stocked with fish, particularly eels, and its margin is finely wooded. On one side stand the tower, and a house of industry for the poor of five adjoining parishes, and on the other the mansion and park of Oatley.

According to the population in 1811, the town and parish contained,

Inhabited houses ........................................ 1064
Families that occupy them .............................. 1091
Families employed in agriculture .................... 613
Families employed in trade and manufactures .... 452
Males .................................................... 2715
Females .................................................. 2924

Total population .................................. 5659

ELLORA, a genus of plants of the class Pentandria, and order Monogynia. See Botany, p. 145.

ELLORA, a town of Hindostan, distant about 18 miles from the city of Aurungabad, and six from the fortress of Doulutabad.

The town itself, of no great extent, is situated in a valley, and is chiefly celebrated for its vicinity to works of Hindoo superstition, scattered profusely over the sides of mountains, about a mile to the eastward.

It has not been ascertained to what period these extraordinary efforts of human labour and zeal may be accurately referred, certainly to a date antecedent to the Mahometan conquests in the Decenn, where the dominion of the Hindoo dynasty of princes was paramount, commanding the wealth, resources, and industry, of that populous region of Asia.

In no quarter of the globe has superstition struck its roots deeper, and taken more complete possession of the human mind, than in Asia; scaling the loftiest and most inaccessible mountains, to fix its shrines on their summits, consecrating the gloom of caverns, and impressing its symbols on almost every remarkable tree and stone.

Though the religion of Brahma rejects proselytism, it is well calculated to flatter the passions of the human heart; to allure by the magnificence of its temples, its dazzling processions and ceremonies, to seduce by the mysterious sublimity of its doctrines, to excite wonder by its numberless penances and mortifications, and to command the blind submission and admiration of the multitude by the sacred character of its priests.

These effects are now but partially produced, as the streams of wealth which fed the Indian pagodas, have been diverted into other channels, and swallowed up by the rapacity of conquerors. And though their dark idolatry is still respected, yet we do not scruple to affirm, that the bulwarks of that once inaccessible superstition are gradually undermining, and the character of the Brahmin himself becoming impaired in the eyes of the Hindoo; the receding influence of the Sanscrit language being unfolded, and the veil of mystery which surrounded his mythology, being removed by British intelligence and inquiry. Some of the most celebrated pagodas having fallen under the control of the East India Company, many of the most sensible Hindoos begin to suspect that they are paying homage to the Mammon of the Company, under an incarnation of Vishnu or Seva.

The caves of Ellora must at all times have powerfully contributed to uphold the superstition of the Hindoo, and are not more remarkable for their wonderful construction, than for the durability of materials which have so long resisted the ravages of time, and the persecuting zeal of the Mahometan. The writer of the present article has surveyed these excavations by torch light, and he can declare that the gigantic forms which frowned on the living rock, must inspire amazement in minds not tinctured with superstition. A minute description of them, however, at a remote period of time, from his own observation, cannot be attempted. But information on the subject is not defective. Intelligent travellers have attentively examined them, and communicated their remarks to the public.

The reader is referred to the article Civil Architecture in this work, for a particular description, and for figures illustrative of some of the most remarkable excavations, taken from Sir C. W. Mallat's account, preserved in the 6th volume of the Asiatic Researches.

Sir Charles, when on the spot, endeavoured to ascertain the date of these works, but without success.

We have two authorities stated by him regarding their antiquity and origin, which we shall quote, more for the amusement than the satisfactory information of our readers.

A Mahometan, named Meer Ala Khan, an inhabitant of Ahmednagar, mentions that a person of acknowledged erudition told him, "That the town of Ellora was built by Rajah Eel, who also excavated the temples, and being pleased with them, formed the fortress of Deogur (Doulutabad), which is a curious compound of excavation, sarcophagus, and building, by which the mountains were converted into a fort, resembling, as some say, the insulated temple in the area of Indur Subba. Eel Rajah was contemporary with Shah Momin Arif, who lived 900 years ago."

On the other hand, a Brahmin, an inhabitant of Roza, quotes a book entitled Senna Lye Mahot, or the graces of the mansion of Sewa, i.e. Mahadev, and relates, "That the excavations of Ellora are 7804 years old, formed by Ellor Rajah, the son of Prashant of Eliehoor, when 3000 years of the Dwarpa Yooq were unaccomplished, which added to 4894 of the present Kal Yooq, makes 7804. Eellor Rajah's body was afflicted with maggots, and in quest of cure he came to the famous purifying water named Sewa Lye, or, as it is commonly called, Sewalla, that had been curtailed by Vislum, (at the instigation of Yen-durham, or Jum, the destroying agent), from sixty bow's length (each four cubits square) to the size of a cow's head. In this water Ellor dipped a cloth, and cleansed with it his face and hands, which cleared him of the maggots. He then built Koond, (or cistern), and bathing therein, his whole body was purified; so that looking on the place as holy, he first constructed the temple called Keymas, &c. to the place of Biskurama."

These two authorities are not more remarkable for the coincidence in the alleged projector Rajah Eel, or Ellor, than for their violent discrepancy of date.

Sir Charles, however, discovered, that the excavations are not all of equal antiquity, having traced the more northerly ones to the works of the Sewras or Juttees, who are esteemed schismatics by the Brahmins, and the sect of comparatively modern origin; but this discovery does not ascertain or affect the date or origin of the other excavations, which is lost in fable. No person, in our opinion, who has surveyed these stupendous works, can imagine them the result of individual zeal. The execution of any of them must be considered a prodigious effort of enthusiasm in one person, but when we take them collectively, and view the sides of mountains shaped by the chisel into temples, caverns, and areas of unparalleled size, all loaded with mythological embellishment of the most elaborate workmanship, we can only ascribe them to the zeal of ages, nourished by the wealth and munificence of succeeding princes.

The Koond, or cistern, is extinct just without the town of Ellora. The holiness of its water still renders it a place of resort. A Teerut, or pilgrimage, is performed to it, under the appellation of Sewalla Teerut, or Koond.

The mythological symbols are considered by Sir C. Malet to be purely Hindoo, without any admixture of Egyptian or Ethiopian origin.

But if Sir William Jones's opinion be well grounded, in which we entirely concur, that a connection subsis-
ed between the idolatrous nations of Egypt, India, Greece, and Italy, long before they emigrated to their several settlements, and consequently before the birth of Moses, we may easily suppose them to have borrowed their symbols of worship reciprocally from each other. Thus the remarkable features of resemblance so ingeniously traced by Sir William between the deities of Greece and India will be accounted for.

In executing these works, the chisel appears to have been the only instrument used, as traces of it are visible all over the granite.

They are dedicated chiefly to Mahedaws, the presiding deity, who appears under a two-fold attribute in the temples of India. He is designated the god of destruction, and is conspicuous as the deity who presides over generation, represented riding on a white bull. His celestial seat is Mount Cailasu, every splinter of whose rock is an inestimable gem. On earth, he haunts the snowy mountains of Himalaya, to the east of the Brahmaputra river, called Chandrasichur, or the Mountain of the Moon.

Whoever visits the caves of Elora, while he admires such amazing efforts of industry, must deplore its abuse, in executing works superior in point of labour and skill to the pyramids, and which, like them, can only serve to be perpetual monuments of human weakness and folly. ELSHOLTZIA, a genus of plants of the class Dildynamia, and order Gymnosperma. See Botany, p. 242.

ELSINEUR, Elsinor, or, in Danish, Helsingor, is a town of Denmark, in the island of Zealand; and is situated on the west side of the Sound, almost opposite to Helsingburg on the Swedish side of the Sound, from which it is distant about 3 or 4 English miles. The town of Elsinore is well built, the houses being chiefly of brick, and is regarded as the second town in the Danish islands. It contains two churches; a grammar school; a custom-house, which is a fine building; several handsome private buildings, and a sugar house. In the year 1753 an attempt was made to form a harbour, but it was found to be impracticable. The road-stead, however, is admirable, and generally contains great numbers of vessels lying at anchor. Those ships, which draw only 8 feet of water, can come up to the quays.

The most interesting object at Elsinore is the fortress of Cronberg, which is situated on the edge of a peninsular promontory. The royal palace, within the fortifications, is a magnificent Gothic building of freestone, and of a square form. From an inscription over the gate, it appears to have been begun by Frederic H. and repaired and augmented by succeeding sovereigns. Besides the royal apartments, which are insignificant, it contains the residence of the commandant, a church, a corn magazine, &c. In one part of the castle is a platform, from which the view is magnificent. The Swedish coast, towards the north, is seen for 40 or 50 miles, while the steeples of Copenhagen may be discerned towards the south.

The Castle of Cronberg is strongly fortified towards the shore by bastions and regular entrenchments; and towards the sea by several batteries mounted with 60 cannon, the largest of which are 45 pounders.

Every vessel that passes the port, lowers the topsail and pays a toll, amounting, exclusive of a small duty for the lighthouses, to ½ per cent. on their cargoes, excepting the English, French, Dutch, and Swedish, from whom only 1 per cent is levied. These tolls supply an annual revenue of L100,000 according to Mr Cox, or of L200,000 according to Kuttner. It was in this castle that the late unfortunate Queen Matilda was imprisoned. The only other object of interest at Elsinore, is the Palace of Marienlust, a new but not extensive building belonging to the Crown Prince. It stands on a small steep hill. The garden is called Hamlet's garden, which, according to tradition, is the place where the murder of his father was perpetrated. An account of the shipping of all nations, which paid toll at Elsinore between the years 1792 and 1804, will be found under our article Baltic. Population 5000.

According to trigonometrical observations, Elsinore is situated in East Long. 12° 38' 2", and North Lat. 56° 2' 17". See Cox's Travels in Poland, Russia, Sweden, &c. vol. v. p. 85; Kuttner's Travels through Denmark, Sweden, &c. letter iv.; Catteau Calleville's Tableau de la Mer Baltique, Paris, 1812, tom. ii. p. 324; and Carr's Northern Summer.

ELY, formerly Jelves, is a city and frontier town of Portugal, in the province of Alentejo, situated on a hill covered with olive trees. The streets are irregular and narrow, and so full of dirt, that it is difficult to wade through them, even in dry weather. The town contains four parish churches, and six religious houses, besides a monastery of capuchins without the gate. Elvas is now the third, and most important fortress in Portugal. The town is strongly fortified, and is defended by two citadels situated on the adjacent hills. One of these is called Fort St Luzia. The other was erected by the Count of Lippe Buckeburg, and has, therefore, received the name of a forte de Nossa Senhora de graça de Lippe. The prince of Waldeck considered it as a master-piece of fortification, and as superior to any thing that he had seen. The great aqueduct of Elvas, called os arcos de Amoreira, from its commencing near a mulberry tree, is a very splendid work. It is a Portuguese league in length; and in the neighbourhood of the town, where it passes across a valley, it consists of four rows of arches, one upon another, of a considerable height. Elvas, being the chief town of a corregimento, is governed by a corregedor, a provedor, and a juiz de fora. The hill on which Elvas stands is formed of granite, consisting of white quartz, felspar, and mica, and in some parts containing steatite. On the declivity of the hill, the granite is covered with a whitish grey foliated limestone, with sulphurous pyrites and fehlerz interspersed. Elvas first acquired the name of a city in the reign of Don Manuel, although it is said to have been rehuilt by Don Sancho H. who granted the conditions under which the settlers accepted the lands. The population of the town and district was 12,000. West Long. 7°, North Lat. 38° 44'.

ELY, the name of a town of England, in the county of Cambridge. It is situated on a rising ground on the river Ouse, in the marshy district called the Isle of Ely. The town is of great antiquity, and is supposed to have derived its name either from Elig, from the great number of eels with which the river abounded, or from the Saxon word helig, which signifies a willow, in consequence of the great number of willows which grew in the neighbourhood. The streets are irregular, and excepting the principal one, which contains some good houses, they are neither lighted nor paved. The principal public building in Ely is the cathedral, which was begun in 1093, and finished in 1166. It appears to be a work of different periods, and is a mixture of...
The length of the cathedral from east to west is 535 feet, but the length within is only 517. The transept is 190 feet long, and the lantern 170. The western tower is 270 feet high, and the tower on the south wing 120. The length of the nave is 203 feet, and the height of its roof 1040. Of late years the choir has been removed to the east end of the cathedral, and in 1792 a handsome painted window has been put up above the altar. St Mary's Chapel, now Trinity Church, stands near the east end of the cathedral. It was begun in the reign of Edward II., and is esteemed one of the most perfect buildings of that age. It is 200 feet long within, 45 feet broad, and the vaulted roof 60 feet high. It has neither pillars nor side aisles, but is supported by buttresses surmounted with pinnacles. The Episcopalian palace is built of brick, and the houses of the prebendaries are near the cathedral, and stand on the site of an ancient convent endowed by one of the kings of the East Angles. There is here a free grammar school for 42 boys, besides two charity schools. The inhabitants are chiefly employed in gardening, the adjacent grounds being principally laid out in gardens, which supply the neighbouring towns, and even Cambridge, with vegetables. The following abstract of the population of Ely is for the year 1811, and includes Chesterton in St Mary's Parish, and Stuntney in Trinity Parish.

Number of inhabited houses 928
Number of families that occupy them 944
Families chiefly employed in agriculture 406
Families employed in trade and manufacture 262
Number of males 2,054
Number of females 2,215
Total population 4,249

EMBALE, or EMBALM. See Boucic.
EMBALMING, the art of preserving animal bodies from decay after death.

Nature, to make way for her successive generations, has decreed, that the cessation of life shall be followed by the resolution of material substances into invisible fluids. This is accomplished by putrefaction; and no sooner has life departed than its operation begins, quickly reducing the most beautiful works of the creation to a loathsome and corrupted mass; subsequent changes ensue, and, by final decomposition, the animate matter totally disappears. Mankind, reluctant to part with beloved or venerated objects, and actuated by religious principles relative to the welfare of the soul, have devised various methods of counteracting the progress of nature, by preserving their bodies from decay. On remounting to periods of high antiquity, we find the Egyptians, one of the earliest nations whose history has been transmitted to our own times, embalming the bodies of their dead, which were then consigned to appropriate cemeteries, or retained in their dwellings, where they might be the subject of pious contemplation.

The preservation of the dead in the dwellings of the Egyptians, and their interment within its walls, was not peculiar to the Egyptians. In scripture it is said, that Samuel was buried in his house at Ramah; and of Job, that "Benaiah, the son of Jehoiada, went up and fell upon him, and slew him, and he was buried in his own house in the wilderness." Nor are examples of this wanting in modern history, as the Chinese are said to keep the bodies of their relatives long unburied beside them; and some barbarous nations on the coast of Africa inter a deceased relative in the hut which he inhabited.

Embalming, as an art, was carried to great perfection by the Egyptians; it was conducted by persons specially initiated in it, and performed at a costly charge to the survivors. So long as the body remained entire and undisturbed, they believed that the spirit would remain in it after the lapse of thousands of years; and in another respect it was no less important, for a son might pledge the body for his own debt, but it was declared infamous not to redeem it. History even relates, that the bodies of ancestors were exposed to the view of strangers, or produced on ceremonial occasions by postern; and it has been inferred from a passage of Lucian, that he sat at table along with the corpse of an Egyptian.

There were different modes in which embalming was performed, as Herodotus and Diodorus, who both travelled in Egypt at different periods, relate, and they seem actually to have witnessed the fact. According to the former, the decease of any person of distinction was followed by great lamentations of the women; and the men expressed similar symptoms of grief, while they religiously abstained from all pleasures and enjoyments. After these emotions subsided, the body was delivered to the professors of the art, to be prepared according to a fixed price, proportioned to the quality of the deceased. The operator first proceeded to extract the brain through the nostrils by means of a crooked instrument, and filled up the cavity with balsamic ingredients. He next laid open the abdomen, and the intestines being removed, were cleansed with wine and odoriferous substances, and then returned; or they were perhaps thrown into the Nile. The cavity was filled with aromatic matter, and sewed up again. After this the body was deposited 70 days in nitre, and having been removed when these elapsed, it was washed once more, and swathed in fine linen besmeared with gum. The process was now completed after the most expensive method. In another method, a quantity of oil of cedar being injected, and the body laid 70 days as before in nitre, the oil on expulsion brought away the intestines, and the nitre consuming the flesh, left nothing but the skin and bones, whereby embalming was also completed. By a mode still more economical than either, the abdomen was merely washed with certain lotions, and the body then dried 70 days with salt. Diodorus differs from this author, in limiting the period of preparation to 30 days.

From the rapid progress of putrescence in a climate so hot as that of Egypt, it appears, that these operations were immediately subsequent to decease, but with one exception, the origin of which must be sought in the depraved manners of the East. Beautiful women were not committed to the embalmers before the lapse of four or five days after death; and the like interval was preserved with respect to those of rank.

When returned to the survivors, the body had ac-
embalming.

Methods of embalming in Egypt.

required a fragrant odour, every member remained entire, no part had undergone any change; the beauty and appearance of the face were exactly as they had originally been, even the hairs of the eyelids and eyebrows remained in their place. "Thus," says Dio-
dorus, "many of the Egyptians who keep the dead bodies of their ancestors in magnificent houses, see the real features of those who died many ages before they themselves were born, and take as much pleasure in gazing on the countenance of each as if they still lived among them." Probably this is not an exaggerated description, for examples of the same, accomplished both by nature and art, illustrate, that in other cases this has really happened.

It has been remarked, that, contrary to the received opinion, embalment was rarely performed among the Egyptians, and being an expensive preparation, was confined to a few of the more wealthy inhabitants; nor is this disproved by the numerous bodies which for many centuries have been withdrawn from the subterraneous recesses appropriated for their reception, as Egypt was a rich and populous country, and long held a distinguished rank amidst surrounding nations. But notwithstanding the succinct descriptions of Herodotus and Diodorus, the real method of embalment is not easily comprehended by the moderns, for some have doubted the possibility of removing the brain as the former specifies, and others have supposed that the intestines were totally destroyed. Reasoning from ancient history, and from an analysis of different subjects on the Continent, and particularly in these islands, they conclude, that two principal processes were adopted by the Egyptians. In one, the whole members, features, and appearance, were preserved entire; in the other and more general operation, the flesh was consumed, and nothing except the skin and bones retained. Examples of the former, so far as we know, are not now extant, but there are two kinds of embalmed bodies or mummies still obtained in Egypt; those in a dry indurated state completely impregnated with a resinous matter, and whose from the hardness, may be broken in pieces; and those which, with the envelope, are soft and yielding from external pressure, prepared with very little resinous matter, and with nothing but vegetable mould, discoverable in the cavities. It has generally been supposed, that asphaltum or mineral pitch was employed; but more recent experiments prove, that the impregnation of the body was accomplished rather by a resinous substance, and that nitre was the salt employed. Although the flesh unquestionably was, in certain cases, preserved, it seems probable that the body was more usually reduced to a skeleton, and boiled in the resinous or antiseptic matter which was used.

The brain was also, in some cases, effectually removed for a substitute of this nature. Mr. Greaves having laid open the skull of a body, apparently that of one of the more wealthy Egyptians, found two pounds of a medication within it: of the colour, smell, and consistence of pitch or bitumen, which softened in the heat of the sun. But the contents of the abdomen, being commonly reduced to dust, are less easily ascertained. A mummy being dissected by Dr. Hadley in 1768, he found the bones in actual contact with the pitchy matter of the envelope; the tibia and fibula being wrapped up separately. The skull was quite bare in some places, and also in contact with the envelope. There were no remains of flesh or integuments about the head, and the flesh and skin of the extremities were gone. But in the dissection of another mummy, the appearances were very different; for the bandages of the face being laid open, it was evidently covered with a varnish or glazing substance; traces of the eye-lids and eyelashes were perceptible, and the eyes prominent. The ears were not in the least decayed, nor had the cheeks fallen. The whole face was kept firm by a resinous or bituminous composition. The teeth, thirty-two in number, were complete, white, and perfectly beautiful, but the lips had been removed, and the cavity of the mouth filled with an odoriferous dust. The nostrils were stopped with cotton and a kind of ointment, which had also been used in the thorax and abdomen. The hair was short, black, and curled, and could with difficulty be eradicated.

In general, however, nothing but naked bones are found on laying open the mummies brought from Egypt, along with a quantity of vegetable mould occupying what had constituted the thoracic and abdominal cavities, though sometimes the tendons, skin, and fleshy parts remain, and gilding is exhibited on the nails.

In both kinds of embalment, a great portion of pitch or resin was used, experiments tending to show that it was usually the latter. Nevertheless it was not the simple employment of the balsamic matter which completed the process, as the body had then to be swathed in an immoderate quantity of linen fillets or bandages, every member, even to each finger, being separately wound up. This envelope consisted of several folds, each fillet being of different breadths according to the part it encircled. Not less than 300 yards of filleting, according to some writers, or 1000 according to others, were thus employed. After every member was separately bandaged, a general bandage, binding all the parts together, surrounded the body, and the whole was inclosed in an exterior case or covering, on which we now see Egyptian characters or hieroglyphics. All this filleting was deeply impregnated with the resinous or bituminous matter, and has apparently been steeped in it while liquified, and in that state applied to the skin or bones. The art of embalming is thus conjectured to have consisted in the imersion of the body prepared with salt, or the skeleton, in melted pitch or some resinous substance, and in filing the scull, as also the thoracic and abdominal cavities, with some balsamic matter. From an ancient period, this substance has been the subject of anxious research among the bodies of the deceased. Mersin, an Arabic author, relates, that in the year 988 of the Hegira, or 910 of the Christian era, while some Egyptians were digging at the distance of several cubits from the pyramids in quest of treasure, they came to a subterranean vault with niches containing figures standing upright. On breaking them up, mummies were found within. Beside each was a case, including the residue of the substance that had embalmed the body, quite inodorous, but on exposure to heat exhaling a fragrance resembling no other perfume. Abdollatip, an Arabian physician of acute observation, who resided in Egypt in the end of the 15th century, describes the constant prosecution of an active search for treasure in the soil and in the catacombs where the mummies were deposited, of which an ample account has already been given in an earlier part of this work. The Arabs and common people having penetrated the latter, carried away the investments of the bodies, or whatever was impregnated with gum, as he designs it, and sold them to apothecaries. The balsamic substance found in the scull and abdomen was carried to Cairo, and offered to sale for a trifle. "I bought three heads," he adds, "for an Egyptian drachm."
This substance Abdollatiph characterizes as being black like pitch, and emitting an agreeable odour when heated.

The Egyptians did not confine their art exclusively to the preservation of the bodies of mankind. Beasts, birds, fishes, and even serpents, were all embalmed with equal care as their fellow creatures; and apparently the same means have been employed. Birds in particular seem to have been objects particularly favoured; and as they have either been less sought after by the predatory Arabs, or as their various repositories have been more recently discovered, they have reached our present era in greater numbers and perfection than mummies of the human species. The latter were inclosed in coffins made of sycamore, but the animals are usually preserved in pots of earthen ware.

Beside these, the ordinary modes of embalming, it appears that immersion in honey was also practised, although the accounts of it are much more obscure. If we may credit a Roman poet, the body of Alexander the Great, which was entombed in Alexandria, had been embalmed in honey.

Duce et oel. Emathios moneb ubi bellator orbis, Condition hic tales perfumus nectare duce. Statius.

Whatever may be the truth, the operation had apparently succeeded here for several centuries subsequent to the decease of that prince: his body was inspected by several of the Roman emperors, who beheld it entire, and Caracalla remarked a brown on the countenance. Abdollatiph, the Arabian traveller, expresses himself thus: "A person worthy of credit told me, that, during a search for treasure near the pyramids, an oblong close vessel was found. This being opened, appeared full of honey, whereof the party present ate, but some of them soon observing hairs sticking to their fingers, on further examination, discovered that a young child, with a certain jewel or ornament on its body, was inclosed."

In respect to the period when this art fell into disuse among the Egyptians, little evidence can be produced. We have seen that it was known in the most ancient times, that it was practised during the most florishing era of their history; but whether it was gradually abandoned as unnecessary, or lost in the convulsions of the kingdom, as other arts became extinct, we have no other evidence but that of conjecture. Count Cauclus considers that embalming has been discontinued in Egypt since its conquest by the Romans, about the time of Diodorus Siculus; while Blumenbach, a more recent author, supposes, in partial conformity with him, that it has not been practised within a thousand years on those mummies brought to Europe. There is a passage in the works of St Augustine, who lived in the earlier part of the fifth century, which, if literally received, would lead us to infer that embalming was still known in Egypt. Treating of the resurrection he says, Nota nihil ius opponas quasi solus opposeris: non maneat resurrectura crederem, Egydi erit soli credenter resurrectionem, quis diligenter essent evadere moutum. Morum, enim, habent siccum corpus et quasi ame vocare: gabbaras ex vocant. Whether this author speaks from personal knowledge of the fact, or merely from hearsay, cannot now be ascertained.

The customs of the Jews, a cotemporary people, coincided, in some degree, with those of the Egyptians; for we read at an early period of their history, that "Joseph commanded his servants the physicians to embalm his father; and the physicians embalmed Israel: and forty days were fulfilled for him, for so are fulfilled the days of those who are embalmed." Of himself it is said, "So Joseph died, being an hundred and ten years old; and they embalmed him, and he was put in a coffin in Egypt." The practice of the Jews, however, is not so well defined as that of the more polished and civilized Egyptians; for in one of the most specific passages we read, that when Asa died "they buried him in his own sepulchres, which he had made for himself in the city of David, and laid him in the bed which was filled with sweet odours, and divers kinds of spices prepared by the apothecary's art; and they made a very great burning for him." Whether this was chiefly for preservation, or merely the burning of incense in honour of the deceased, does not appear: but in another passage of sacred writ, Jeremiah prophesies of one of the kings, "thou shalt die in peace, and with the burnings of thy fathers, the former kings who were before thee, so shall they burn odours for thee." At a later period of Jewish history, the custom may be more distinctly recognized at the death of our Saviour; because Joseph of Arimathæa having obtained leave too remove his body, Nicodemus brought an hundred pounds of myrrh and aloes, "then took they the body of Jesus, and wound it in linen clothes with the spices, as the manner of the Jews is to bury." There is another ancient nation among which embalming was extensively practised, the Gauches of the Canaries. The history of this people is involved in great obscurity, and their existence is best proved by the remains of their dead, for their posterity is almost if not entirely extinct. The mode of performing embalming is not explicitly illustrated, but apparently the brain and intestines were completely removed, after which it is said the body was washed with an infusion of pine bark. Next, it was anointed with butter or warm grease, which had been boiled along with such penetrating and odoriferous herbs as were peculiar to the country, and then it was exposed to the sun. Being well dried, the same operations were repeated, and also subsequent drying until the body was completely impregnated with the aromatic unguent. When reduced to very inconsiderable weight, the process was deemed complete, and the deceased was wrapped in an envelope, consisting of three successive layers of bandages of tanned buck skin or goat skin about three inches broad. Bodies thus embalmed were carried with funeral ceremonies to caves in a mountain, and there placed in niches upright. Several such caverns or catacombs may be now seen in the Canary Islands, and in some the mummies repose supine, sewed up in goat skins, and still bearing the hair.

We are unacquainted with the antiquity of this treatment, but it was not less effectual than the embalming of the Egyptians. In one of these mummies lately examined, the features of the face were still perceptible: the skin of the whole body was well preserved, dry but pliant, and of a deep brown colour. The hair was very long, black, and in good preservation, though it could easily be detached from the head. In the jaws were thirty-two teeth, so firmly fixed as to require an instrument, or considerable exertion to remove them. The back and belly were covered with hair also in preservation. The scull was empty; but the thorax and abdomen full of grain resembling rice.

Embalming seems to have been practised by the inhabitants of Peru, at the date of the invasion of the Spanish, and was probably known from an ancient period. Acosta mentions the body of one of their sove-
EMBALMING.

It is commonly credited, in which the body had been immersed for preservation; and, on the whole, it was concluded that it had been produced by the dissolution of the body itself. The fact, however, is not clearly proved; and a singular discovery was made about the middle of the preceding century at Rome, in Auvergne, of a body swathed in fine linen, externally imbued with a thick balsam. The extremities were swathed up separately, and the hands and feet inserted into small cases filled with balsam. As the body was quite entire, this balsamic substance, which was extremely fragrant, could not have been produced by any disease of the parts.

Whether the Europeans could actually embalm bodies in equal perfection with the ancient Egyptians, seems to have been a point of controversy in the beginning of the preceding century; but it has been concluded, in the affirmative, and different receipts are given, consisting principally in emptying the cavities, in copious lotions, in partial desiccation, and in the abundant use of aromatic and balsamic substances. We do not here speak of anatomical preparations, for these are of a different kind from what is understood by embalming, and injecting wax into the veins, so successfully practised since the time of Ruysch, the reputed inventor, seems totally unknown to earlier ages. But either by the means of art, or by that aberration which sometimes occurs from the ordinary course of nature, the conservation of human bodies has been complete after the departure of animation. The approaches of death are not always announced by convulsions, nor does a distortion of the features necessarily follow. Examples are seen, where nothing but placed quiescence proves the transition from life, while the mortal remains are preserved from decay. Thus St Jerome says of Paulina, a noble Roman lady, "Quodque mirum sit, nihil pallor mutaverit faciem, sed its dignitas quaedam omnin compleverat ut putaveres non mortuam sed dormientem." "What is surprising, her countenance, not in the least changed by paleness, preserved its dignity, so that she might rather have been thought asleep than dead." In the pontificate of Innocent VIII. about the year 1494, the body of a female was found in a marble sarcophagus at Rome, which must have reposed there for ages, yet the joints were flexible, the flesh was pitted by the touch, and assumed its figure when the pressure was withdrawn. This is not confined to the warmer climates, as repeated examples have proved in these kingdoms. In the year 1497, while some workmen were digging the foundation of a wall within a church of London, they found a coffin of rotten timber, wherein lay the body of a woman "whole of skynne, and of bones undissovered; and the joyntes of her armes playable without breaking of the skynne." An inscription denoted, that it must have lain there above 170 years. In the same city, about the year 1797, three coffins were accidentally laid open at the depth of 18 feet from the surface. One dated 1665, contained the body of a man perfect and soft, just as if breath had departed; another, the corpse of a female, in a similar condition; and the third, that of a child, entire and beautiful as wax-work, the eyes being open and clear. But within twelve hours after their exposure, all these bodies began to decompose, which is an invariable consequence if not counteracted by desiccation. We cannot affirm, that artificial means had been employed in preserving the semblance of life in any of these instances. But in others it has not been wanting. Thus a few years ago, the decay of a wooden coffin at Kyleth in Scotland, having lain open a Leonard one to view, some sacrilegious individuals, in tearing up the latter, removed the
Embalming.—The lid of another included within it. This exposed the body of a female, whose countenance scarcely indicated the cessation of life; every feature was fresh and entire, and the limbs full and perfect as if still animated. At her knee lay an infant, with a glow of colour resembling vigorous health. The surrounding substances were in equal preservation. The shrud was complete, and the ribbands binding it, as vivid in hue as if recently applied. The coffin had contained a liquid, which, now partly evaporated, had become vapid, and odoriferous substances were interposed between the corpses. These proved to be Lady Kilisith and her infant son, who, 77 years before, had been accidentally killed in Holland, and, being embalmed, were sent to Scotland to be entombed. With still greater certainty we know, that an inhabitant of London, to enjoy an amity devised to his wife, in terms equivalent to as long as she should remain upon the earth, had her body embalmed on her decease, and was accustomed to exhibit it with great unconcern to strangers. In another recent instance, where a French officer had lost the object of his warmest affections by sudden death, in the prime of youth and beauty, he caused her body to be embalmed in the most skilful manner. The semblance of life in sleep was restored; even the bloom of animation was preserved. The body was constantly kept in a glass case in his bed-chamber, where it appeared as if only repose.

Although the art of embalming is seldom practised by the more civilized nations, it is not rare among those still comparatively rude. An anxiety to "sleep with their fathers" has animated the greater part of mankind; and where this has been precluded by the perishable condition of decaying bodies, the bones or the heart have been selected for interment in a chosen sepulchre. Thus, if one of the Abiponians, an erratic South American people, should decease at a distance from his principal residence, the body is converted to a skeleton, and carried along with the tribe, until there be a fit opportunity for inhumation. If some of the North American Indians lose a relative on a pressing march, he is interred; but when more at leisure, they return to despoil his bones of the putrid flesh, and convey them to the cemetery of his kindred. Perhaps a similar custom of carrying the bones of their leaders along with them prevailed among the Jews.

At Nukashiwa, one of the Marquessas, we are told by the late Russian circumnavigators, that embalment is practised at the present day. The body of the deceased is washed and laid on a platform, after which it is constantly rubbed during nine months with cocoa-nut oil, to repel putrefaction. By this continued application it becomes as hard as stone, and quite incorruptible. In twelve months, a feast takes place among the survivors, to thank the gods for having permitted the deceased to arrive safe in the other world, when the body is broken into pieces, which, being packed in a small box, is carried to the morai, or burying-place. Captain Cook had previously remarked, that the Otaheitians, by withdrawing the intestines, stuffing the body with cloth, and using cocoa-nut oil, preserved their chiefs a long time for public exposure.

We know that of old, a devout monarch or noble sometimes appointed his heart to be embalmed and transmitted to the Holy Land: or when one died in a remote country, it was frequently inclosed in a silver urn, and sent to the cemetery of his family, which is practised at the present day. Thus urns or cups containing hearts are occasionally discovered in vaults and churches, or even among the family archives long unopened. Such was the fact regarding the heart of Arthur Lord Capel in England, who suffered for his attachment to Charles I.; and very recently the heart of a young nobleman who had many years ago been killed in a duel, was found in the church of Culross in Scotland. It was wrapped in linen, and inclosed in a silver cup with a cover, but had greatly shrunk from its original size.

Somewhat analogous to this subject, is the preservation of the dead by simple desiccation, at Palermo in Sicily. There it is said none of the higher ranks are interred according to the fashion of other European nations, but consigned to the catacombs of a Capuchin convent about a mile without the city. After the performance of a funeral service, the body is dried in a stove heated by a composition of lime, and then placed upright in niches in the subterraneous galleries, clothed in its usual attire. Although they have remained there three hundred years, the flesh dried hard is still upon the bones, but the contraction and distortion of the features exhibit a hideous picture of mortality. The inhabitants pay frequent visits to their deceased friends in this repository, which some years ago is said to have contained a thousand bodies. It is wonderful how little of the animal substance remains in the human frame, thus intentionally or accidentally preserved. A mummy from Teneriffe weighed only 30 pounds; and the body of Robert Burybrough, Bishop of London, who died in 1404, weighed but nine pounds 270 years afterwards.

There are extensive catacombs near the city of Kiow, on the banks of the Dnioper, containing great numbers of bodies in a state of perfect preservation; but it is not known whether they have undergone any artificial process, or how long they have been there, though it has been conjectured that the catacombs were constructed in the tenth century.

Sometimes the progress of corruption is arrested by means which are little understood or explained. The bodies of travellers who perish in the sands of Arabia, or in the snows of the north, frequently remain entire. We have heard that on the hill of Busaco in Spain, the scene of a sanguinary contest a few years ago, some of the bodies of the slain are still seen in preservation. But more permanent preservation ensues with persons who are lost in moses, of which, besides others, a remarkable example occurred in the year 1747. In an extensive morass in the Isle of Axholm, in Lincolnshire, the body of a woman was found lying bent together, on one side, the head and feet almost in contact. From the figure of her sandals, and other circumstances, it was conjectured that her death had taken place 400 years previous to this discovery. It is not animal substances alone which thus resist decay, for nosegays and branches of bays deposited along with the dead, have preserved their verdure for ages.

EMBRYOPTERIS, a genus of plants of the class Diccia, and order Polyantra. See Botany, p. 338.

EMDEN, or EMBRO, a town of Prussia, and capital of the province of East Friesland. It is situated near the lake Dollart, and on the east side of the river Elbe, not far from its mouth. The town is large, strong, and well fortified, and consists of the Old and New Town, with two faubourgs. The principal public buildings are the Hotel de Ville, three Calvinist churches, and places of worship for the Roman Catholics, Lutherans, Mennonites, and Jews.

Emden has long been known as a place of considerable commercial importance. It was declared a free port in 1750 by the King of Prussia, who established here an East India Company, which was, however, abolished in 1759, and replaced by the ancient company for the herring fishery. This fishery employed 60 boats, and produced annually about 1000 tons of herring.

The harbour of Emden is large and commodious, and is capable of holding 400 vessels. By means of a canal upon the Elbe, the ships can come up to the Hotel de Ville. The following statement of the shipping will convey some idea of the state of trade at Emden.

In the year 1784, Emden possessed 273 vessels of the tonnage of 38,578, besides 43 vessels engaged in the herring fishery. In 1804, they employed 500 ships in the carrying trade alone. Linen cloth and hosiery are manufactured here, but to no great extent. The population of the town in 1785, was 7908, without reckoning the garrison; in 1802, the inhabitants amounted to 16,400. According to trigonometrical observations, Emden is situated in East Long. 7° 10' 1", and North Lat. 53° 22' 3". (w)

EMERALD. See Oryctonosy.

EMERSON, William, an eminent mathematician, was born on the 14th May 1701, at Hurworth, near Darlington, in the county of Durham. His father, Dudley Emerson, who appears to have been possessed of some little property, taught a school, and seems to have been a person of some information and genius. From him William received the rudiments of his education in reading, writing, and arithmetic, and a little Latin, perhaps as far as the Cordery or Beza's Latin Testament. It appears that he made some further progress in the learned languages afterwards, and received assistance in acquiring them from a young clergyman, then curate of Hurworth, who was boarded at his father's. In his early days he appears to have been idle and inattentive, and exhibited none of those symptoms of superior genius for which he was afterwards so remarkable. Indeed, so careless and inattentive to learning was he, at this period, that he was frequently heard to say, till he was nearly twenty years of age, that his principal and favourite employment for one season of the year, was looking after birds nests. But his attachment to childish amusements was soon to pass away, and as he advanced in years, his mind began to relish, and to be sensible of the charms and beauties of science. He went first to Newcastle, and afterwards to York, where he applied himself with considerable attention and diligence to the study of the mathematics, under the directions of schoolmasters whose names he always mentioned with respect. He used also to say, that his father was a tolerable mathematician, and without his books and instruments, his own genius would, perhaps, never have been unfolded. After his return from York he resided principally at Hurworth, where he continued to pursue his studies and amusements at intervals, till the time of his marriage, which happened about his 32d year. From this period we may date the commencement of his mathematical labours, or, perhaps, rather the communication of them to the public. What he had done before in this line was merely an occasional application for his own amusement, or for the exercise and employment of his leisure hours. But one of those accidents, which, Dr. Johnson observes, produce that particular designation of mind, and propensity to some certain science, commonly called genius, took place on this occasion, and added a powerful stimulus to his native thirst for knowledge and for fame. His wife was the niece of a Dr. Johnson, rector of Hurworth, vicar of Manfield, in the county of York, and a prebendary of Durham. A man, who, by practising surgery, and from the emoluments arising from his livings, had accumulated a considerable fortune.

Johnson had promised his niece, who lived with him, five hundred pounds for her marriage portion. Some time after the marriage, Mr. Emerson took an opportunity to mention this matter to the Doctor, and to remind him of his promise. The Doctor, who appears to have been a man destitute of honour with regard to his word, did not choose to recollect any thing of the matter, but treated our young mathematician with some contempt, as a person of no consequence, and beneath his notice.

Emerson's independent mind could easily have surmounted pecuniary disappointment, his patrimony, though not large, being equal to all his wants, but this contemptuous treatment excited his indignation. He went home, packed up his wife's clothes, and sent them off to the Doctor, swearing, at the same time, that he would scorn to be beholden to such a fellow for a single rag, adding, with great vehemence, that he would prove himself the better man; and, in order to demonstrate this, he determined to labour till he became one of the greatest mathematicians of the age.

Emerson made himself a perfect master of the whole circle of the mathematics; and having carefully planned and digested the work to his own satisfaction, he published, in the 42d year of his age, his book of Fluxions, and at his first appearance as an author, he obtained a respectable place among contemporary mathematicians. Having thus secured his fame upon a firm and solid basis, he continued from time to time to favour the public with other valuable publications, on several branches of the mathematics, a list of which may be seen in an excellent and well written account of his life, by the Rev. W. Bowe, prefixed to his Tracts, from which the chief
part of this account is taken. He was also a frequent correspondent to the Ladies Diary, a work which has greatly contributed to the diffusion of mathematical knowledge, and added a stimulus to youthful exertion.

Emerson was, in person, somewhat below the middle size, but firm, compact, and strong; his face was of an open countenance, with a rude and complexion, a keen penetrating eye, and an air of eagerness of look that was very expressive of the texture of his mind. His dress was simple and plain, or, perhaps, some might say slovenly and grotesque; but Emerson was a man of independent mind, and, therefore, was no way uneasy about the appearance he might make in other people's eyes — he knew his own value as a man, and disregarding the opinion of the superficial observer, who places all worth in outward appearances, he claimed kindred, and wished to be ranked only with the intellectual nobility. His diet also was as plain and simple as his dress; and his meals gave him little interruption in his studies, employments, or amusements. During his days of close application he seldom sat down to eat, but he would make a cold pie, or make up any kind in his hand, and retiring with it to his place of study, he satisfied his appetite for knowledge and food at the same time. And when his stock of groceries, or other necessaries in the article of house-keeping, run low, on Monday morning he took his wallet, which he flung obliquely across his shoulders, and set forward to the market of Darlington, three miles distant, and after providing the necessary articles, he would set himself contentedly down in some public house for the remainder of the day, and frequently for the night too, sometimes not returning home till late on Tuesday or Wednesday: he remained talking or disputing on various topics, mechanics, politics, or religion, according to his company. Being seldom possessed of any stock of ale at home, he would sometimes indulge in these protracted potations at Hurworth, and he was always remarkably exact in appportioning each man's share of the reckoning.

His style in conversation was generally very abrupt and blunt, and often ungrammatical, and this led many people to suppose that he could not write his own papers; but this was no rule to judge by, as we cannot with any degree of certainty determine how a man will write from his conversation. It will ever be a lasting reproach to the rich and great of his day, that such a man as Emerson was suffered to end his days in obscurity. It is true he possessed a small farm, which rendered him in some measure independent; but his abilities deserved greater encouragement, and it is probable his name would scarcely have been known in the republic of letters, but for the friendship of Mr Montagu, who first recommended him to that eminent bookseller Mr Nourse of London, who engaged him on very liberal terms, to furnish a regular course of the mathematics for the use of students. It does not appear that he was very anxious about literary distinctions or titles: He did not wish to be admitted a fellow of the Royal Society, because, he said, it was a hard thing that a man should burn so many farthing candles as he had done, and then have to pay so much a year for the honour of F. R. S. at his name. Emerson, like other men, had his foibles and defects. He was singular and uncouth in his dress and manners, and hasty and impetuous in his temper. But whatever failings he had, they were more than overbalanced by his virtues. He had a firm and independent mind, that could not be brought to submit to anything mean, base, or ingenious; a pure, genuine, and ardent love of truth, and a detestation of falsehood of every species. His honesty and integrity were such, that all who knew him reposed in him the most implicit confidence, and no man could ever justly complain that Emerson had deceived him.

His abilities as a mathematician will not rank him amongst those of the first class. Though he cannot be said to have added any remarkable discovery to the science, yet when we take into consideration the many valuable works which he has written, and the astonishing progress which he made in every branch of the mathematics, perhaps without any assistance but the exertions of a vigorous mind, we cannot fail to regard him as a mathematician of wonderful acquirements, and as entitled to the gratitude of posterity: He died May 21, 1782, and lies buried in the churchyard at Hurworth, at the west end of the church, against which is erected to his memory a stone, with a short Latin inscription; but his works furnish a more splendid, as well as a more durable monument to his memory and fame. For a more detailed account of the life of this celebrated mathematician, and of his works, see his Treats, new edition, printed in London, 1793, by F. Wigrave. (q.)
their migrations were frequent, but they were not extensive, and a large river, an extensive desert, or an arm of the sea, commonly proved limits to them.

The ancient inhabitants of many of the temperate regions of the globe were accustomed to such easy migrations; and these have been also practised, in modern times, by the tribes that occupy the vast plains of Tartary.

The frequent passage of trading parties and caravans, through a country peopled by such wandering hordes, has proved a temptation to robbery, and Lis added this feature to the character of many of the Arab tribes.

Emigration to remote countries is an occurrence more serious, being accompanied with greater danger and difficulty. It is particularly affecting when those who emigrate have no expectation of again returning to their native land; yet there is evidence of many such occurrences in remote ages, and the discovery of the New World has rendered them frequent in latter times.

The local attachments of the natives of Switzerland are so remarkable, as to have become proverbial; yet, in former times, the people of that country deliberately resolved to abandon it, and persisted in that resolution. Ambition had led a distinguished individual to exert his influence among them, for the forming of this resolution, but they persevered in it after he was gone, and were prevented only by the superior discipline and power of the Roman people. In altered circumstances, it therefore appears, that in the same country, the people, in general, may possess the strongest local attachments, or may become resolved on a general emigration.

By this it appears, that moral causes may induce a nation to emigrate, and that political influence may be employed extensively and successfully with this view. Natural causes do not appear to be so prevalent, though it cannot be doubted that their influence may have some effect. The Swiss and the Scottish Highlanders inhabit the most rugged countries in Europe, and yet they possess as warm attachments to their native lands as any nation on earth; but the Swiss occasionally quit their country, to serve in small bodies as warriors in other lands. And frequent emigrations have taken place from the Highlands of Scotland without any hope or prospect of return.

For these vast migrations of brave yet barbarous nations, by which the Roman empire was overwhelmed, we may assign very natural causes. The Romans had become a wealthy and a dissipated, and they were therefore a degenerated people. Their luxury and weakness at once tempted and encouraged their invaders, who emigrated in great multitudes, hoping to obtain at one time the glory of conquest, and settlements in a richer and better country.

Accident seems to have sometimes opened a way for emigration. The occasional passage of some river or sea, of some forest or desert, or chain of mountains, which had served as a barrier, has opened a way at one time to the noble spirit of discovery, and the insatiable spirit of cupidty and ambition. Exaggerated reports have commonly been made of the new discovered country, and if these have been employed in artful hands, in order to excite emigration, great effects have taken place.

Savage tribes have often been driven to emigrate by war. Jealousy of their liberty, and wanting only a suitable extent of territory in which they may live by the chase, they can readily remove out of a land in which they possess no cultivated fields, and no dwelling but such as are slight and temporary. This view of things furnishes an explanation of the numerous, extensive, and yet seldom recorded migrations which have taken place among the tribes of North and South America.

The spirit of colonization was nearly as ardent among the commercial and powerful cities of antiquity, as it is in modern times; but the means of gratifying that spirit were more limited. If the use of the mariner's compass had been known, discovery and colonization must have extended themselves much earlier over the world. It is rather to be wondered at, that occasional storms and other accidents had not earlier and more widely conveyed the knowledge of nations to each other; but while the ocean intervened, and seems durst not venture to sail much beyond the sight of land, extensive emigrations to remote parts were not practicable.

That considerable migrations, notwithstanding those difficulties, have occasionally taken place, is believed on grounds apparently good. Whatever it may be that has impressed a strong and easily discriminated character on the different races of mankind, it seems undeniable that some of these races which belong to one quarter of the globe have found their way into another. History does not record the time, nor the means of these migrations; but an established resemblance in features, in stature, and complexion; in habits also, and even in language, appears demonstrative of the fact.

Few subjects of discussion can be more interesting than it would be to trace the causes and means of such migrations; but as neither the moral, nor the natural, or political causes of such events can now be certainly ascertained, it seems better to restrain curiosity within due bounds, and to attend particularly to events which cannot fail to be interesting in this kingdom, especially to those parts of it from which emigration has most frequently and extensively drained away the inhabitants.

Very discordant and even opposite opinions are held by different persons, with respect to the causes and the consequences of emigration from the Highlands of Scotland. The author of this article has long attended the subject; he has no disposition in these matters to gratify, no interest to promote, and no end to accomplish, the views that he submits he conceives to have been fairly impartially formed.

Many of the Scottish Highlanders resort to the different colonies of Great Britain, with a view to employment or fortune; and many betake themselves to the lower districts of Scotland, or to England, and reside mostly in the chief towns, or cities, with similar views.

It is not to these persons, however numerous, that this article is intended to apply: They have migrated as individuals for private objects; and their choice of a place of residence, or mode of employment, is not an object of public attention. In many respects, their migration has been productive not only of private but of public advantage.

But when vessels are hired and chartered, for the purpose of conveying great bodies of emigrants from a country but thinly peopled; and when the destination of these is to remote countries, to which it is often difficult for them to procure a passage, and from which there is no prospect of their returning,—the matter becomes, in no slight degree, interesting to the public.

The history of emigration from the Highlands of
Scotland, the cause of it, the consequences, and the means of prevention if such exist, appear to demand particular notice.

An historical view of Scotch emigration, would not go back much above half a century. The discovery of the vast regions of America, was accomplished ages before they could be colonized. Few attempts are attended with more difficulty than the peopling of a distant wilderness. The superior wealth and population even of England, stimulated by a spirit of enterprise, and countenanced by the sovereigns of her distinguished country, made subsistence in a mode which proved abortive a gross want of knowledge of those remote countries, and perseverance, at last succeeded.

The Scots disappointed and indignant at the fate of their favourite colony of Darien, were not soon or easily induced to embark in any similar design; and it is not probable that emigration would afterwards have taken place from that country on a large scale to America, if there had not occurred a great alteration in the mode in which lands were let and occupied in the Highlands.

The introduction of sheep-farming on the great scale into that part of Scotland, undoubtedly occasioned the removal of a great proportion of the inhabitants. Whether this effect was unavoidable or not, may be a subject for consideration in a posterior part of this article; the fact is undeniable.

In former times, the farming stock of the Highlands consisted principally of horned cattle, and these not only required more people to attend on them, but furnished the means of subsistence in greater variety than sheep. A few straggling goats also appeared there; and a very small number of sheep, of the small dun faced and fine woolled breed, now almost extinct. Large tracts of country were left by the great landholders, to be occupied mostly as forests for their deer. The chase furnished some degree of employment and subsistence; the cattle were conveyed in summer to the high grounds or heathings, in so far as these were accessible, and then brought down to the straths or vales on the approach of winter. From these were obtained considerable quantities of milk, butter, and cheese; and, though seldom well fed, there was a proportion of the cattle that became fat, and were slaughtered for use. A very severe winter and spring occasionally occurring, consumed the little stock of provender that could be raised in the country for such multitudes of cattle, and great numbers of them perished; while the surviving animals were so reduced, as to become of little value. The manner of so many beasts, however, enabled the people to cultivate many spots of land in all parts of the Highlands, and, one way or other, there were means found for supporting a considerable population. But under such a system, the Highland mountains were occupied by a stock not adapted for them, and of this kind of stock there were more than could be preserved during the severe months on the straths. In short, the country was at one time improperly stocked, and overstocked. It required many articles, the produce of other parts of the kingdom; but it raised by much too little to serve as articles of exchange by export.

The introduction of large flocks of sheep to stock the mountains of the Highlands was rather hazardous. Vast numbers of birds and beasts of prey existed there, and proved extremely destructive to them; and the native inhabitants were naturally jealous and hostile. By degrees, however, it became quite apparent, that sheep were the safe and proper stock of those mountainous regions. They could wander in safety where cattle could not go; they fed and threw where cattle could not have subsisted; and in winter they could feed on the coarse pastures, or dig through ordinary falls of snow, without requiring dried provender. But what turned out of most importance, in point of consequences, was this, that the produce of sheep flocks might be mostly exported, and commanded a regular and ample price in other parts of the kingdom.

All these particular co-operated in recommending preference in the systems of sheep husbandry; and the last circumstances appear to have been decisive. Landholders would not give up the advantages to be derived from such a profitable stock, and as the produce was destined mostly for exportation, many of the inhabitants were obliged to remove.

A very liberal increase of rents, was the invariable consequence of introducing sheep stocks: They were safer, they required much less attendance, and the returns were adapted to go regularly to the markets of the south of Scotland and of England at little expence. The numerous population could not then be supported, and their labour was not much wanted; emigration of course began, and went on.

It happened, that at this critical period uncommon encouragement was held out for new settlers to assist in peopling the wilds of America. Highlanders dispossessed of their farms, having no immediate view of employment in their own country, and not well adapted nor much inclined to engage in manual labours in other parts of the kingdom, were naturally attracted by the prospect of becoming, on easy terms, proprietors of better lands in the colonies. A portion of inclination, on account of their removal from lands which had long been occupied by their ancestors, naturally mingled in their feelings on such an occasion. Mutual understanding led them to courage and perseverance. They rose above those tender feelings of attachment to their native soil and country, for which they had been long distinguished; and they freighted vessels, and embarked for America.

The plastic genius and vigorous constitution of such Highland a people, rendered them uncommonly valuable settlers in a new country. They were equally fitted for labour and for mutual defence, and were therefore encouraged and courted to remove. The success of those who had first emigrated, likewise encouraged others to follow their example, as they also were in succession removed from their possessions, and flocks of sheep introduced. In a short time, land proprietors in the Highlands were reduced to the necessity of deciding between their feelings and their interest. If they yielded to the former, they devised such measures as they could for preserving their people; if they gave way to the latter, the people had scarcely a choice left them,—they were obliged to emigrate.

To describe the affecting scenes which occurred, alternative when a vessel charted for America arrived, and when lives of the several hundreds of these people were preparing to quit their proprietors for ever that land to which they were ardently attached, would be a painful task, and in the altered views and circumstances of those emigrants it is now unseemly. Many of their descendants in the New World, have long ago ceased to possess those warm attachments for the land of their fathers; but others residing in the British colonies, retain the noble spirit of their ancestors, and employ it with distinguished effect in their defence.

Accordingly the number of emigrant cargoes increased, it began...
EMISSION.

The emigrant bill, which passed in 1803, has a tendency rather to prevent imposition on the part of ship contractors, than to prevent emigration. The securing of ample space and provisions, removes the first and most formidable danger which emigrants had to dread. No doubt they must pay more liberally for so much better accommodation; but this difference is not so great, as to prevent any considerable number who had it at heart to embark. As a measure of policy, therefore, its influence cannot be great, but it must obviously have considerable effects as a measure of humanity. In one view, by discouraging artful and insidious contracts, it may operate in both characters.

A more powerful bar to the progress of emigration is presented at this time (1814), in the second American war. It is also to be expected, that the gradual diminution of the wilds of America must proportionally reduce the demand and encouragement held out for settlers; but this will depend on the arrangement of territory at the conclusion of the war, and on the further progress of the policy of colonizing.

The most pleasing means that can be employed for the purpose of preventing emigration must be devised at home; and this has not escaped the attention of a liberal and enlightened legislature.

A rugged and uncultivated country, destitute of proper means of communication, can hardly be expected to furnish means of subsistence for a growing population; and it cannot be supposed, that any country, in such a state, can afford to pay for such expensive works as canals and roads, capable of opening it up. The Highlands of Scotland were precisely in that state, when the great and liberal plan was formed, of opening a passage from fort George by fort Augustus to Fort William, by means of the Caledonian Canal. This great undertaking must necessarily require some years to complete it; and afterwards time will be required, in order to render it extensively useful. The important objects of this work, are likely to be greatly promoted by the invention and use of steam-boats employed on the lakes. In the mean time, a field of useful labour is opened within that country; and in the end, it cannot be doubted, that very great advantages will be derived from such a splendid national work.

In prosecution of the same general plan, the Highlands of Scotland have been intersected by roads in the most useful directions, executed under the authority of parliament, partly at the public expense, and partly at that of the landholders of the country: and provision is made also for keeping these roads in due repair. Thus there is laid a great and promising basis of public industry and improvement in that country; and if unforeseen events do not prevent the proper use of it, there can be little doubt, that such improvements as are suitable to the country will naturally follow; and these must have a powerful effect in preventing the necessity of such extensive emigration.

The navigation of the Caledonian canal is not only well defended by the chain of forts at the two extremities and the centre of it; but the lakes not being liable to freeze, there is an advantage not commonly to be obtained in canals, which may be expected from this property in its waters. Vessels of great burden, it is intended, shall have depth of water to convey them from the Murray Frith to the Linneleoch, and thence to the Sound of Mull and the Atlantic. A communication thus opened between the eastern and western seas, without going round by Cape Wrath, or encountering the dangerous passage of the Pentland Frith, must be

PUBLIC ATTENTION DRAWN TO IT, AND MEASURES DEVIRED FOR PREVENTING THE CRUEL ABUSES PRACTICED.
Emigration.

extremely useful to the commerce of the kingdom; and the transit of merchandise and vessels through the canal, must eventually tend to the improvement of the country.

Placing of forest trees on the great scale may now be accomplished with every prospect of a free market, and ample remuneration. This alone, over a country such as the mainland of the Highlands, may, in time, be an improvement more than sufficient to repay the great expense incurred by the public in opening it up. In the mean time, planting on a liberal scale will adorn and shelter the country, and may become a source of high attraction and elegant amusement for the landholders. A supply of timber in sufficient abundance in the country, and the use of water-borne coal, may naturally be expected to furnish means for introducing manufactures, especially that of wool, which is raised in great abundance in the Highlands.

Facility of conveyance of lime and farm-produce, must naturally suggest to the people of the country to open quarries, and burn the limestone that abounds in many districts; and there cannot be a doubt of a market, on a growing scale, for the returns.

Trade and population require supplies of fat cattle and sheep; and, of course, many would, in improving circumstances, be fattened within that remote district. This new demand would improve the general style of farming. Green crops and inclosures would be necessary on most farms; and these naturally associate with corn, and require the labours of an increasing population, furnishing also the means of their subsistence.

Growing interest and activity naturally discover new sources of employment for the people. The iron forges of the Highlands might be renewed on a greatly improved and enlarged scale; mines and minerals of different sorts might be worked to advantage; quarries of marble, blue slate, or useful stone, would probably be opened; and this country, so long threatened with desolation, might smile, and might be able to rear and support an augmented population.

Ignorance alone, or prejudice, can maintain, that sheep farming is inconsistent with such views in the Highlands. Even this legitimate system is imperfect and incomplete, without cultivation. Plantations to shelter the sheep stocks, (which they do admirably, and without being injured, when of sufficient age,) are necessary to the prospering of the improved breed of sheep; and no stock or breed of sheep can be brought to perfection, without the benefit of green crops to fatten, and of inclosures to separate them, and to enable the farmer to manage them to advantage. The best cultivated pastoral districts present such an arrangement; and they discover such a due proportion of black cattle as is necessary to secure the means of comfort and of improvement, together with the largest returns from the soil. The milk, hides, and tallow of these, afford comfortable means of employment and of subsistence; and a much greater number of people is maintained, than could have been supported under an exclusive sheep system. Woods, cattle, and the mixed culture of hemp and flax, naturally present extending advantages in prosecuting the fisheries, and in attending to various useful manufactures, besides promoting the comfort of the inhabitants, and co-operating with the other modes of improvement in preventing emigration.

The Highlands, thus opened up and improved, would furnish useful employment and ample subsistence for a much greater number of inhabitants than they have ever yet contained. It is true, that the remarks made above apply chiefly to the mainland, and that other views would be necessary in respect of the northern and western isles.

If the mere crofting system were all the resource that is now accessible to the Highlanders, it could not much be depended on. There is a considerable waste of time and labour in it, and the means and skill employed in this way are commonly deficient. No doubt, it may in some degree be useful, particularly if the crofters can also find occasional employment as labourers to the farmers; but an altered and improved system of farming appears to open the great resource on the mainland. The rise of a competent number of inclosures, and a proper stock of cattle, together with calcareous manures and green crops, and corn of course, properly selected, and cultivated with judgment, would not only furnish employment and subsistence, but would greatly increase the produce and value of those extensive tracts which are capable of improvement; and the consequence would be, that the country at large would be converted from a sheep-waste into a fertile alpine territory. It would then be in the power of landholders, at a moderate expense, to clothe it with rich and ornamental plantations; and afterwards that country would present many inducements and attractions to reside in it; and manufactures, together with the fisheries, would more certainly be supported. In short, there would no longer be any occasion for the people to emigrate in bodies from the mainland of the Highlands.

With respect to the isles, they already possess two State of the considerable sources of employment—the fisheries and the manufacture of kelp; but these isles are generally naked, without fences, and, of course, almost in the state of mere wastes, excepting only the lands in tillage; and these are incapable of improved cultivation while they are open every winter. The making of kelp, and attention requisite to the fishing business, being commonly in the hands of those who labour the soil, correct and regular cultivation is obstructed, and scarcely practicable. There appears to be no remedy for this, until a regular system of inclosures be introduced; and then it is no exaggerated supposition, that the sheep stocks may become triply valuable, and the cultivated soils greatly more productive. After this plan has been adopted, the regular tillage of the arable will naturally become the creed; and the increased value of proprietors will accompany inclosures, the labour will divide itself into the proper seasons, and fewer hands, regularly employed, will perform it. What encroachments may then be made on the waste lands cannot be computed; but they will naturally be of considerable importance and extent. Islands possessing a great extent of low situated lands, numerous herds of black cattle, and calcareous manures in many parts of the land or the shores, together with seas-weed, are subjects adapted by nature for improvement; and the climate is not very unfriendly to early corn, while it suits admirably for turnips, potatoes, and grass with seeds. On the larger islands, and on some of the smaller, stone may be obtained for exterior fences, and sometimes also for subdivisions; and on these isles where stone cannot be got, ditches well designed, and properly executed and preserved in repair, with such hedges as may best answer according to circumstances, may operate at once as fence, drain, and shelter.

This general and improved system is no speculation. It is already introduced with great advantage by some of the most intelligent and public spirited proprietors.

Artificial manures would be encouraged.

An improving style of agriculture would follow.

Quarries and mines.

These advantages and improvements naturally associate with each other in other districts of the kingdom.
of estates in these isles; and it proves an increasing source of employment and subsistence for the people. Judicious planting of suitable parts naturally accompanies a system of this kind; and, by selecting proper situations, planting the slips with suitable trees, and then putting in seedling trees in large bodies, there is much less risk of their failing by the breeze. No person acquainted with the country can hesitate in believing that profitable employment, and growing means of support, would thus be furnished, for all the present inhabitants of the isles; although they should not be occupied with kelp at all, or with fishing. The great object is to get them trained to labour so as to perform it well, and with dispatch; and after this, it will be in the power of landholders to arrange the leases of their lands, with views of regular and progressive improvements.

Kelp-making and fishing now connected with crofting.

A growing population, in the mean time, can furnish hands for the kelp-making and the fishings; and these are, perhaps, the people that ought to be accommodated for the present with croft lands. In time it may become expedient to separate these professions, finding other occupation for the people employed in these departments, when they are not engaged in them. Such a resource may be naturally obtained within the country in jobs or piece work,—if they are trained to make use of their spare time, in building dykes, cutting drains or ditches, planting trees, quarrying stone or slate, making roads, paring and burning waste lands, preparing composts for meadows and other purposes. The opening of the country by roads and canals may further introduce the manufacture of wool, or flax, or hemp, and other useful branches of the arts; and even in the low and smaller isles, ample occupation may be found for the inhabitants.

Such a system would impede emigration, and in due time bring it to an end.

Consequences of emigration in many ways hurtful.

Discourages inhabitants, and prolongs the deplorable state of the country.

Removes a supply of men for the army and navy.

Counteracts the purposes of public works.

Impedes the progress of the fisheries.

Consigns the Highlands to a sheep waste.

Happy effects of a general and rational system of improvement,

In promoting the interest of all classes.

In causing emigration to cease.

SHEEP WASTE. Even timber for dwelling-houses, and materials to build them, could hardly be expected in a remote and rugged country, drained of most of its people. With opposite views, the subject of emigration has been treated with considerable ability by various writers; but the real history of emigration, its causes and effects, and above all, its prevention, have scarcely been understood. Interested or partial views of a subject are well known to mislead authors of eminent talents; and a person of narrow conceptions, who could view only the present state of the Highlands, might be surprised into the opinion that the country cannot support a growing population. But if our views be extended to what the state of this country may and ought to be, we must resist and at once dismiss that idea. Views of improvement may be cherished even by a landholder, which are not sufficiently liberal towards the people at large; but the true plan of occupation and improvement in that country must embrace enclosures; and then it may become the basis of a system, equally judicious and profitable to all concerned.

Even the prospect of such a system, as would steadily and progressively add to the resources of that remote but interesting part of the British territory, is pleasing to the mind. It would certainly increase the value of the lands, and add materially to the comfort of the inhabitants. Opened by means of the great canal and the numerous roads intersecting the country, together with its various and extensive seas, and their indenting arms; enjoying the benefit of well planned and executed fences, at once inclosing, draining, and sheltering the numerous fields capable of being gained from extensive wastes; adorned with rising plantations of forest trees, and accommodated with the timber and the shelter they would afford; possessing well cultivated fields, enriched by the manures which abound in the country, and productive in early grain, and green crops; having improved stocks of the valuable breed of Highland cattle, together with sheep of superior quality, to the maintenance of which an improved system would be adequate; and possessing a population growing at once in point of numbers, industry, and comfort, equal not only to the labours of husbandry, but also to the fishings and various useful branches of manufacture; while commerce opened the way, and gradually furnished the means to acquire wealth; with all these growing advantages in their favour, the Highlands and isles of Scotland would possess many attractions; and the last and melancholy resort of a people driven to despondency, emigration, would cease.

EMISSION OF HEAT. See Heat.

EMISSION OF LIGHT. See Optics.

EMOY. See China.

EMPEDECLES, was the son of Meto, a wealthy citizen of Agrigentum in Sicily, and flourished about the 84th Olympiad, or 440 years before Christ. It is not probable that he was born at so early a period, as to have been a hearer of Pythagoras; but he adopted the doctrines of that philosopher, and appear evident, from his own tenets, to have belonged to the Ionic school. He was remarkable for the variety and extent of his attainments; and his name became so celebrated, that when he went to the Olympic games, the eyes of all the people were fixed upon him as one of the wonders of the age. He excelled in oratory, upon which he was the first who gave lessons in Sicily; and the celebrated Gorgias Leontinus was one of his pupils.
Empedocles. He was possessed of considerable poetical talents, and has been supposed to be the author of that ancient fragment, which bears the name of "The Golden Verses of Pythagoras." The fragments of his verses, dispersed through various ancient writers, have been collected by Henry Stephens in his "Poetry of the Philosophers;" but, if credit may be given to the high commendations bestowed by Aristotle, Lucretius, and others, upon his poetry and eloquence, the greater part of his productions in both these departments must have perished at an early date. He was not less distinguished by his skill in medicine, and seems to have owed much of his influence and reputation to the wonderful cures which he was understood to have performed. These he did not hesitate to pass upon the multitude as the effect of magic, or of some miraculous power; and pretended not only to cure all diseases, but to drive away old age, and to restore the dead to life, to raise or moderate the winds, to produce rain or heat, and to check the progress of epidemic diseases. He may be supposed, indeed, by his medical and physical knowledge, to have rendered several actual services to his country, as when he is said to have removed an enemy by fumigation, and thrown a chasm in a neighbouring mountain, from which he observed pestilential effluvia to proceed, and another by correcting the corrupted waters of the river Seleus, by directing two small streams into its channel; but he appears to have taken advantage of the ignorant admiration which he received, and is reported to have been highly gratified with the divine honours which were paid him on some of these occasions. He made a liberal use of his large paternal estate, especially in giving dowries to young women, and procuring them suitable marriages. He took an active interest in the political state of his native city, and was a determined enemy to tyrannical measures, and a zealous advocate for the popular form of government. He at length became an object of so great veneration to his fellow citizens, that they were ready to acknowledge him as exalted above the nature of man, and finally offered to invest him with the sovereign power. Preferring the simplicity of private eminence to the dispensations of public life, he declined to accept the office and title, while, at the same time, he evinced a strong disposition to assume all the distinctions and appearance of royalty. Clothed in a purple robe, crowned with laurel, with brazen sandals on his feet, with long flowing hair, with a grave and commanding aspect, habitad, in short, like the gods, and accompanied by a number of attendants, he was fond of parading the public ways, and receiving the plaudits of the people. He is said by Aristotle to have died at sixty years of age; but very various accounts are given of the manner of his death. Some authors relate, that he broke his leg by falling from a chariot, which brought on a mortal distemper. Others say, that he terminated his own existence by throwing himself into the sea, or by strangulation with a rope. Another account affirms, that, in his anxiety to examine the crater of Mount Etna, he advanced too far, and accidentally fell into the burning gulf. While another report bears, that, after a sacred festival, he ascended Mount Etna during the night, and threw himself into the volcano, in the hope that, the manner of his death being unknown, he might afterwards be accounted a divine person; but that one of his brazen sandals having been thrown out in a subsequent eruption, his mortality was sufficiently confirmed.

But the most probable opinion is, that, as Timaeus relates, he went to Greece about the latter part of his life, and never returned to his native country, so that the time and manner of his death was never certainly known. A statue was erected to his memory at Agrigentum, which was afterwards carried to Rome; and the inhabitants of that city, even in the time of Lucretius, made it their highest boast, that it had given birth to so eminent a person as Empedocles, whose poems particularly they still regarded as oracles. Of the few of his sayings which have been preserved, the most frequently cited is his reproof of the luxurious manners of the Agrigentines, namely, that "they pursued pleasures with as much eagerness as if they were to die before to-morrow, and that they built houses with as much magnificence as if they were to live for ever." His philosophy, as far as it can be collected from his fragments, is evidently rational; that the first principles of nature are of two kinds, active and passive; that the active is unity or God, a subtle ethereal fire, intelligible and divine, which gives being to all things, animates all things, and into which all things shall be finally resolved; that one spirit thus pervades the universe, uniting all created beings to itself and to one another, and that it is therefore unlawful to kill or eat animals, which are allied to us in their principle of life; that the passive principle, viz. matter, is divided into round corpuscles, indefinitely small, originally eternal, and never capable of being annihilated; that these corpuscles, being put into motion by the intellectual fire or divine mind, the homogeneous particles united by a principle of affinity, and the heterogeneous separated by a principle of discord, and thus formed the four elements, fire, earth, water, and air, of which all bodies are composed; that the world is one whole, surrounded by the heavens, which are a solid body of air crystallized by fire, the sun a fiery mass, the stars fixed in the crystal of heaven, while the planets wander freely beneath; that many demons, emanating from the divine nature, inhabit the region of the air, and administer human affairs; that the soul of man consists of two parts, the sensitive, produced like the elements, and the rational, a demon sprung from the divine soul of the universe, and sent down into this world as a punishment for crimes committed in a former state, to be purified by transmigrations through animal and vegetable bodies; that he distinctly remembered himself to have been successively a girl, a boy, a bird, a fish, a shrub, and, lastly, Empedocles; and that all nature is subject to the immutable and eternal law of necessity. See Cudworth's "Intel. System;" Stanley's "Lives of the Philosophers;" Fenelon's "Lives of the Philosophers" translated by the Rev. J. Cormack; Castellani's "Phil. Medic. Hist.;" and Brucker's "Hist. Phil." by Enfield, vol. i. (q).

EMPETERUM, a genus of plants of the class Diccia, and order Triandria. See Botany, p. 335.

EMPLEUNON, a genus of plants of the class Monocotyledons, and order Tetradria. See Botany, p. 324.

ENAMEL is a substance of the nature of glass, but differs from it principally in two points: first, in being more easily fusible, which quality is given to it by the manner in which the flux is compounded; secondly, in having a large proportion of either earth, or metallic oxide, united with the flux, to produce opacity. Some enamels are, however, very transparent, possessing...
The best enamel that can be had for the purpose of making large plates for painting pictures upon, is the Venetian white opaque, with the name of Bertolini stamped upon the cakes, which cakes in general weigh about two pounds each. This article has not been imported for some years past, owing to the exclusion of the British trader from the continent. The writer of this article has, however, been informed, that the maker of the best white enamel, whose name we have just mentioned, fell a sacrifice to French tyranny during their struggle for power in Italy and Naples. That this valuable article was the sole production of an individual, the manufacture of which was unknown to any but himself, may be inferred from the non-importation since the change of government in Italy, although every exertion has been used by those interested in the use of it, to obtain it at any price.

When enamel could be brought to England without restriction, it was generally sold for about six shillings per pound; but as it grew scarce, 30 shillings per pound was given, and, at the present time, it is as high as fifty shillings. This high price proved a great stimulus to those, who knew anything about the nature of its ingredients, to exert themselves in their endeavours to find a substitute, and numerous were the trials of various persons to make an imitation. All attempts, however, were ineffectual, until, very lately, when Mr Griffiths, of Round Court, Long Acre, London, succeeded in producing a hard enamel, superior to the best Venetian in whiteness, and much more valuable to the dial-plate makers. But the Venetian is still preferred for fused plates, used for portrait and historical paintings; and, as these plates have always a coat of pure flux laid over the enamel, upon which the colours are laid, it requires a peculiar texture in the enamel, so that when the flux is melted upon it, a partial separation or cracking should not take place, which arises from the unequal expansion of the two substances. We have no doubt that the colouring material used with the flux to produce the white Venetian enamel, is the pure oxide of tin, commonly called putty. The manufacturers of putty in London, are in the habit of using 30 per cent. of lead mixed with the tin, which assists the oxidation, causing it to proceed much faster than when the tin is used alone; but the article made in this manner has a considerable tinge of yellow, which renders it useless for the purpose of enamel, although it may suit the lapidary or stone mason equally well as if it was made pure. (r.e.)

ENAMELLING, the art of covering thin plates of metal with the substance called enamel. As this curious art is carried on to a considerable extent among the manufacturers of watch dial plates, we shall give our readers a general idea of the art of enamelling, by explaining the nature of their manufacture.

**Dial Plate Manufacturing.**

Dial plate making is divided into hard enamelling, in which the surface of the plate is covered with hard or Venetian enamel; and into glass or soft enamelling, in which the surface of the plate is covered with the English soft glass enamel, which is always considered much inferior to hard enamelling.

The metals that suit this kind of enamelling best, are fine gold or fine copper; the former may be had from Enamelling any goldsmith, the latter at the flatting mills, known by the name of enamellers copper. It is necessary to caution persons unacquainted with the art against using the copper too thick, as, in that case, the plates would crack in the fire.

The slips of copper being cut into square pieces, put them into a clear fire, till they have attained a red heat; when cold they are forced into the intended shape of the dial. Before proceeding, however, to explain this process, we shall here introduce a description of the tools required in the operation.

1st. The dies are small circular plates of brass, about ¼ th of an inch thick. Their edges should be turned a little conical, and in their centres should be holes nearly as large as those to be made in the dial plates. An enameller ought to have at least forty of these, from 3ths of an inch, up to ½ inches diameter, observing that the gradation from one size to another should be exceedingly small, having three sizes between every division on the gauge. See Fig. 1. of Plate CCLII.

2d. A round ended punch made of steel wire, about ¼ ths of an inch thick and ¼ long. This should be fixed in a convenient handle, and is then fitted to punch up the copper into the centre holes of the dies. See Fig. 2.

3d. A clock maker's round broach. This should be firmly fixed into a strong handle, being used to burrish up an edge to the copper, and likewise to square up the centre holes. See Fig. 3.

4th. A die or block, to set the copper of the desired concavity. This should be turned of box or any other hard wood, and should be a little larger in its diameter than the largest brass die. This must have a hole through the centre something wider than the hole in the dial plate. See Fig. 4.

5th. A large pair of scissors to cut the copper with. Horse scissors are most proper for this purpose.

6th. A setting spatula, which should be made of steel wire, about ¼ ths of an inch in diameter and 5 inches long. One end of this should be bent flat and thin. The end so prepared is then to be filed a little round, and the flat part bent so as to form a segment of a circle, somewhat smaller than the curve of the setting die. The outer part of the curve should then be smoothed on an oil stone, and the tool is fit to be used. See Fig. 5.

7th. A smooth needle maker's file, used for filing the plated wire, which will be hereafter explained, and likewise the edge of the copper, after it has been burnished up to the edge of the brass die.

8th. A small steel point, which should be rather stouter than a stocking needle, used for marking the place where the feet of the dial should be put, and other purposes to be described. See Fig. 6.

9th. A large soldering lamp, which should hold at least a quart of oil. This must have a cylindrical spout for the cotton, at least one inch and a quarter in diameter, that the oil may have free access to the lighted end of the cotton. See Fig. 7.

10th. A pair of corn tongs, or tweezers. These are so well known as to need no description.

11th. A blow pipe for soldering the feet upon the copper, of a convenient length, and the hole a little more open than for other purposes.

12th. A watchmaker's glass and dial gauge. See Fig. 8.

13th. A pair of nippers to cut the feet from the plated wire.

The tools being ready, the workman should proceed
to measure the frames of the watches; and supposing that he finds the frame to correspond with one of the divisions on the gauge, he should choose a die half a size larger, as the dial must always be one size larger than the frame, which will be the case when the thickness of the copper is included. It will be found, if all is conducted according to our directions, that the dial, when completed, will extend over the frame just enough to fill the groove in the inner case of a watch, which will be turned for that purpose. If the dial is to be made to a brass edge, the die should be full one size less than the inner rim; for as the dial has to lie within the rim of the edge, an allowance must be made for the thickness of the copper, and likewise for the swelling of the plate in the fire, which is a circumstance that invariably happens. The proper die being chosen, place one of the pieces of copper on that side of the die which has the smallest diameter, and as nearly in the centre as possible; lay the die, with the copper upon it, flat on a table or board, and the round ended punch, Fig. 2, being put on the centre, press it down and wriggled round till the end of it is forced as far as it can go into the centre hole of the die. The copper is then to be taken off, and the bulge thus formed must be filed nearly through. Let the copper then be placed on the die in the same manner as before, and the round broach gently thrust through the centre hole, till it fits it nearly tight to the die. When this is done, holding the die and copper in the left hand, with the die upwards, let the copper be cut as nearly round as possible, leaving it about \( \frac{1}{2} \) th of an inch larger than the smallest side of the die. This may be best accomplished by holding the scissors a little aslant, till the desired breadth is obtained. The die, with the copper uppermost, is then to be laid on the work board, and gently rubbed or burnished over with the round broach, till the copper lies quite smooth and flat on the die. Hold the die and the copper firmly in the left hand, and having the broach in the right, burnish that part of the copper which extends beyond the edge of the die, which is best done by rubbing the broach round the copper, and pressing it close to the edge of the die. The copper is now to be taken off the die, and the edge or rim thus formed must be finished by filing it till it is equal on every side. The centre hole must be filed a little to take off the ragged parts, but it must not be made so low as the edge; and the bur that is formed by filing should be scraped off with the edge of a graver. The copper is then set up to the desired convexity, by placing it in the setting die, and rubbing it with the setting spatula till the copper touches in all parts; after which the feet is soldered on.

The inconveniences that attended the use of plain copper wire soldered with spelter for the feet, are now entirely obviated, by employing copper wire plated with silver. When the copper is set up properly, place it exactly on the frame of the watch. Hold the copper and frame in the left hand, and with the point or needle mark through the holes in the frame where the feet should be placed; then place the copper in the setting die, and describe small squares, about each of the marks that have been made with the point, observing that these must be large enough to admit the foot wire to be placed within, as the intention of the squares is nothing more than to throw up a bur or ridge, to prevent the foot from slipping out of its place during the operation of soldering. The feet for the copper must now be cut, by fixing an iron peg into the work board, and the pieces of plated wire being held against it, it will be found to form a very good resistance to the action of the file. It should be observed, that if coppers are to be made for flat plates, the feet should be filed at right angles; but if the plates are convex, they should be filed at an angle as nearly as possible corresponding with the curve formed in the hollow part of the copper, because when the foot is placed on the copper, it will be found to stand perpendicular to the base line, or edge of the copper. The feet thus filed should be cut off with the nippers; if for frame plates, about three-sixteenths of an inch long; but if for flat plates, one-eighth will be sufficient. A small quantity of borax should now be rubbed upon a piece of slate, with the addition of a few drops of water, into which the filed parts of the feet being slightly dipped, will greatly facilitate the soldering. The copper is then to be held in the left hand, and the feet taken up with the tweezers are to be set in their proper places on the copper, when it will be fit for soldering. When a great number are to be done at once, it will be the best way to hold up all the feet before any are soldered. In this case, the frames set on the board with the pillars upwards, make very convenient stands to place the coppers on till they are soldered. It must be carefully observed in this kind of soldering, to use the borax very sparingly; for as it blisters up when the heat first comes to it, the feet would be thrown down, which would occasion much difficulty and loss of time in replacing them.

Take now a large piece of charcoal of a close texture, and hollowed out, so that the copper may lie conveniently in it, and having your lamp near the edge of the board, and the copper placed on the coal, which should be held in the left hand, put the end of the blowpipe into the centre of the flame, and holding the copper nearly under it, give a very slight but steady blast till the copper is red hot. The pipe should now be withdrawn from the centre, that the whole of the flame may be collected, which will be done if the operator blows as hard as he can. When the copper is arrived nearly to a white heat, the centre of the blast must be placed immediately over each of the feet till the solder runs down to the copper, and the soldering is complete. If the feet have kept in their places, they will fit into the holes of the frames; but if they have shifted a little, which will frequently be the case, fit them into the frame, by placing the copper in the setting die with the feet upwards, and the frame being held over the feet, bend them whichever way may be requisite, by introducing the setting spatula between the frame and the copper, pressing it against that side of the foot or feet that may be necessary, till they fit into the holes of the frame. When this is done, the copper is to be gently withdrawn from the frame; and if, upon examining the upper side, any dints or bulges have been made, they must be taken out by putting the copper into the setting die, and rubbing the spatula round the feet till such imperfections are removed. When a copper is made to a brass edge and frame for a second watch, the second, or eccentric hole, must be made in the following manner, after the copper has been soldered and set. Place the copper in the brass edge and frame, holding the copper downwards on the board, with a fine needle or point put perpendicularly through the seconds hole of the frame; prick quite through the copper a very small hole, which must be bulged or raised, by having a corresponding hole drilled in one of,
the dies. The copper is then to be placed on the die, and the hole that has been prickled, must be placed exactly over the hole that has been drilled in the die. A smaller round-ended punch should be used to bulge up the hole, which is to be done in the same manner as was directed for making the holes in the centres of the plain coppers. The hole must be finished by filing the upper side; and if upon examination it does not correspond with the hole in the frame, it must be made to fit by placing it on the die again, and opening the hole with the point, bearing most on that side that is most out of the centre. It should be observed, that although the plate for a seconds watch is desired to be as flat as possible, yet the copper should be set a little rising; for if it was not kept up a little in the centre, when the enamel is put on and the plate fired, it would sink in the centre, an imperfection for which there is no remedy. We would recommend, that all copper used for flat plates should be annealed and planished before they are put to the die. This may be done on a piece of flat marble; and the hammer should be made of elder, or hard boxwood, having a very smooth face. The use of this operation is to take away the cockling kind of spring, that is always left in the copper when it comes from the flattening mills. To perform this nicely, requires much judgment in the operator; for if the copper is promiscuously struck with the hammer, it is ten to one but the imperfection is increased; therefore to proceed rightly, the copper must be examined, and that part which is found to be the tightest, or least stretched, and upon which the other parts will appear to twist and play, must be hammered till an uniform flatness is obtained. The best method of ascertaining when the spring is gone, is to let the piece of copper fall from a small distance upon the marble slab, and if there is no vibration or ringing noise, we may conclude that the operation has succeeded. We should not have been so particular on this point, had we not been convinced of its utility; for if this is not done, the metal will expand unequally in the fire, which will certainly cause the enamel to crack in the fire, or warp in such a manner as to be wholly useless. We must not omit the method of cleansing, (or picking the copper as it is technically called,) it being necessary in all cases where great nicety is required. This is done, by making a solution of the best double aquafortis and water, about one part of the former to eight of the latter. Put the coppers, as soon as they are all soldered, into as much of the solution as will cover them, and when they have remained two or three minutes, let one of them be taken out and washed in clean water, and brushed with a soft brush and a little white sand. If the scale comes all of, and the copper looks quite bright, they are sufficiently done; if not, let them remain sometime longer in the solution, and, when brushed as before, dry them with a soft napkin.

**Description of the Tools used in Enamelling.**

The first is an agate pestle and mortar to grind the enamel. The best kind are those that are most transparent, and free from opaque spots and veins. See a section of this in Plate CCLII. Figs. 9, 10.

The second is a small hammer about an ounce and a half in weight. One face should be flat, and the other of the shape commonly used in riveting.

The third is a flat spatula seven-eighths of an inch broad, and a little thicker than those used for paint knives.

The fourth is a spatula rather thicker than the last, but of equal breadth. One side of this should be flat, and the other a little curved. This must be made of good steel, and is used to spread the hard enamel on the copper. See Plate CCLII. Fig. 11.

The fifth is the spatula, for spreading the hard enamel on the under side of the copper. This is called a bottom spatula. The end of this should be just the same as the end of the setting spatula described in the copper tools, excepting that it should be a little broader.

The sixth is a quill cut just like a tooth-pick. This is used to clear the enamel out of the centre holes of the coppers.

The seventh are two damask napkins, for drying the water from the enamel. These should be very clean, and always kept separate.

The eighth is a small basin with a cover, to hold the enamel that is to be used for the tops of the dial plates.

The ninth is a gallipot, to hold the enamel that is to be used for the bottoms, or under side of the dials.

The tenth is a cylindrical block of wood, to fix the copper on when it is ready to have the enamel laid on the top. This for common sized plates, may be about an inch and half diameter, and about six inches long. On one end of this some soft wax must be fixed, so that it may form a kind of cap to the block, being about one-third of an inch thick on the top, and the same on the sides. See Fig. 12.

The eleventh is a box to hold the plates in, when the enamel is spread on them. This may be about 16 inches long, and 9 broad. The depth may be one inch and a half; but it must not have any side under the opening of the lid.

The twelfth is a small steel-faced anvil to hold in the hand, to break the enamel into small pieces. The face may be about one inch diameter, the other part in proportion.

**Method of grinding the Soft Glass Enamel, called by Enamellers Glass.**

Take a cake of glass enamel, and with the riveting face of the hammer strike it as near the edge as possible, holding, at the same time, the forefinger of the left hand just under the place where the blow falls. By this means, the vibration that would be given to the whole cake will be prevented, and it will be broken into thin flakes. When thick solid pieces happen to fall off, the anvil must be held in the left hand, with the face upwards; and the piece being laid on it, must be broken with the flat face of the hammer, till it is small enough to be ground. To prevent the enamel from flying about, the anvil should be so held in the hand, that part of the fore finger and thumb may form a kind of rim.

The centre is generally the foulest part of the cake, and is often intermixed with black and red streaks. When this is the case, the coloured parts should be rejected, as they would otherwise contaminate the whole enamel. When the enamel is broken as small as is necessary, no piece being left larger or thicker than a small pebble, the agate mortar must be set on a piece of coarse linen cloth four times doubled, and made thoroughly wet with clean water. This should be laid on the work-board, and the mortar about half filled with enamel, which should be nearly covered with
ENAMELLING.

Clean water. The pestle is then to be wiped perfectly clean, and, being grasped by the middle with the left hand, the right hand placed on the top, and pressing against the right breast, the operator thus leaning over the mortar, must give a kind of twisting motion to the pestle, by bringing the right elbow round the pestle, forming the axis of the circle; while the body, being permitted to rise a little after each twist, fresh particles of the enamel will fall under the pestle, and be completely crushed. This part of the operation should be continued as long as any large pieces of the enamel are felt under the pestle; for it should be observed, that if this great pressure, or breaking down, as it is technically called, is pursued beyond the proper time, some parts of the glass would be reduced to almost an impalpable powder, while the other part would remain comparatively coarse. To prevent this unevenness, the pestle should be held firmly down in the mortar, with the left hand grasping it as before, while the right hand gives a circular motion to the upper part, at the same time using as much strength as can be conveniently exerted. In a very short time after this method is begun, the large pieces that have escaped the pestle in breaking down, will present themselves under the pestle, and cause it to jump and twist in contrary directions. This may be prevented, by feeling for them with the pestle, and crushing them against the side of the mortar, holding it at the same time firmly with the left hand. As the fine flour, into which some parts of the enamel is ground, would prevent the rest from being evenly ground, it must be washed away four or five times during the grinding. This is best done by nearly filling the mortar with clean water, and agitating the enamel with the broad flat spatula, stirring it from the bottom till the water appears quite milky; the enamel should then be suffered to settle to the bottom, and the water poured off. A small quantity of water must then be put into the mortar, sufficient to keep the enamel from clinging to the sides of the pestle, and the grinding continued till there appears a difficulty of getting the pestle to touch the bottom of the mortar. When it is arrived at this state of fineness, the pestle must be held in the middle with the right hand, giving it a circular motion, clearing the enamel from the sides of the mortar at each revolution. When this kind of motion is begun, it will be necessary to hold the mortar with the left hand, taking great care not to throw the enamel over the sides, because the dirt that it would contract by such an accident could not be got rid of without an infinite deal of trouble. Besides the risk of breaking the work in getting the specks from the surface of the dial plates, when the enamel has been fired. As it would be almost impossible to lay down a certain rule for the fineness to which the glass enamel should be ground, as different parcels, or pots, (as they are called at the glasshouse,) require to be varied, we can only say, that the finest should never exceed fine grain gunpowder, while the coarsest must never be left larger than made-seed. When the enamel is completely ground, wash the flour thoroughly from it, and put it in the basin, then keep it covered with water till it is wanted for use, taking great care that it receive no dust or dirt.

Method of grinding the Venetian hard enamel for the bottoms or under sides of the dials.

This method is to be broken with the hammer in the same manner as the glass enamel; but, instead of breaking it down in the agate mortar, it should be done in one made of iron, of a cylindrical form. The bottom of the mortar should be faced with steel, possessing a small degree of concavity, that the enamel may return to the centre after each blow. The pestle should be about one inch and a fourth in diameter, and about six inches long, with the face of steel, about one inch and a half in diameter, and a little convex, to suit the mortar. The depth of the mortar should be about four inches; and with respect to thickness, as there will be no strain upon the sides, the lighter it is made the better. It should also be observed, that the arris of the face of the pestle should be rounded, so as to leave no sharp edges near the part where it comes in contact with the enamel, as they would be soon broken off, and spoil the other part of the face. After the enamel has been broken with the hammer, it must be put into the steel mortar in small quantities, and pounded till it is as fine as the glass enamel, (when it has been broken down in the agate mortar; it should then be put into the agate mortar, and ground till it appears to be reduced almost to an impalpable powder. It must be remembered not to wash the enamel that is to be used for bottoms, as the flour will, in this case, be more serviceable than detrimental. When this enamel is ground, put it into a clean gallipot, and always keep it covered with water; for observe, if ever it gets dry after it is ground, it will be necessary to give it two or three turns in the agate mortar, otherwise the enamel is likely to blister in the fire.

Method of grinding and pickling the Venetian hard enamel that is to be used for the tops of dial plates.

When a piece of enamel is chosen for hard plates, great attention should be paid to the colour, that which is the whitest being considered the most valuable. The piece that is to be ground must be laid upon a clean planch (or, what would be much better, a thin plate of platinum), and placed under the enameller's muff if it is red hot; it must then be quickly drawn from the fire, and quenched in very clean spring water. This will cause the enamel to fly into very small pieces, which must be collected and put into the agate mortar. The intention of breaking the enamel in this way, is to do away, as much as possible, the necessity of using the hammer and steel pestle; because, if any small particle of the steel gets into the enamel, it will cause much trouble to get it out. The method of grinding it is just the same as that employed for the other hard enamel, excepting that this must be rather coarser; and great care must be taken, when the enamel is washed, not to throw away the water which contains the flour, which may be collected after it has settled, and put into the gallipot with that which is to be used for bottoms. When the enamel is ground fine enough, it must be put into a wide-mouthed glass bottle with a glass stopple, and covered with strong nitrous acid; and in this state it should remain till wanted for use.

Method of enamelling with the Soft Glass Enamel.

The napkin that is to be used for laying or spreading the bottoms, must be laid on the work-board four times doubled. The copper is to be held in the left hand, with the feet upwards, and a small quantity of the hard enamel for bottoms is to be taken out of the gallipot on the end of the bottom spatula, and spread roughly on the copper, covering it closely up to the feet and centre holes. It must then be laid between the folds of the cloth till a little of the water is absorbed,
ENAMELLING.

when it must be smoothly spread with the convex side of the spatula. If too much of the water is not absorbed, it will be found that the enamel may be very easily removed from the parts where it lies thickest to those that are too thin, till a general evenness is produced. It must then be smoothly spread, by drying it more with the napkin, and spreading it again with the spatula, observing always to bear proportionally lighter as the enamel gets drier. The centre hole must be cleared out by twisting the quill in it till it brings out all the enamel that is in it, and the operation of laying the bottom is complete.

A clean napkin is then to be folded in the same manner as for laying the bottoms; but it must be laid on the board so as to hang over the edge about three or four inches; and, to prevent its falling, it is best to put some kind of weight upon it. When the wax upon the last block has been softened, and made of a shape fit to receive the copper, it must be placed evenly on, and the feet pressed into the wax, till the under side of the copper nearly touch. This will be best done by placing the setting die on the copper, and pressing it down, as, by this method, the shape of the copper will be preserved, and the upper side secured from the perspiration of the hands, which might prove injurious to the work, as any thing of a greasy nature is very apt to make the enamel blister. The copper must now be brushed quite clean with a soft hair brush, or hare's foot, taking great care not to leave any of the hard enamel on the surface, or about the edge. The block with the copper on it is now to be held in the left hand, and a small quantity of the glass enamel is to be taken upon the end of the flat spatula, and laid upon the copper, near the centre hole, taking very great care not to let the water through the centre hole; as that would take the enamel from the bottom, which could not be replaced without taking the glass from the top, an operation that would be exceedingly dangerous, as the two kinds of enamel would get mixed together, which would inevitably spoil them both. If a careful attention is paid to what we have said, an evil of this kind need not be feared, as the enamel need not be taken out of the basin with so much water as to render it at all hazardous, if it is lifted slowly, and by that means suffered to drain a little. When a sufficient quantity of the glass enamel has been put upon the copper, it must be roughly spread, by repeatedly indenting the edge of the flat spatula into the enamel, crossing it in all directions till it lies of an uniform thickness all over the copper. The surface, in this state, will have various little inequalities and indentations, which may be reduced by just tapping the side of the block two or three times with the edge of the spatula. The water which this operation will cause to flow on the surface of the enamel, must be dried a little with the corner of the cloth, but not so much as to render the enamel difficult to be moved; for the intention of putting it in this state is to take away the superfluous water that floats on the surface. If, however, the napkin should at any time absorb so much of the water that the enamel could not be moved without such a degree of pressure as would lessen the feet of the copper from the wax, or risk bending the copper, a drop or two of water may be taken upon the end of the spatula, and applied to different parts of the enamel, till the desired effect is obtained. It rarely happens that the enamel, in this state, is so evenly laid as to want no adjusting; it must therefore be carefully observed, that the side or part which is too thick, must be reduced; by removing a part to places that appear deficient. This may be done by Enamelling spreading the spatula over the enamel, turning the block round with the fingers and thumb of the left hand, till it lies generally even. It must then be dried again with the napkin, and the surface made smoother, by passing the spatula over it in all directions, bearing a little harder on the enamel as it gets drier. As the rubbing and spreading the enamel in this manner will attract the moisture to the surface, and hinder the enamel from laying so smooth as is necessary, it must therefore be dried again, and the laying finished by gently passing the spatula lightly over the surface till the enamel lie very smooth and even.

In determining the thickness of the enamel, an allowance must be made for its granulated state previous to melting, when it occupies a larger space than it does subsequently. The enamel should therefore be spread a little thicker than the depth of the edge and centre would seem to require. In all cases, however, it will be better to have the enamel a little below the edge and centre when it is melted in its first fire, for reasons which we shall afterwards explain. One thing is to be particularly observed in enamelling the tops of convex plates, that the shoulder, which is about 4th of the distance from the edge to the centre, should be laid somewhat thicker than towards the edge, because the edge being lower than the centre, the enamel when in a fluid state in the fire, will flow down to it, and will thus produce an equality of thickness on all parts of the copper.

When the copper is covered, it must be carefully taken from the block, by gently raising it with the back of the thumb-nail, under the edge, and as near each of the feet as possible. After it is free from the wax, it may be lifted with the finger and thumb from the block, and placed under the lid of the box, to keep it from the dust till it is wanted to be fired.

Description of the Method of Hard Enamelling.

When the copper is nicely picked, fix it on the laying block, in the same manner as was directed for the glass enamelling, and lay a coat of glass enamel about two-thirds of the thickness that was directed for making glass plates. This must be fired till the enamel is melted down to a tolerably smooth surface; and when cold, should any specks of dirt appear on the surface, they must be cut out with the point of a square graver whetted to a very obtuse angle. After this, the plate must be put into a solution of nitrous acid and water, just strong enough to cleanse the scale from the edge of the copper, being careful not to leave the plate longer in the solution than is sufficient to clean the edge, and washing it immediately in clean water.

Let the plate now be fixed on the laying block, in the same manner as if it were a copper, keeping the wax soft enough to admit the feet to pass into it without any great pressure, as that might strain the enamel, and cause it to crack in the fire. Take a small quantity of the hard enamel, thoroughly purified of the acid by several waters, and, with the rounded part of the round-sided spatula, spread it as equally as possible over the whole surface of the plate. When this is done, the enamel must be dried by laying the corner of a clean napkin upon it till it has absorbed a part of the water. It will then be in a fit state to be spread more equally over the surface of the plate; and, when it is spread nearly smooth, and of equal thickness, it must be dried again with the napkin, and the spreading continued for full ten minutes, or longer, pressing harder.
ENAMELLING.

It rarely happens that any plate will come out of enamelling the first fire without a number of small black or green specks, which, perhaps, were in the enamel, and had escaped the notice of the operator. In addition to this imperfection, the union of so many small particles of enamel in one mass throws up to the surface a scummy and mottled appearance, which renders the plate, when cold, very unpleasing. It will be necessary to remove these imperfections by first carefully removing the specks with a square graver, whetted so that the face makes nearly a right angle with the plane of either side, observing to hold the index finger of the left hand immediately under that part of the plate where the speck is situated, so as to counteract the pressure given to the graver, and prevent any strain upon the whole, which might cause the enamel to crack when it again approaches the fire. When all the specks are removed, the centre hole of the copper, if all has been conducted right, will appear to rise above the surface of the enamel. This must be very carefully filed down, and the same operation practised at the edge, which will be found to have a similar appearance, and the plate is then ready to undergo a process, technically called using off. This is performed by rubbing the surface of the plate on a grit stone, with fine sand and water, until all the glazed appearance is completely obliterated, and one uniform and equally rough surface is produced. The intention of this part of the process, is to remove the mottled appearance on the surface, and give a more equal convexity to the plate. It may likewise be observed, that the flux in the enamel being always in the greatest quantity near the surface, gives a semi-transparent appearance to the plate. The using off removes this imperfection, and greatly increases the intensity of the enamel, adding at the same time much to its beautiful opacity. After the using off is completed, the plates should be brushed with a stiff haired brush and wet sand, to remove any light stain; when, being well washed in clean water, they must be dried with a clean napkin, and they are ready to receive the finishing fire.

As the specks that have been picked out generally leave some deep holes in the enamel, they must be filled up with some of the finest enamel, nearly as fine as flour; and being placed in a proper sized ring, must be set on the iron hearth of the furnace, gradually placing it nearer to the fire, until it attains such a heat as will permit it to be placed in the hottest part of the furnace without danger of cracking, which would be very likely to happen if this gradual annealing was not attended to. The ring and plate may now be lifted upon the planch with the tongs, and kept in motion, turning it gently round until it attains a white heat. As soon as this is observed, it must be brought out of the fire, and blown upon with the breath for two or three seconds, and immediately returned into the furnace, where it may be suffered to attain a white heat, which will bring it to a most beautiful gloss, and a degree of whiteness not to be exceeded. The plate must not be permitted to remain one moment longer in the fire after it has arrived at the desired heat, but must be quickly withdrawn from the furnace, and set to cool gradually; when, if it is found to be free from specks, the operation is finished, and the plate ready to have the figures painted upon it.

If the enamel should have any specks upon the surface, they can only be removed by the graver, and the firing repeated, omitting the using off in this case.
This is the process for firing and finishing the glass enamel plates. We shall now describe the method adopted to fire and finish the hard enamel dials.

The firing of these when the enamel is laid on, is the same as for the glass enamel, the apparatus being used for both purposes; but the heat applied to melt the Venetian hard enamel must not be so great, and the plate must be taken from the fire as soon as the enamel is found to form one tolerably compact body, as any longer continuance would have a tendency to spoil the intended shape of the plate, which is always considered a most essential quality in hard enamel plates. The method of using off the hard enamel plates is different from that made use of in the glass enamel; for as the proportion of flux in the Venetian hard enamel is considerably less than in the glass, and as diminishing the flux by using it off, (if carried to the extent we before described,) would render the surface very porous, great care is necessary to be observed that the flux may be raised to the surface in the first fire as little as possible; which is done by giving the plate a very slight heat, barely sufficient to unite the particles of enamel into one solid mass. Should any specks appear, they must be taken out with the graver, as was directed in the glass enamelling, and the surface must be reduced to perfect evenness, by rubbing it with a grey stone, or what is still better, the water of air stone found in Scotland, and now much used by mathematical instrument makers. This method of using off must be continued until the surface is smooth, and all the old or first gloss is removed. This part of the process should be very carefully performed, for should the plate receive any strain, it would be cracked in the fire, and inevitably spoiled, to prevent which, it will be best to hold the plate in the fingers of the left hand while being fired lightly over every part of its surface. The plate must then be well washed with very clean water; and to prevent any particles of the stone remaining in the pores, it is customary to rub the surface for about five minutes with a piece of soft smooth hoop wood, or what is still better, if it can be had, soft dog wood cut quite flat and smooth. When this is done, the plate must be well washed and wiped, and then be ready for the fire.

The heat for finishing may be rather more than that used in the first fire, as in that instance the intention was only to unite the particles of enamel into one solid mass. But the principal object in finishing being to raise the flux to the surface as much as possible, a greater heat may be used with advantage; but the plate must be taken from the furnace the instant that the surface appears bright and glossy.

We shall conclude our directions for firing the plates, with some general observations upon the accidents that are most likely to occur in both kinds of enamelling, and point out the best methods to remedy them when they happen. Where good Venetian enamels are obtained, and mixtures of various kinds are resortcd to, it frequently happens that the glass enamel plates crack when they are brought to the second fire. This is no doubt owing to the unequal expansion of the two enamels; and where the cracking takes place at the top or upper side of a plate, it requires very delicate treatment to preserve the dial from being completely spoiled.

To do this successfully, as soon as the crack is observed, the plate must be withdrawn from the fire; and if it extends only from the centre hole to the edge, it will, in most cases, bear mending, but if it has taken place in two or three places, it will be useless to make the attempt, as it will rarely succeed. If the dial plate was to continue in the fire, after it is cracked, a sufficient time, the enamel would close, and the plate become sound again. But as the copper on its surface is in a state of oxidation, the oxide of copper, uniting with the enamel, would rise to the upper surface of the plate, producing by its union a faint and sometimes a dark green line, which would evidently render the plate useless. The operator, therefore, must observe the time when the crack has opened to its greatest width; and before it unite or close at the bottom, the plate must be withdrawn from the furnace and allowed to cool. The opening must then be filled with fine enamel, laid sufficiently high to allow for its running down in the fire; but to adjust the quantity, so as to prevent the appearance of a seam across the plate, will require much judgment; and, indeed, however well the operation may succeed, it will still remain visible, because the mending cannot be submitted to the process of using off, as the plate would, by such means, be rendered in parts very porous, and thereby contract dirt when the fingers touch its surface.

Another very common accident in making glass enamel plates, is to over fire them, (as it is technically called.) Whenever this happens, the arsenic, which gives opacity and whiteness to the material, is converted into a flux by the extreme heat, and that part of the plate which has been so treated becomes semi-transparent and of a light blue colour. The only method that can be used in that case, is, to return the plate into the fire, and give it a long or close at the bottom, it will be best to hold the plate in the fingers of the left hand while being fired lightly over every part of its surface. The plate must then be well washed with very clean water; and to prevent any particles of the stone remaining in the pores, it is customary to rub the surface for about five minutes with a piece of soft smooth hoop wood, or what is still better, if it can be had, soft dog wood cut quite flat and smooth. When this is done, the plate must be well washed and wiped, and then be ready for the fire.

The heat for finishing may be rather more than that used in the first fire, as in that instance the intention was only to unite the particles of enamel into one solid mass. But the principal object in finishing being to raise the flux to the surface as much as possible, a greater heat may be used with advantage; but the plate must be taken from the furnace the instant that the surface appears bright and glossy.

We shall conclude our directions for firing the plates, with some general observations upon the accidents that are most likely to occur in both kinds of enamelling, and point out the best methods to remedy them when they happen. Where good Venetian enamels are obtained, and mixtures of various kinds are resortcd to, it frequently happens that the glass enamel plates crack when they are brought to the second fire. This is no doubt owing to the unequal expansion of the two enamels; and where the cracking takes place at the top or upper side of a plate, it requires very delicate treatment to preserve the dial from being completely spoiled.

This is no doubt owing to the unequal expansion of the two enamels; and where the cracking takes place at the top or upper side of a plate, it requires very delicate treatment to preserve the dial from being completely spoiled.
Under the article Britain, will be found a history of the island from its first population by the Celts, until the arrival of the Saxons in 449. This people had been invited over from Germany by the Britons, to assist them in repelling the inroads of the Scots and Picts. Led on by Hengist and Horsa, two brothers, who were celebrated as among the noblest and bravest leaders of the nation, they soon finished the task which they were called to accomplish. The northern barbarians were unable to resist their valour. They were defeated in several encounters, and at last compelled to retire within their mountain barriers, which have ever since continued to form the boundaries of England and Scotland.

Vortigern, king of the Britons, rewarded his brave auxiliaries with large possessions in the country which they had delivered; but he soon found in them a more formidable enemy than those from which he had been freed. The Saxons in Germany, allured by the fertile soil and soft climate of Britain, flocked in great numbers to the standard of their countrymen. Conscious of their superior valour, they now thought of conquering the island for themselves; and from being the protectors, soon became the masters of the country. They soon found a pretext for quarrelling with the inhabitants; and, forming an alliance with the Scots and Picts, turned their arms against their former friends. The Britons, roused to indignation at such treacherous conduct, threw aside their indolence and effeminacy, and began to exert their ancient valour when it was too late. They deposed Vortigern, who had rendered himself despicable by his vices and his weakness, and entrusted their fortunes to his son Vortimer. Vortimer opposed the Saxon arms with various success. In one battle near Aylesford, Horsa, the Saxon general, was slain; but Hengist being continually reinforced by fresh troops from the continent, overcame all opposition, and spread his devastations over the whole country. In his bloody career, he spared neither age, sex, nor condition; the priests were slaughtered on the altars; and the bishops and nobility were mingled with the vulgar in the common calamity. Some accepted of life and servitude under their conquerors; and others fled to the continent, and gave to their new settlement the name of Brittany. But Hengist prosecuted his conquests until he extended his authority over the counties of Kent, Middlesex, Essex, and part of Surry, which was denominated the kingdom of Kent, and was the first Saxon state established in England. Hengist fixed his royal seat at Canterbury, and, after reigning 40 years, he died about the year 488.

Saxons, Angles, and Jutes, from Germany, encouraged by the success of their countrymen, from time to time, flocked in multitudes into Britain, and spread their conquests over the country, until the natives were either reduced to entire submission, or were compelled to seek for independence among the inaccessible mountains of Cornwall and Wales.

After a violent struggle of near 150 years, the Heptarchy, or seven Saxon kingdoms of Kent, Sussex, Wessex, East Anglia, Mercia, Essex, and Northumberland, were established in Britain; and the whole southern part of the island, except Wales and Cornwall, had changed its inhabitants, language, and customs. Kent, as we have observed, was founded by Hengist. Sussex owed its establishment to Ælla, a Saxon chief, who arrived with a band of adventurers in 477; and, after many battles with the natives, secured to himself the county of Sussex and a great part of Surry. Wessex, comprehended Hants, Dorset, Wilts, Berks, and the Isle of Wight, and was founded by Cerdic and his son Kenric. They landed in 495, but their progress was long retarded by the valour of the Britons. Nazan-Leod, who is styled by Henry of Huntingdon, "the greatest of all the British kings," assembled almost the whole strength of the natives to meet the invaders. A desperate battle ensued, which was long and obstinately contested on both sides; but the Saxons prevailed, and Nazan-Leod, with 5000 of his army, perished on the field. Upon the death of their king, the southern Britons applied for assistance to Arthur, prince of the Sires. This prince, by his wisdom and valour, supported their sinking cause. He is said to have defeated the enemy in twelve pitched battles; but his military achievements are so disfigured by the fictions of the bard, that some have even doubted of the existence of such a person. It is certain, however, that about that time the Saxons were opposed with considerable success; and it was not till after 55 years of almost constant warfare, that Cerdic was enabled to settle and enjoy his conquests. East Anglia, containing Norfolk, Suffolk, Cambridge, and the Isle of Ely, was established by Ælla, in 575; and about 10 years after, Crida laid the foundation of Mercia, which extended over seventeen counties, viz. Gloucester, Hereford, Worcester, Warwick, Leicester, Rutland, Northampton, Lincoln, Huntingdon, Bedford, Buckingham, Oxford, Stafford, Nottingham, Derby, Shropshire, Cheshire, and part of Hertford. The kingdom of Essex, under Erkenwin, was dismembered from Kent, and comprehended the county of the same name, with Middlesex and part of Hertford. Northumberland embraced the counties of York, Lancaster, Durham, Cumberland, Westmoreland, and Northumberland, with some of the southern counties of Scotland, and was at first divided into the kingdoms of Bernicia and Drieth. Ida established the first in 542; and Ælla the other nearly about the same time; but Adelfrid, the grandson of Ida, having married Aella, the daughter of Ælla, expelled her brother Edwin from his throne, and united the two kingdoms into one.

No sooner had the Saxons established their dominion over the country, and driven the natives from their homes, or reduced them to slavery, than dissensions and emulations began to appear among the conquerors. Fierce and uncivilized, they thought only of war. The
different states vied with each other in maintaining the ascendency over the rest; and all the misery, that ambition, treachery, or war could bring upon a people, was the consequence of their fierce contentions. A detail of their quarrels would neither be interesting nor instructive; indeed, the barbarous and credulous annalists of that age have so obscured the various events and revolutions of the Heptarchy by their exaggerations, that it would be impossible to produce any thing like a particular and continued narrative. It is sufficient to know, that, after above 200 years of almost continual animosity between the different kingdoms, Egbert, king of Wessex, by his prudence and valour, united them into one great state.

Egbert was of the royal family of Wessex, and a nearer heir to the throne than Brithric, the reigning monarch. His talents and promising virtues had excelled the jealousy of Brithric; and he was forced to retire into France, where, at the court of Charlemagne, he acquired those Hælthrythiochs which enabled him to prosecute, with such success, his schemes of conquest and aggrandisement. On the death of Brithric, he was called to the throne by the unanimous voice of his countrymen. His first efforts were directed against the Britons of Cornwall, whom he defeated in several engagements; but he was stopped in his progress by the intelligence, that Bemulf, king of Mercia, had invaded his dominions. Egbert met him at Ellandum in Wiltshire, and defeated him with great slaughter. Kent, Essex, and East Anglia, which had been subdued by the Mercians, became the prey of the victors; and Mercia itself was soon compelled to acknowledge the authority of Egbert. He allowed Wiglief, a Mercian, to retain the title, while he himself exercised the powers of a sovereign. The Northumbrians submitted upon the same conditions. Sussex had formerly been united to Wessex; and thus Egbert became sole monarch of England about the year 827.

Tranquility and union being now restored to the kingdom, Egbert by the conquests of Egbert, and firmly united under the dominion of this fortunate and valiant prince, they promised themselves the enjoyment of a permanent peace. But scarcely had Egbert established and regulated his infant monarchy, when a new enemy unexpectedly appeared on the coast. A swarm of barbarians from the shores of the Baltic, under the names of Danes and Normans, had filled the western countries of Europe with slaughter and devastation. Their first appearance in England was in the year 877. They afterwards made a descent upon Northumberland, where, being attacked by the inhabitants, they were defeated, and all put to the sword. They now entered the Thames, and having plundered the Isle of Shepey, retired without molestation. In 833, they landed a formidable army in Dorsetshire, where, being met by Egbert at Charmouth, they were routed with dreadful slaughter; and about two years after, being joined by the Britons of Cornwall, they made another descent upon Devonshire, where they were again defeated by Egbert at Hengistrow.

But the death of Egbert was the signal for new and more formidable invasions. His son and successor, Ethelwulf, was unable to stem the torrent of invasion. He had neither the valour nor abilities of his father; and began his reign by weakening the vigour of his government, in assigning part of his territories to his son Athelstan. The domestic dissensions which might have been the consequence of this partition of dominion, was prevented by the continual dread under which the whole kingdom was held by the inroads of the Danes. No place could be considered secure from their attacks. When repulsed in one quarter, they made their appearance in another, ravaging and destroying wherever they came; and carrying off to their ships, goods, cattle, and even the inhabitants. Though often defeated, they were not discouraged, but always returned with increasing numbers, till, after some years of various success, they firmly established themselves in the isles of Thanet and Shepey; from whence they made frequent and successful incursions into the neighbouring counties. During this distraction of public affairs, the piety of Ethelwulf carried him to Rome, where he remained about a year. He there bestowed many presents upon the principal ecclesiastics of that city; and made an annual grant of 300 mancuses to the see of Rome, for pious purposes. On his return, he found himself almost excluded from his throne. His eldest son, Athelstan, had been during his absence; and his second son, Ethelbald, had not only assumed the government of his brother's dominions, but had formed the design of removing his father from a station which his weakness and superstition had rendered him so ill qualified to fill. A civil war, however, was prevented, by Ethelwulf resigning the western part of the kingdom to his son, and retaining the eastern part to himself. Affairs being thus amicably adjusted, he convoked the states of the whole kingdom, and yielded to the importunities of the clergy, conferred upon them a perpetual grant of tithes, for which they had long contended; and exempted them at the same time from all public burdens whatever.

Ethelwulf survived this transaction only two years; Ethelbald and by his will, divided his dominions between his two eldest sons, Ethelbald and Ethelbert. The reign of the former was short and licentious. Ethelbert then became sole master of the kingdom, and governed in a manner more worthy of his birth. He was succeeded by his brother Ethberht, in 866.

The Danes still continued their incursions; and the Ethelred, valour of Ethelred, and his brother Alfred, who attended him in all his enterprises, was unable to stop their ravages. Encouraged by some partial successes, and the assistance they received from the East Angles, they now left the sea coast, and penetrated into the interior. They took up their winter quarters at Nottingham, but being dislodged from thence by the English monarch and his brother, they retired to Northumberland. They next established themselves at Reading, from whence they issued to the battles of Aston and Basing. In the former, the English were victorious; in the latter, the Danes prevailed; and Ethelred, having received a mortal wound, bequeathed the sceptre to his brother Alfred.

When Alfred ascended the throne, he was only 22 years of age. He had accompanied his father Ethelwulf in his pilgrimage to Rome, and on a second visit to that city, it is said, with many of his subjects; and when he then displayed, Pope Leo III. prognosticated his future greatness, and even gave him the royal anoint. His reign began with war. The Danes had overrun the kingdom, and treated the inhabitants with the greatest cruelty and scorn. They had fortified posts, and built castles for the defence of their borders, and the whole country was in some measure covered with their redoubts. Alfred, in his first engagement, near Wilton, was compelled to retire before
the superior numbers of the enemy. He continued, however, to harass them with such vigour, that they at last sued for peace, and agreed to evacuate the kingdom. But this, and several other similar treaties, were no sooner sworn to than violated; and the Danes being continually reinforced by fresh bands from Denmark, became so powerful, that, after various struggles, the English submitted, in despair, and Alfred was obliged to seek safety in disguise. He retired to Somersetshire, and attached himself as a servant to a near-herd, waiting in anxious solicitude for a favourable opportunity to resume his former dignity, and to bring deliverance to his country. Leaving this retreat, he secured himself, with a few followers, in the isle of Eathelingay; at the confluence of the rivers Thame and Parret, which was rendered almost inaccessible by the forests and morasses with which it was surrounded. From this place he made frequent and unexpected attacks upon the Danes, who often felt, but knew not who gave the blow. Here he remained a twelvemonth, when information was brought, that the Earl of Devonshire, who had been besieged by the Danes, in the castle of Kinvith, had routed the enemy, killed Hubba their chief, and taken the famous \textit{renfen}, or enchanted standard.

Alfred, animated by the success of his countrymen, was eager to encourage them by his presence; but being unable to procure any correct intelligence respecting the situation of the enemy, he resolved first to penetrate the Danish camp, which he did in the disguise of a harper. He found them indulging in idleness and careless security, and, having ascertained their numbers, and the strength of their position, he rejoined his followers. He then summoned his friends to meet him at Selwood forest, from whence he led them against the Danes. Filled with surprise at the unexpected appearance of an English army, and with terror at the name of Alfred, they made but a feeble resistance, and imploded the clemency of the conqueror. Alfred allowed them to settle in East Anglia and Northumberland, but stipulated, that they should immediately embrace Christianity. The Danes submitted, and Guthrum their chief, at baptism, was received by Alfred as his adopted son, under the name of Athelstan. The more turbulent, with Hastings at his head, retired to Flanders, in quest of plunder, and ravaged for a time the northern provinces of France.

England, shaken by so many violent convulsions, now enjoyed a state of tranquillity; and Alfred improved this period in regulating the internal administration of the kingdom, and providing for its future security. He rebuilt and strongly fortified the city of London, repaired the ruined cities, and raised castles and fortresses in different parts of the country. He established a regular militia, and built a fleet of 120 ships, which he stationed upon the coast, to prevent the approach of the piratical Danes. For several years the kingdom was secured from the ravages of these restless barbarians, until Hastings returned with a formidable army, and landed in Kent. Alfred hastened to the assistance of his people, and, after a long and arduous struggle, completely cleared the country of its invaders, and ruled, in full tranquillity, during the remainder of his life. He died in the 30th year of his reign, in the full strength of his faculties, and vigour of his age, an ornament and a blessing to the country which he governed. He may be considered as the greatest warrior, legislator, and scholar of the age in which he lived; and he deservedly attained the appellation of Alfred the Great, and the title of the founder of the English monarchy. For a more particular account of his character and exploits, see the article \textit{Alfred}.

Edward, the oldest surviving son of Alfred, and de-

Deeds of Edward.
ed the nomination of \textit{Elder}, as being the first monarch of that \textit{Elder} name that sat upon the English throne, inherited the kingdom and military genius of his father. His reign, from beginning to end, was a continued but a successful struggle against the Northumbrians and Danes. He had scarcely taken possession of his father's sceptre, when his claim to the throne was disputed by his cousin Ethelwald, who was the son of king Ethelbert, the elder brother of Alfred. Ethelwald having brought over the Northumbrians and Danes to his party, made an irruption into Gloucester, Oxford, and Wilts, where they exercised their usual ravages, and escaped with their booty before the king could assemble an army to oppose them. Edward, however, overran and ravaged East Anglia in revenge; but the Kentish men, when their sovereign retired, remained behind, in expectation of more plunder, and took up their quarters at Bury. Here they were attacked by the rebels; but made such a vigorous resistance, that Ethelwald fell in the action. Though freed from a dangerous rival, his exertions were still demanded to compel the submission of the Northumbrians, who, assisted by the Danes of Mercia, committed their devastations in the very heart of the kingdom. He routed them at Tatenhall, Tensford, and Maldon, and, at length, reduced them under his dominion. He improved the defence of his kingdom, by fortifying the principal cities. He forced the East Angles to swear allegiance to him; expelled the two rival princes of Northumberland; subjected several tribes of the Britons; and even obliged the Scots to give him marks of submission. It is said that he derived considerable assistance, in his enterprises, from the activity and prudence of his sister Ethelfleda, who was widow of the Earl of Mercia, and who retained the government of that province after her husband's death. This princess was distinguished for her masculine endowments, and disdaining the occupations of domestic life, employed her talents in directing the affairs of the cabinet or the field. She died before her brother, who, during the remainder of his life, held the government of Mercia. Edward reigned 24 years, and Athelstan, his natural son, succeeded to the throne.

The unsettled state of the kingdom required the mature age and abilities of Athelstan, in preference to the youth and inexperience of the legitimate children of Edward; and he found little difficulty in maintaining his pretensions. Some discontent attended his accession; but his authority was soon so firmly established, as to allow him to direct his attention to more distant objects. He marched into Northumberland, to provide against the future insurrections of the Danes. He found them impatient of the English yoke; but, in order the better to secure their allegiance, he conferred upon Sithrie, a Danish nobleman, the title of king, and gave him his sister Editha in marriage. On the death of Sithrie, however, which happened soon after, his two sons Anlaf and Godirid, by a former wife, seized upon the sovereignty; but Athelstan soon compelled them to fly, when the former took shelter in Ireland, and the other found protection from Constantine king of Scotland. Constantine thus incurred the displeasure of the English monarch, who demanded of him to surrender up his guest. Constantine at first consented; but, detest-
ENGLAND.

ing such treachery, assisted Godfrid to escape, who turned pirate, and soon after died. Athelstan, however, resenting this conduct, penetrated into Scotland, and exacted the most humble submission from the Scottish king. But no sooner had the English retired, than Constantine entered into a confederacy with Anlaf, and some of the Welsh princes, and made an irruption into England. Athelstan met them at Brunsbury, where they were overthrown with terrible slaughter, and Constantine and Anlaf with difficulty escaped. This monarch passed the remainder of his days in peace, employing his talents in the internal regulation of his kingdom. The encouragement which he gave to commerce, evinced a mind superior to the prejudices of that age; and he enacted a law, that a merchant, who had made three long sea voyages on his own account, should be raised to the rank of a thane or gentleman. He died at Gloucester, in the 16th year of his reign, leaving the kingdom to his brother Edmund.

The beginning of a new reign was always the signal for domestic convulsions. The Northumbrians again revolted, but were soon reduced to submission; and Edmund took this opportunity of removing the Danes from the towns of Mercia, and thus preventing any further disturbances in the heart of the kingdom. He also took Cumberland from the Britons, and conferred it on Malcolm king of Scotland, upon condition of his doing homage for it, and protecting the northern frontiers from the incursions of the Danes. His reign, however, was but short. Leof, a notorious robber, had presumed to seat himself at the same table with the king and his attendants at dinner. Edmund, enraged at his insolence, commanded him immediately to leave the room; the robber refused to obey, upon which the king, naturally choleric, seized him by the hair; but during the struggle, the dagger of Leof found its way to the heart of Edmund, who expired in the arms of his murderer. His children were too young to wield the sceptre of such a kingdom, and his brother Edred ascended the throne.

The Northumbrian Danes, as usual, rose in rebellion; but on the appearance of Edred with an army, they immediately submitted; and, to secure himself against their revolts in future, he placed garrisons in all their principal towns, and appointed an English governor to watch their motions. Edred, though neither destitute of abilities nor warlike vigour, became the slave of superstition. It was in this reign, that the celibacy of the clergy began first to be insisted upon; and this dispute, together with the introduction of a new order of monks, under the protection of Dunstan, abbot of Glastenbury, excited in the kingdom the most violent commotions. Dunstan had obtained a complete ascendency over the mind of Edred, and had the direction of the most important matters, both in the church and state. He had acquired, by his austerities, a high reputation for sanctity and devotion. Having lost the favour of the former king by his licentious manners, he determined to recover his character by a life of mortification. He secluded himself from the world, in a cell so small, that he could neither stand erect nor stretch out his limbs in it. Here he employed himself in penance and devotion; and pretended that he received frequent visits from the devil, whose strongest temptations he was enabled to resist. It is said that the evil spirit one day assailed him in the shape of a beautiful woman; but the saint discovering the deceit, seized him by the nose with a pair of red hot pincers, and held him there, till he made the whole country resound with his howlings. This and similar stories were not only industriously propagated by the monks, but seriously believed by the people; and Dunstan on his exaltation to the head of the treasury under Edred, supported with all his power the monks against the secular clergy. He had introduced celibacy into the convents of Glastenbury and Abingdon, and wished to make it universal throughout the kingdom. The secular clergy, however, were numerous and rich, and would not renounce the advantages which they enjoyed. The monks accordingly inveighed against the vices of the clergy, and stigmatised their wives with the name of concubines. These invectives produced retaliation on the part of their adversaries, and the whole kingdom was involved in religious contumelies and animi-

Celibacy of the clergy introduced by Dunstan.
Edgar had long heard of the beauty of Elfrida, the daughter and heiress of Ogar, Earl of Devonshire; and his curiosity and desire were so excited, that he resolved, if report spoke true, to make her his wife. To ascertain, however, whether Elfrida was such a person as she had been described, he sent Earl Athelwold, his favourite, upon a pretended message to her father, with orders to bring him a correct account of the beauty of his daughter. Athelwold, as soon as he beheld Elfrida, was so overcome with her charms, that he forgot every other consideration but the gratification of his own passion, and demanded her from her father for his own wife. The favourite of a king was not to be refused, and they were married in private. Athelwold, pleased with the treacherous part which he had acted, returned with tidings very different from what Edgar had expected. He represented Elfrida as possessed of none of those accomplishments for which she had been so highly praised, and assured him that she was altogether unworthy the hand of a king. When he heard the thought of what from Elfrida, he took an opportunity, some time after, of remarking, that the fortune of Ogar's daughter, rendered her a very advantageous match for himself; and he requested permission to pay his addresses to her. Edgar, without hesitation, consented, and even recommended him to his parents. Athelwold returned to his wife, and had their nuptials solemnised in public; but, to secure himself against all possibility of detection, he used every precaution to detain Elfrida in the country, and to keep her at a distance from the eyes of the king. The enemies of the favourite, however, soon exposed him to his master; but Edgar, dissembling his resentment, merely expressed to Athelwold his surprise that he never brought his lady to court, and intimated his desire of being made acquainted with one of whom he had formerly heard so much. The favourite was thunder-struck at such an intimation, but could not refuse such an honour, and requested a few hours to prepare his wife for the king's reception. He was at her bed, confessed the treachery of which he had been guilty, and intreated her, if she had any regard for his life or her own honour, to conceal, by every means, from his sovereign, that beauty which had been so fatal to his fidelity. Elfrida promised obedience; but, instead of complying with the wishes of her husband, she was exasperated against him for having deprived her of a crown, and with the hope of still captivating the heart of Edgar, appeared before him in all her charms. The monarch was overcome by her beauty, and determined to obtain her; but for the present concealed his sensations from Athelwold, who was soon after, however, secretly murdered by the king's command, and Elfrida was raised to the throne. Such was Edgar; yet Edgar was placed by the monks among the number of the saints. His reign is remarkable for the extirpation of wolves from England. He himself took great pleasure in hunting these animals; and he changed the tribute which had been imposed upon the Welsh princes by Athelstan, into an annual tribute of 300 wolf-heads, which produced such diligence in destroying them, that they soon became extinct in the island. 4
England, and his the voice at harbour. A. 9T3. of the horse, of he hind. Edward, Elfrida his, and the clergy. However, was rendered unsuccessful, by the treachery of Alfric, Duke of Mercia, whose repeated perfidy brought many calamities upon his country, and whose name is infamous in the annals of that age. He informed the enemy of their danger, and even deserted to their standard. But such was the weakness of the English court, that it was found necessary again to entrust this nobleman with his former government.

The Danes now began to feel their superiority; and the divisions among the nobility, and the weakness of the king, encouraged them to continue their incursions. In 993, Sweyn, king of Denmark, and Olave, king of Norway, sailed up the Humber with a considerable force, and spread their ravages all around. The army which was assembled to oppose them, was defeated in battle by their leaders, Ferna, Prithgeud, and Godwini, who were all of Danish extraction, and offered an easy victory to the invaders. Encouraged by this success, and inspired with contempt for such an enemy, they penetrated into the heart of the kingdom, and were stopped in their depredations only by another compromise. Ethelred promised them subsistence and tribute, if they would leave the kingdom. The sum of L.16,000 was immediately paid, and they soon after departed. A short respite was the only consequence of this compromise. The Danes again appeared, and laid waste, with fire and sword, the whole southern coast, from the Severn to the Thames. The miseries which the English now suffered, reduced them almost to despair; and they had again recourse to the expedient of buying tranquillity with money. But the invaders rose in their terms, and demanded L.24,000, to which they had the meanness to submit. Ethelred saw that there was no end to these submissions, and betook himself of other expedients to resist these merciless ravagers. He entered into an alliance with Richard Duke of Normandy, by receiving Emma, the sister of this prince, in marriage; and he further endeavoured to secure the peace of the kingdom, by getting rid of his Danish subjects. Many of these had been employed as mercenaries by his predecessors; but, instead of defending the inhabitants against their invaders, they generally took part with their countrymen, and assisted in their depredations. They had also rendered themselves most obnoxious to the English, by their violence and licentiousness; and the animosity which subsisted between the two nations was at its height, when Ethelred formed the bloody and impolitic purpose of massacring all the Danish troops throughout his dominions. The festival of St. Brice (Nov. 13. 1002) was fixed for the execution of this design, and secret orders were dispatched to commence it everywhere on the same day. The

The king murdered by Elfrida. A. D. 973.

Ethelred's weak reign.
populace, enraged by the recollection of former injuries, and stimulated by the commands of their rulers, did not distinguish between innocence and guilt, and spared neither age nor sex. Even Gunilda, the sister of the Danish monarch, who had married Earl Polding, and had embraced Christianity, was included in the fate of her countrymen.

This barbarous and perfidious policy, however, instead of relieving the English from their miseries, was only a prelude to greater misfortunes. Sweyn, king of Denmark, exasperated by the slaughter of his countrymen, and of his own sister, soon filled the kingdom with his vengeance. The English, though now prepared to make a vigorous resistance, were dispirited and betrayed by their leaders. Alfric, the commander of the English armies, feigned sick, and refused to lead them against the enemy. Their calamities were augmented by famine; and they were obliged to buy a precarious peace with L.30,000. New and formidable preparations were made against the return of the enemy. Every proprietor of eight hides of land, was commanded to provide a horseman and a complete suit of armour; and those possessing 310 hides, were to equip a ship for the defence of the coast. This equipment amounted to about 800 ships, and 50,000 men. But all these preparations were frustrated, by the treachery of Duke Edric, and the animosities and factions of the nobility. Edric had succeeded his father Alfric in the government of Mercia, and in the command of the English armies; and had married the king's daughter. He was even a greater traitor than his father, and, like him, found it his interest to prevent all successes that might tend to establish the royal authority, and consequently endeavour to counteract every plan that was formed for the defence of the country. General consternation, and mutual disaffection and dissension, prevailed. The enemy appeared in every quarter of the kingdom. The governors of one province refused to march to the assistance of another. General councils were summoned, but nothing was done; and they at last agreed to stipulate for peace at the expense of L.48,000. The Danes accepted the money; but finding themselves masters of the country, disregarded the treaty. They continued their ravages, and under new contributions; and the nobility saw no prospect of relief by acknowledging allegiance to the Danish monarch. Ethelred immediately fled to Normandy, whither he had previously sent his Queen Emma and her two sons, and where they were treated by Richard with every mark of kindness and honour.

Sweyn, however, survived his exaltation to the throne of England but a few weeks, and Ethelred was recalled by the prelates and nobles. But adversity had wrought no change upon his character, and cowardice and credulity were its prominent features. His son-in-law, the perfidious Edric, notwithstanding his repeated treasons, still retained his influence at court. Affairs soon became as desperate as formerly; and the English found in Canute, the son and successor of Sweyn, an enemy no less terrible than his father. He ravaged the eastern coast with merciless fury, and then broke into the counties of Dorset, Wilts, and Wiltshire. An army was there assembled to oppose him, under the command of Prince Edmund, the eldest son of Ethelred, and Duke Edric. But Edric again betrayed his trust; and, after attempting to get the Prince into his power, he deserted to Canute. Edmund still kept the field, but was obliged to commit equal ravages with the Danes, in order to procure supplies for his soldiers. He afterwards retired to London, determined to lose the capital only with his life. On his arrival there, however, he found every thing in confusion by the death of the king, who expired after an unhappy reign of 38 years. Edmund immediately ascended the throne. He was surnamed Ironside, from his hardy valour; but his abilities and courage, though great, were unable to save his sinking country. He protracted for a while an unequal war, but was at last obliged by his subjects to put an end to those convulsions, by dividing the kingdom with his rival. Canute retained the northern division, consisting of Mercia, East Anglia, and Northumberland, while Edmund kept possession of the southern part. He was soon after murdered at Oxford by his two chamberlains, at the instigation of the infamous Edric.

The tender years of Edmund's children, were unable to oppose the ambition and the power of Canute. But to give some appearance of justice to his usurpation, he pretended that in the last treaty with Edmund it was agreed, that, in case of Edmund's death, Canute should either succeed to his dominions, or be guardian to his children. He had no sooner taken possession of the throne, than he sent the two sons of Edmund to Sweden, with secret orders to the king, to free him from all future anxiety by their death. The Swedish monarch, too humane for such a deed, sent them to be educated at the court of Hungary. Edwin the elder brother died without issue, and Edward married Agatha, the sister-in-law of the king of Hungary, by whom he had Edgar Atheling, Margaret, afterwards queen of Scotland, and Christina, who retired to a convent.

Canute, to secure himself in his dominions, cut off many of the English nobility on whom he could not rely, and whom he hated on account of their disloyalty to their former sovereign; and among the rest perished the traitor Edric, who was publicly executed, and his body thrown into the Thames. He then married Emma, the queen of Ethelred, whose children, supported by their uncle Richard Duke of Normandy, had laid claim to the English throne, and thus he acquired both the friendship of that prince, and the confidence of his English subjects. Though the beginning of Canute's reign was marked with severity and injustice, he afterwards reconciled the English to the Danish yoke, by impartiality of his administration. He made no distinction between the two nations in the distribution of justice; he restored the Saxon customs in a general assembly of the states, and thus gradually incorporated the Danes with his new subjects. Having firmly established his power in England, he made an expedition to Denmark, to resist the invasion of the Swedes. Here Earl Godwin, and the English troops under his command, performed such important services, that the King gave him his daughter in marriage, and treated him ever after with the greatest confidence. Canute afterwards attacked and added Norway to his dominions; and also compelled Malcolm king of Scotland, to acknowledge himself a vassal to the English crown for the county of Cumberland. The latter years of his life were spent in the exercises of religion. He undertook a pilgrimage to Rome, built churches, and endowed monasteries; and died at Shaftesbury, the greatest and most powerful monarch of his time, after a reign of 18 years. He left three sons, Sweyn and Harold by his first wife Alfwyn, the daughter of the Earl of Hamps-
In the treaty with the Duke of Normandy, Canute had stipulated, that he would leave his kingdom to the children of Queen Emma; but, Hardicanute being yet a minor, and unfit to rule such an extensive and newly conquered kingdom, he left the succession to Harold. Hardicanute, however, was supported by Earl Godwin, the most powerful nobleman in England; and a civil war would have been the consequence, had they not agreed to divide the kingdom between them. Harold had London, with all the provinces north of the Thames, and the southern parts were assigned to Hardicanute. Queen Emma immediately fixed her residence at Winchester, and governed in the name of her son.

The ambition of Harold, who was remarkable for no virtue, and whose only accomplishment was agility in running, by which he acquired the surname of Harcfoot, was not satisfied with a divided authority; and his fears were awakened by the recollection, that he had other competitors in Alfred and Edward, the two sons of Ethelred. These princes had arrived from Normandy, on a visit to their mother at Winchester; and Harold, having gained over Earl Godwin by promising to marry his daughter, resolved to get rid of his fears by their death. Alfred was accordingly invited to London, under the mask of friendship, and was waylaid by the vassals of Earl Godwin, who, having murdered 600 of his attendants, seized him as a prisoner, put out his eyes, and threw him into the monastery of Ely, where he soon after died. Emma and Edward were no sooner apprized of Alfred's fate than they left the kingdom, when Harold took possession of his brother's dominions.

A. D. 1039.

His triumph, however, was but short. He died after a reign of four years, neither regretted nor esteemed by his subjects.

Died of a debauch.

A. D. 1041.

Edward, surnamed the Confessor, the son of Ethelred, was called to the throne by the universal consent of the nation. The English were overjoyed at the restoration of their native prince, and congratulated themselves with the hope of their never again being subject to a foreign dominion. The only fear of opposition on this occasion was from Earl Godwin, between whom and Edward there subsisted an open animosity, on account of the murder of Prince Alfred. Edward, however, was obliged to soothe his resentment for the present. He submitted to a reconciliation, and, as a pledge of his sincerity, he promised to marry Editha, the daughter of Godwin. New causes of dissension soon arose. Edward, who had been educated in Normandy, had contracted a partiality for the manners and usages of that country. Whatever was Norman was sure to meet with his favour. His court was, consequently, in a short time crowded with foreigners, who soon introduced their customs and language among the natives. The attention and confidence of the king was chiefly confined to these strangers. He bestowed upon them the highest ecclesiastical prelatures; and the seats of Canterbury, London, and Worcester, were filled by Normans. This excited the jealousy of the English, particularly of Earl Godwin, who had also been irritated by the treatment which his daughter had met with from Edward. The reconciliation of the king with that nobleman was forced upon him by political considerations; but he could not bring himself to bear the injuries he had suffered. His hatred to the father was transferred to the daughter; and the beautiful Editha, though possessed of many amiable accomplishments, could never acquire the love of her husband. It is even said, that, during the whole course of her life, this frigid monarch abstained from all matrimonial intercourse with her; and it is asserted by the monks, that he married this princess purely to exercise his virtues, by withstanding a continual temptation; and it was for this absurd continence, whether pretended or real, that he obtained the title of Saint, or Confessor. As Godwin, however, could not openly assign this as a ground for disaffection, he seized upon the more popular pretence—the great power and influence of the Normans in the government; and an occasion was soon offered him for declaring his animosity, and bringing it into action.

The Count of Boulogne, on his return from a visit to the court of England, had been stopped at Dover by a tumult of the populace, which had been excited by the insolence of one of his vassals, and from which he had difficulty escaped. He hastened back to Edward, and complained of the ill treatment which he had met with. The king immediately ordered Godwin, under whose jurisdiction Dover was, to punish the inhabitants. Godwin, instead of complying, threw the whole blame of the disturbance upon the Count and his followers; and, under pretence of preparing for an expedition against the Welsh, he assembled a large army, and marched directly to Gloucester, where Edward then resided. The king, totally unprepared for such a proceeding, endeavoured to gain time by negotiation. In the meanwhile, he was joined by Siward, Duke of Northumberland, and Leofric, Duke of Mercia, and soon assembled an army sufficient to set his opponent at defiance. He immediately proceeded to London, and summoned a council to judge of Godwin's rebellion. That nobleman, finding himself unable to make head against the power of his sovereign, fled into Flanders with his three sons, Guitli, Sweyn, and Tosti; while Harold and Leofric, two others of his sons, took shelter in Ireland. Their estates were immediately confiscated; and Queen Editha was confined in a monastery at Wareweal.

Godwin, however, was not discouraged by this unpromising aspect of affairs; and he was too strongly supported by powerful alliances both foreign and domestic, to remain quiet under his misfortunes. He assembled an armament in Flanders; and, when a favourable opportunity presented itself, he set sail for the Isle of Wight, where he was joined by his son Harold with a squadron from Ireland. They traversed all the southern coast, entering the harbours, and carrying off the ships. Edward had no fleet capable of opposing them; and, as they declared that they came only to procure justice for themselves, and to relieve their country from the tyranny of foreign influences, they were soon reinforced by great numbers. They with an army then entered the Thames, and appeared before London. The king was compelled, by necessity, to come to an accommodation. It was agreed, that Robert, archbi-
shop of Canterbury, who was a Norman, and the most obnoxious of his countrymen, should be banished, and that Godwin should give hostages for his future obedience. This turbulent nobleman was thus reinstated in all his former power; but his hostages, for greater security, were sent by Edward to his kinsman, the Duke of Normandy. Godwin's death, however, relieved the king, for a time, from farther disquietude; but his son Harold inherited the power and ambition of his father, and was superior to him in talents and in virtue. By his insinuating address, he had softened, in some degree, the hatred which Edward had always borne to him; and his popularity was daily increasing, by his generosity and affability of manners.

The king saw the growing authority of Harold, but had not vigour to oppose it; and at last had recourse to the dangerous expedient of setting up as a rival, Algar, the son of Leofric, Duke of Mercia, who possessed the government of East Anglia. Algar, however, was unable to stand before the power and the intrigues of Harold, whose influence obtained his expulsion from his government, and his banishment from the kingdom; and the death of Algar, and his father Leofric, which happened soon after, freed Harold from any farther apprehension from that quarter. His power was also considerably augmented, by the accession of his brother Tosti to the dukedom of Northumberland. Sиward, the former duke, had greatly distinguished himself, by an expedition to Scotland against the usurper Macbeth, whom he defeated and killed in battle, and restored Malcolm Kenmore to the throne of his father; but he lost in that enterprise his eldest son Osbern; and as his second son, Wulstan, was too young to be entrusted with such a government, Harold had the influence to procure it for his own brother. Edward could not but perceive, that this nobleman was aiming at the succession to the throne; and, as he felt himself broken down by age and infirmities, he invited his nephew Edward, the son of Edmund Ironside, from Hungary, and appointed him his successor in the kingdom. The death of that prince, however, which happened a few days after his arrival in England, and the tender age and inexperience of his son Edgar Atheling, threw the king into new difficulties. He still retained his dislike to the family of Godwin; and could not brook the idea, that they who had risen on the ruins of his authority, should succeed to his throne. He therefore cast his eye on his kinsman William, Duke of Normandy, and even secretly commissioned Robert, archbishop of Canterbury, to inform William of his intentions.

Duke William had displayed the greatest abilities, both as a statesman and a warrior. He had come to the government when a minor; and the regency established by his father could with difficulty maintain themselves, amidst the dangers of foreign invasion and internal dissension. But the prince no sooner came to maturity, than he struck terror into his enemies, by the vigour and wisdom of his administration. His valour and conduct prevailed in every action. He compelled his invaders to retire; reduced his turbulent and licentious barons to submission; and soon established his dominions in complete tranquillity. The intelligence of Edward's intentions excited his ambitious hopes; and he endeavoured, by every means, to secure his object. Harold, however, was equally unremitting in establishing his power, and preparing for the expected vacancy. He had extorted, by his intrigues, the king's consent to release the hostages which had been given by his father, and which were still in the hands of the Duke of Normandy. He was unwilling that such near relations should remain prisoners in a distant country, and was afraid that they might be retained as pledges for his own good behaviour, in the event of any dispute about the succession. He therefore had no sooner obtained Edward's sanction for their release, than he set sail with a numerous retinue for Normandy. He was driven by a tempest on the territories of the Count of Pontchen, who, being informed of his quality, detained him prisoner, and demanded an exorbitant sum for his ransom. Harold, however, found means to acquaint the Duke of Normandy with his situation; and William immediately seized this favourable opportunity of gaining over Harold to his views. Insinuating to this powerful nobleman, he thought his succession to the throne of England would be secured; and he accordingly compelled the Count of Pontchen to set him at liberty, and received him at Rouen with every demonstration of respect and esteem. They were both ignorant of each other's pretensions; and Harold was not a little surprised, when he heard, for the first time, of the intentions of Edward to make William his heir. He was obliged, however, to conceal his feelings. William offered him his daughter in marriage, and promised to raise his family to still greater honours, if he would assist him with his power. He also required him to take an oath that he would be true to his engagements: to all of which, Harold was obliged to feign compliance; and they parted with all the appearance of mutual friendship.

The ambition of Harold soon made him forget the oath which had been extorted by necessity; and the discovery of Edward's design tempted him the more to strengthen his power, and augment the number of his friends. He took every opportunity of encouraging the English in their hatred to the Normans, and always deprecated their subjection to foreign influence. He thus attempted to reconcile them to his succession; and, by a show of great power and influence, he deterred Edward from openly declaring his intention in favour of William.

About this time, Harold also acquired very general favour, by an opportunity which he had of displaying his abilities and justice. The Welsh, under their prince Griffith, had made repeated inroads, and committed great depredations on the frontiers, and had been always able to shelter themselves from pursuit among their inaccessible mountains. Harold was determined to repress these troublesome plunderers. He attacked them both by sea and land, and followed up his successes with such vigour, that, in order to save themselves from total destruction, they were compelled to deliver up the head of their prince, and submit themselves to the authority of Edward.

An insurrection had also broken out among the Northumbrians, which was headed by Morcar, Duke of Mercia, and his brother Edwin; and which had been occasioned by the tyrannical temper and injustice of Duke Tosti. Harold was commanded by the king to suppress the insurgents; and he marched a considerable army into Northumberland for this purpose; but, before coming to action, Morcar, relying on the generous disposition of his opponent, requested to be heard in his own defence; when he represented, in such strong colours, the cruelties and indignities which the Northumbrians had suffered from Tosti, and their determination to perish rather than be exposed to a renewal of them, that Harold abandoned his brother's cause, and refused to be the instrument of his tyranny. He even
Edward, worn out with age, weak and irresponsible, though hostile to the claims of Harold, yet employed no decisive measures for securing the succession to the Duke of Normandy; and, while still undetermined how to act, he was cut off by death in the 65th year of his age, and 25th of his reign. Harold immediately ascended the throne without opposition. The voice of the people supported his claim, and he was crowned the day after Edward’s death, by Aldred, archbishop of York. His private virtues also entitled him to a crown, which might be considered as elective; but he possessed but for a short time what he was so worthy and able to wear. William of Normandy could not conceal his disappointment, at the intelligence of Harold’s exaltation; he had indulged himself with the hope of an easy accession to the crown of England; but he now saw it torn from his brow, by one equal in abilities to himself, and who had acquired, by his many virtues, the love and confidence of his subjects. His indignation burst forth in menace and upbraidings: he dispatched an embassy to Harold to reproach him with his breach of faith, and to demand an immediate renunciation of the throne of England, of which, by the will of Edward, he was the rightful heir. Harold coolly replied, that an oath was only binding when voluntary: his was extorted by fear, and therefore could not be regarded as obligatory. He had obtained the crown by the unanimous voice of the nation: he should prove himself worthy of their choice, by maintaining to the last those liberties which they had entrusted to him; and he was determined to lose his kingdom only with his life. William was prepared for this answer; and, as he had resolved upon prosecuting his claim by force of arms, he continued his levies. His intention was no sooner made known, than he was joined by numerous adventurers from different parts of Europe, who, impatient of peace and tranquillity, were ready to embark in any enterprise which promised them plunder or renown. He thus found no difficulty of completing his armament, which, besides his own troops, who were distinguished for their valour and discipline, was composed of the flower of the continental warriors, commanded by the most celebrated champions of the age. He was also encouraged by the Emperor Henry IV, who promised to guarantee his Norman dominions during his absence; and by Pope Alexander II, who sent him a consecrated banner, and a ring with one of St Peter’s hairs in it.

William, in order to divert Harold’s attention from his own preparations, and to embarrass his affairs the more, seduced Tosti, and Halfagar, king of Norway, to make a descent upon England. This they did with a considerable army, and overran all the northern parts of the kingdom. They were first opposed by the Dukes of Northumberland and Mercia, whom they defeated and put to flight; but Harold having hastily collected an army, engaged them at Stamford. The Norwegians made a most obstinate resistance, but were at last totally routed. Tosti and Halfagar fell in the action; and the Norwegian fleet became the spoil of the conqueror. Prince Olave, the son of Halfagar, however, was generously restored to liberty, and allowed to depart with 20 vessels.

The news of this defeat spread the greatest joy throughout the kingdom; but their joy was soon repressed by the intelligence, that the Duke of Normandy had landed in Sussex with a formidable army of 60,000 men. William had been some time detained by contrary winds; but, as Harold had dismissed his fleet, on receiving false intelligence that William had discontinued his preparations, he met with no other obstacles in his voyage. He quietly disembarked, and prepared for the arrival of the enemy.

The victory of Stamford had so weakened the English army, that it may be regarded as the cause of Harold’s subsequent overthrow. He had lost many of his bravest officers and soldiers, whose place he could supply only with raw and undisciplined troops, little capable of resisting the discipline and valour of the Normans. Elated, however, with success, and relying on the confidence and bravery of his subjects, he hastened forward to meet his new invader. His brother Gurth renounced his fortunes on the issue of a battle, while he had easier means of victory in his power. It was depriving himself of those very advantages which he possessed over the invader. He was in the midst of his resources, surrounded and beloved by his people; while the desperate situation of the enemy required a speedy termination to the contest. The Norman leader possessed the greatest military talents, and his troops had been long familiar with conquest. Their valor and discipline rendered them more formidable than their numbers; and, as they had full confidence in the abilities of their chief, they would fight to the last extremity. But if their ardour was allowed to cool for want of action; if they were harassed with skirmishes, and straitened in provisions, they would be compelled to retire, or fall an easy and bloodless prey. If, however, he was determined upon an engagement, he entered him not to risk his own person, and thus deprive his country of its chief resource in resisting a foreign dominion.

Harold was deaf to persuasion, and approached the Norman camp at Hastings. He offered William a sum of money if he would depart the kingdom. William returned, that he must resign the kingdom, or hold it of him in fealty, or submit his cause to the pope, or fight him in single combat. Harold replied, that the god of battles would determine their differences.

The hostile armies were encamped in sight of each other during the night, and waited with anxiety for the return of day. The English passed the night with songs and feasting; the Normans in silence and prayer. The dawn of morning beheld both armies in battle array. William harangued his soldiers on the greatness of the prize for which they were to contend; and represented to them the inevitable destruction which awaited them, should they fail of success. His army was divided into three lines: the first, consisting of archers and light-armed infantry, was led by Roger de Montgomerie; the second, composed of heavy-armed battalions, was commanded by Charles Martel; while he placed himself at the head of the cavalry. They advanced to the attack, singing the song of Roland. Harold had drawn up his army on a rising ground, and had secured his flank by deep trenches. He commanded on foot the Kentish men, who were placed in the van, and encouraged his troops, by sharing with them the post of danger. He was resolved to stand
ENGLAND.

599

The Norman cross-bows at first dreadfully gall'd the English; but as they came into closer action, the English bills mowed down their ranks, and checked the fury of their onset. The combat was long and desperate, and disputed with equal bravery on both sides. The Normans at length began to give way; William saw the imminence of his danger, and hastened with fresh forces to the support of his retreating bands. His presence revived the courage of his followers, and the English were in their turn compelled to retire. Aided, however, by the advantage of the ground, and animadverted by the voice and example of their king, who had toiled all day in the front of the battle, they renewed the fight, and the Normans were falling in great numbers. William, finding that he could make no impression on the enemy's position, ordered his troops to make a sudden retreat, and deceive them by the appearance of a flight. The artifice succeeded. The English followed them to the plain, when the Normans suddenly facing about, and attacking them in both flanks with their cavalry, drove them back with great slaughter. They were again rallied by the bravery of their prince; and though William repeated the same stratagem, yet the English were enabled still to maintain themselves in firm array, and seemed determined to dispute the victory to the last. But the death of Harold, who was slain by an arrow while fighting in the foremost ranks, decided the battle in favour of the Normans. The English were dispirited by the loss of their brave but unfortunate leader, and gave way on all sides. The victorious invaders followed up their success with dreadful slaughter: but darkness soon put an end to their bloodshed. In this memorable action, the Normans lost 15,000 warriors, and the duke had three horses killed under him. The loss of the English was still more considerable; besides the death of their king and his two brothers. The body of Harold could scarcely be distinguished among the heaps of slain. It was brought to William, who restored it without ransom to his mother. The Normans gave thanks to heaven for their victory on the field of battle; and immediately prepared to improve, to the utmost, the advantage they had gained.

The English, considering their great resources, might have done much to retrieve their affairs; and had they been unanimous, might have worn out their invaders by a protracted warfare. But they were divided and dismayed. The intelligence of the battle of Hastings spread terror and consternation throughout the kingdom, and no one appeared to whom the nation could entrust its fortunes. Edgar Atheling was proclaimed king, and Morcar and Edwin, Harold's brothers-in-law, endeavoured to make a stand in his defence. But their plans were disconcerted by the rapid advance of the conqueror to the capital. The clergy were the first to bow before his consecrated standard, and even insisted that the pope's bull called for general submission to the authority of William. On his approach, Edgar, the new elected king, with Stigand, Archbishop of Canterbury, and the chief nobility, entered his camp, and made him a formal offer of the crown of England, upon condition that he would govern according to the customs of the country. Though by right of conquest he could have demanded the crown, yet he chose rather to accept it as a voluntary gift; and he was consecrated in Westminster Abbey, by Aldred, Archbishop of York. Edwin and Morcar, who had retired with their troops to their own provinces, and others of the principal nobility, who were not present at the coronation, soon after came and swore fealty to the new sovereign.

The beginning of William's reign was marked with mildness and humanity. Though all real power was placed in the hands of the Normans, he took care that they should use it with moderation. Every disorder or oppression met with severe punishment. He built citadels in London, and other towns best situated for commanding the kingdom, where he quartered his army, among whom he had distributed considerable sums as the reward of their valor; but he governed them with rigid discipline, and restrained every appearance of insolence towards the natives. He received, with affability, all who approached his person, and seemed desirous that the two nations should live in the closest amity.

Peace and tranquillity seemed now to be firmly established; and William, nowise apprehensive of any disturbances by his new subjects, went over to Normandy to receive the congratulations of his countrymen. His brother Odo, Bishop of Bayeux, and William Fitz-Osborne, were entrusted with the administration of the kingdom during his absence; and the better to secure their authority and the fear of chief of the English nobility. These not only served to grace his court by the magnificence and costliness of their equipages, but might be considered as hostages for the fidelity of the nation. His departure, however, was soon followed by conspiracies and insurrections. The Norman captains, no longer under the eye of their sovereign, grudged the restraints which had been imposed upon their rapine, and treated with contempt a people who had surrendered their liberties so easily. Their insults and depredations produced a general disaffection among the English, which in some places broke out into open rebellion. A secret conspiracy was even formed for a general massacre of the Norman soldiery, which was to take place on Ash Wednesday, during the time of divine service, when the Normans would be unarmed; and Earl Coxe was murdered by his vassals, because he refused to join in this enterprise. The presence of William, however, disconcerted all their schemes. Many of the conspirators fled, whose estates were forfeited, and his Norman followers; and, as a further mean of gratifying their rapacity, he renewed the tax of Danelagel, which had been so odious to the nation. This only produced new insurrections. In Exeter, Cornwall, and Devonshire, the inhabitants took up arms, but were soon suppressed. But in the north they assumed a more formidable appearance. Edwin and Morcar, impelled by private injuries, as well as public wrongs, and encouraged by the promise of assistance from Wales, Scotland, and Denmark, resolved to attempt the deliverance of their oppressed countrymen; but they were surprised by the king before any of the foreign succours had arrived, and were obliged to submit to his clemency. They were pardoned and restored to their possessions; but their followers were treated with greater rigour, and their lands were divided among his foreign adventurers. Many fied from oppression into foreign countries; and Edgar Atheling, distrusting the insidious caresses of William, sought refuge with his two sisters, Margaret and Christina, in the court of Malcolm King of Scotland, who soon after married Margaret, and treated with kindness all the English exiles who sought his protection. William now began to view the English as unworthy of his clemency, and
as a people on whom he could place no dependence; and henceforth he was determined to treat them with the utmost rigour. All offices of trust and confidence were consequently bestowed upon the Normans, who committed continual insults and depredations.

Finding no redress for such injuries from their governors, the English took vengeance with their own hands, and assassinated Normans were daily found in the woods and highways, without any possibility of bringing the perpetrators to justice. Many of the Norman chiefs finding themselves continually exposed to the fury of an incensed people, and under constant apprehensions of danger, longed for the peace and security of their native country. They desired to be dismissed from the service, which William granted, but at the same time resented, by confiscating all their possessions in England. New insurrections were followed by new forfeitures and attainders; and the Normans found it their interest to instigate rebellion, as they were sure to be benefited by its suppression.

The three sons of Harold, Godwin, Edmund, and Magnus, who, after the battle of Hastings, had retired to Ireland, encouraged by the general dissatisfaction of the English, made a descent with a considerable force on the coast of Devonshire; but, being defeated in several actions, they were compelled to return to their ships. About the same time, the Northumbrians again took up arms, who, being joined by Edgar Atheling and the chief of the English exiles from Scotland, and assisted by a body of Danes, attacked the Norman garrisons of Durham and York, and put every man to the sword. The inhabitants of the southern counties had also risen, and a general effort seemed now to be made for the recovery of their liberties; but it proved only the means of rivetting their chains more closely. William having bought off the Danes, and encouraged his followers with the hope of plunder, inflicted a signal punishment on the restless Northumbrians. He laid his desolating hand upon their fertile country between the Tees and the Humber, for the extent of about 60 miles; burned their habitations; destroyed their implements of husbandry; and drove away their cattle. The inhabitants were compelled to seek for subsistence in the southern counties of Scotland; but about 100,000 are said to have perished miserably in the woods, of cold and hunger. The other malcontents had submitted to the conqueror, except Hereward, a nobleman in East Anglia, who took shelter in the Isle of Ely, and continued his inroads into the neighbouring country.

William, however, to prevent any repetition of such disturbances in future, transferred almost the whole of the landed property in England into the hands of his Normans; and for this injustice he considered it a sufficient pretence, that most of the ancient proprietors had been involved in conspiracies and insurrections against his government. Many noble families were thus reduced to beggary, and had the mortification of seeing the meanest and lowest of their enemies possessing their castles and demesnes. He next divided the kingdom into baronies, which he exclusively conferred upon the most considerable of his followers, with the reservation of stated services and payments. These amounted to about 700, who again parcelled out their lands, with similar conditions, among their vassals or knights; of which there were 60,215. As the English were totally excluded from the first rank, those who still retained any property were glad to be received as knights, under the protection of some powerful Norman. The clergy also felt the effects of his resentment. All Englishmen were expelled from the higher offices of the church, which were immediately filled by foreigners; and the Bishop of Worcester was the only English prelate that was permitted to retain his dignity. He even extended the feudal laws to them; and all bishops and abbots were obliged to furnish, during war, a number of knights, proportioned to the extent of the property possessed by each see or abbey.

William, as he had extinguished the very semblance of liberty among the English, now attempted to obliterate their name, by the destruction of their language. He ordered, that, in all the schools throughout the kingdom, the youth should be instructed in the French language. This was the language of the court, and of all fashionable company; and all laws and deeds were composed in that idiom. The English now saw themselves beyond the reach of deliverance: they were treated with every mark of insolence and indignity by their conquerors; and the plans of oppression which the king formed, were wantonly executed by his followers.

The two great earls, Morcar and Edwin, finding themselves despised, and without authority in the state, the only effort to make another effort to recover their independence. The former took shelter in the Isle of Ely with the brave Hereward, while Edwin proceeded to organize an insurrection in the north. But William frustrated their plans, by the capture of the Isle of Ely. He surrounded it with flat-bottomed boats, and compelled the rebels to surrender at discretion. Hereward alone forced his way through the enemy; and the king was so charmed with his bravery, that he received him into favour. Morcar was thrown into prison. Edwin, in attempting to escape into Scotland, was betrayed, and killed by a party of Normans; and many of the prisoners were punished with the loss of their hands or their eyes, and were dispersed throughout the country as monuments of the king's resentment.

A more formidable rebellion, however, soon followed. The Norman barons had also felt the arrogance of William's temper, and disgraced to stoop to his arbitrary authority. At the head of the discontent were the Earls of Hereford and Norfolk, and Waltheof, Earl of Northumberland, the only Englishman that retained any power in the kingdom. They perceived the opportunity of William's absence in Normandy, to throw off their allegiance, and entered into a secret correspondence with the king of Denmark, to assist them in their designs. Waltheof, however, who had married Judith, the king's niece, reflecting on the improbability of a successful overthrow of William's power, and fearing that, by changing one tyrant for many, it would be the means of increasing, rather than of alleviating the miseries of his countrymen, revealed the conspiracy to his wife. Judith had fixed her affections upon another, and viewing this as a favourable opportunity of getting rid of her husband, conveyed the intelligence, with every exaggeration, to her uncle. Waltheof, immediately after, passed over to Normanody, to inform William of every circumstance, and to make some atonement for his treason, by an early confession. His departure was no sooner known, than the conspirators flew to arms, before their plans were sufficiently matured, and before the promised assistance from Denmark had arrived. They were consequently soon suppressed; and the king, on his arrival, found order and tranquillity again restored. Many of the rebels were hanged; others were punished with the
loss of their eyes or hands; and Fitz-Aubert, a noble Norman, and Waltheof, the only two noblemen who suffered death on this occasion, were beheaded. The fief of Waltheof was greatly lamented by his countrymen; and it was supposed that he owed his death to the instigations of his wife.

When William first formed the design of invading England, he had, on the application of the French court, declared Robert, his eldest son, his successor in Normandy, and had obliged his barons to do him homage as their future prince; but after he found himself firmly established upon the English throne, he still retained the sovereignty of that duchy; and when Robert put him in mind of his promise, he positively refused to fulfill it. Robert inherited his father's military valour and was equally haughty and impatient of control. The denial of what he supposed his just right, kindled his indignation, which he had not the policy to conceal. He openly showed his discontent; and being further irritated by an imaginary affront, he left the court, and attempted to enforce his claims, by taking up arms against his father. He made an attempt to surprise the citadel of Rouen; but his design was frustrated by the vigilance of the garrison. He was fled to Hugh de Neufchateau, a powerful Norman baron, who assured him of his protection and assistance; and was soon after joined by most of the young nobility of Normandy and Maine. This unexpected and almost general insurrection of his Norman subjects, compelled William to have recourse to England. He assembled an army of Englishmen under the command of his ancient captains, and passing over into Normandy, soon re-established his authority in all his continental dominions. Robert, with the principal insurgents, shut himself up in the castle of Gerberoy, which the king of France had prepared for his reception, and where he was immediately besieged by his father. The garrison made a vigorous defence, and, conscious of their treason, were determined against submission. They harassed the besiegers by continual sallies; and many a bloody encounter took place under the walls of Gerberoy. In one of these, Robert and his father were opposed with the knowledge of others, their faces being concealed by their helmets; and being both charged with such fury, that William was dismounted. The arm of Robert was just lifted to strike, when it was arrested by the voice of his father. Stung with remorse for his unnatural conduct, he immediately fell on his knees, and implored his father's forgiveness. William, smarting under the disgrace of his fall, was at first inapplicable; but afterwards, reflecting on the generosity of his son, and influenced also by the mediation of the queen, he again received him into favour.

William employed the interval of peace in making a general survey of all the lands in the kingdom. He appointed commissioners for this purpose, who entered in their register, by the verdict of juries, the extent of lands in each district, their proprietors, their tenures, and their value; describing also the quantity of meadow pasture, wood, and arable land, which they contained; and in some counties, the number of tenants and peasants who lived upon them. This register was called Domesday Book, and is still preserved in the Exchequer. Had William always employed his leisure in such praise-worthy undertakings, it would have done honour to his memory; but he was generally occupied with other pursuits, which, while they ministered merely to his amusement, often brought poverty and wretchedness upon his unhappy subjects. His love of hunting, particularly, was carried to such a pitch, that, not content with the extensive forests which former kings possessed in all parts of England, he resolved to make a new one near Winchester, and for this purpose depopulated the county of Hampshire for an extent of thirty miles. The inhabitants were driven from their homes, their habitations demolished, and their property taken from them, without any compensation being made to the sufferers. The severest laws were also enacted against those who should hunt in the king's forests; and the killing of a deer or a boar was punished by the loss of the offender's eyes, while the crime of murder could be expiated by a moderate fine.

A.D. 1076.

The amusements of the king, however, were interrupted by the death of his consort Matilda, to whom he was tenderly attached; and about three years after he was called to Normandy, to repress the insolence and violence of some French barons, who had been encouraged by their sovereign to make inroads into his territories. In all the diversions in Normandy, the insurgents had been in general instigated, and secretly supported, by the French; and William knew well, that they were at best but insidious friends. He therefore resolved to make his vengeance fall upon those who were the real disturbers of his tranquility. His rage was on this occasion greatly heightened by the raileries of Philip, the French king. He had become very corpulent, and, being confined to bed by sickness, the Frenchman observed, that his brother of England was long in being delivered of his big belly. When William was informed of this, he sent Philip word, that he would soon be up, and that in churching would present such a number of lights at Notre Dame as would set all France in a flame. He accordingly took the field, and, entering the Isle of France, reduced the town of Mantes to ashes, and carried slaughter and desolation wherever he appeared. His progress, however, was stopped by an accident which put an end to his life. When leaping a ditch, the pommel of the saddle bruised his belly, which was soon followed by a mortification. On his deathbed, he endeavoured to atone for the many cruelties and acts of violence which he had committed upon his English subjects, by ordering Earl Morcar and the other English nobles to be set at liberty, and by making rich presents to churches and monasteries. He left Maine and Normandy to his eldest son Robert, England was bequeathed to William, and Henry was put in possession of the greatest part of his personal treasures. He died in the 63d year of his age, and 21st of his reign over England.

A.D. 1087.

William II., surnamed Rufus, from his red hair, immediately hastened to England, before intelligence of his father's death had reached that kingdom, and having secured the fortresses of Dover, Pevensey, and Hastings, and seized upon the royal treasure, he was crowned by Lanfranc the primate. His accession, however, was soon followed by conspiracies and dissensions. The barons were more attached to Robert, on account of his open and generous character, as well as his preferable title, being the eldest son. Many of them also possessed estates both in England and Normandy, and were unwilling that the two territories should be separated, as, in the event of a war, they would be obliged to resign either their ancient patrimony, or their new acquisitions. At the head of the discontented were Odo, Bishop of Bayeux, and Robert, Earl of Mortain, maternal brothers of the Conqueror, who, being joined by some of the most powerful noblemen in the kingdom,
and being encouraged by the expectation of success from Normandy, took possession of the fortresses of Pevensey and Rochester. The king, sensible of his brother’s superior claim to the kingdom, and of the strength of the conspirators, endeavoured to conciliate the English, by granting them liberty to hunt in the royal forests, and by general promises of lenity in his government. He was thus enabled to draw together a considerable army, and, entering Kent, compelled his uncles to surrender the fortresses which they had seized. The other rebels were soon reduced to submission, their estates were confiscated, and many of them banished the kingdom.

But William forgot, in his deliverance, the promises which he had made. Instead of ruling with lenity, and respecting the rights of his people, he became a greater tyrant than his father. Ambition and avarice were the principal features in his character. The English were now exposed to the most arbitrary exactions, and the church itself felt the effects of his oppression. He seized the temporalities of all vacant bishoprics and abbeys, and set up to sale such as he wished to dispose of. He even turned his eyes towards the duchy of Normandy, and having excited some of the Norman barons to revolt from his brother, he led a formidable army to their assistance. But the interception of the nobles on both sides brought about an accommodation, in which it was agreed, among other matters, that on the death of either without issue, the survivor should inherit all his dominions. Prince Henry, who had sided with Robert in this contest, finding his interests overlooked in the treaty, retired to St. Michael’s Mount, a strong fortress on the coast, and ravaged the surrounding country. He was there besieged by his brothers; and being obliged to capitulate, was despoiled of all his patrimony.

The interested and rapacious spirit of William, however, was continually exciting him to new acts of oppression. After a short and successful war with Malcolm, king of Scotland, in which his brother Robert commanded the English army, and obliged that monarch to do homage to the king of England, he again attempted the conquest of Normandy. He levied an army of 20,000 men, and, conducting them to the coast, as if for immediate embarkation, he demanded ten ships—a man in lieu of their services, and then dismissed them home. With this money he bribed the Norman barons to rebellion, and purchased the neutrality of the French king; but he was prevented from prosecuting his schemes of ambition by an interruption of the Welsh, which obliged him to return to England. He soon compelled them to retire, but was unable to follow them within their mountain barriers. His attempt upon Normandy was further suspended by another conspiracy, headed by Robert Moubray, earl of Northumberland, which contemplated the dethronement of the king, and the advancement to the throne of Stephen, count of Anjou, nephew to the Conqueror. Their plans, however, were discouraged by William’s dispatch, and Moubray was seized and thrown into prison, where he died.

The conquest of Normandy was still his favourite object; and the crusades, which now engrossed the attention of Europe, gave him quiet possession of those dominions which he could not obtain by force of arms. Duke Robert was brave, enterprising, and fond of military glory. He was anxious to join the warriors who were hastening to the Holy Land; and, in order to appear in a manner suited to his rank, he offered to mortgage his dukedom to his brother for 10,000 merks. William immediately accepted the proposal, and, little solicitous about the means by which the money was to be obtained, levied the greatest part of it upon the clergy and the convents, who were obliged to melt their plate in order to furnish the sum required. Robert was thus enabled to join the crusaders with a magnificent and numerous retinue; and Normandy was again united to the crown of England. This acquisition, however, instead of adding to the power of William, was followed by continual insurrections on the part of the Normans, who were always encouraged and supported by the French king; and was, indeed, the cause of all those wars between England and France, which afterwards continued, for whole centuries, to depopulate and weaken both nations. These insurrections, together with a quarrel which he had with Anschin, the primate, respecting the privileges of the clergy, kept William in almost constant inequity. Not content with the extent of his territories, he entered into an agreement with William, Earl of Poictiers and Duke of Guienne, who had also been infected with the enthusiasm of the age, to receive his dominions in mortgage, for a sum of money sufficient to conduct his vassals into Asia. But the fulfilment of it was prevented by his death.

When hunting in the new forest, attended by Walter Tyrril, a French gentleman remarkable for his skill in archery, a stag suddenly started before him, when his companion let fly an arrow, which, glancing from a tree, struck him to the heart. Tyrril, terrified at the accident, immediately fled to France, and joined a crusade of his countrymen who were then setting out for Jerusalem. The body of the king, when found by the country people, was buried at Winchester without either pomp or ceremony. His violence, rapacity, and prodigality, had estranged from him the affections of his subjects, and none were found to perform the funeral honours belonging to a king. He died in the 40th year of his age, and 13th of his reign.

Robert, who was the rightful heir to the crown, both by birthright and by the agreement with his deceased brother, was, after many a rough campaign in the Holy Land, indulging himself in ease and pleasure in the delicious climate of Italy, where he had married Sybilla, the daughter of an Italian count, when he received the intelligence of William’s death. He returned to Normandy about a month after that event, but found his brother Henry in possession of his crown.

Henry was hunting in the new forest when William met his death, and was no sooner informed of the circumstances, than he hastened to Winchester and secured the royal treasures. He then proceeded to London, where, assembling some noblemen and prelates whom he had gained over to his interest, he was solemnly crowned by Maurice, bishop of London. Henry, aware of the weakness of his pretensions, endeavoured to strengthen his authority, by curtailing the affections of his subjects. He confirmed the ancient Saxon laws, and restored the clergy to their former privileges. He promised to remedy many of the grievous oppressions which had existed during the two former reigns; and for this purpose passed a charter, in which, among other things, he engaged that he would never seize the revenues of any vacant see or abbey, or let to farm, or dispose of for any ecclesiastical benefice; that, instead of the violent exactions which had been imposed upon heirs by his father.
and brother, he would permit them to take quiet possession of their property, upon paying a just and lawful relief; that he would not dispose of any hearness in marriage, but by the advice of all the barons; that the barons should have the power of bequeathing, by will, their money and personal estates; and that all debts due to the crown should be remitted. A copy of this charter was commanded to be lodged in some abbey of each county, that all his subjects might be acquainted with it; but it was intended merely to serve his own ends, and to ingratiate himself with his people, and never to be seriously acted upon. In all his proceedings, indeed, he made his own will and pleasure the sole rule of his government; and this charter, within a century, had fallen into such neglect, that when the barons of King John wished to make it the model of the great charter, a copy of it could with difficulty be found.

Anselm, the primate, who had been obliged to leave the kingdom by the violence of William, was recalled by Henry, and reinstated in all his dignities. Henry knew well the influence which this prelate had acquired, by his piety and austerity of manners, over the minds of the people, and expected that his authority would be strengthened by having such a person for his friend. He found, however, that the religious zeal and stubborn integrity of Anselm, would not bend to his purposes; and scarcely had the prelate arrived, than a quarrel arose between them respecting the investitures in ecclesiastical benefices. The prelate refused to do homage for his spiritual dignity, and declared that he would not so much as communicate with any one who had paid such submission. Henry, for the present, did not press the demand, but sent messengers to Rome to accommodate matters with the pope. In the mean time, he married Matilda, daughter of Malcolm III. king of Scotland, and niece to Edgar Atheling. This circumstance added greatly to his popularity; and the English congratulated themselves with the hope of a more equal and mild administration, when the blood of their native princes should be mingled with that of their conquerors.

While Henry had thus endeavoured to establish himself on the throne, Robert appeared to assert his claim. On his return from the Holy Land, he had taken quiet possession of his ancient dukedom; and, being encouraged by many of the Norman barons in England, who promised him their assistance to recover the kingdom, he landed at Portsmouth with a considerable armament. Henry, by his caresses and promises, had gained over Anselm to his interests; who so exerted his influence with the nobility and the people, that the king was enabled to meet his brother with a firm and united army. The two sovereigns, both apprehensive of the issue, refrained from coming to action for some days; when, by the mediation of the primate, a treaty was entered into, by which Robert was to receive an annual pension of 3000 marks, upon resigning his claim to the crown of England during the life of Henry; and that, when either of them should die without issue, the other should succeed to his dominions. Henry was no sooner freed from the danger of invasion, than he began to wreak his vengeance upon those nobles who had distinguished themselves by their adherence to the cause of Robert; and scarcely one of them escaped without banishment or confiscation. It is true, they were prosecuted upon other charges; but men easily saw that their punishment arose from their attachment to his brother. Robert, considering such conduct an infringement of the treaty, ventured to appear in England, and remonstrate with Henry in person; but his reception was such, that he was glad to purchase his liberty with the loss of his pension.

Robert, with all his amiable qualities, wanted prudence and firmness. He was open, generous, and humane. His bravery and military glory had procured him the respect and admiration of Europe; and in peace he had filled a place of dignity and authority. He had long been accustomed to be born to be the sport of fortune. After a life of toil and ambition in the Holy Land, where he refused to be crowned king of Jerusalem, he found himself, on his return, deprived of his birth-right. Confined to his patrimonial dukedom, he was too mild to restrain, by severe discipline, the turbulent spirit of his barons, and Normandy, during his reign, became a scene of violence and depredation. His brother took advantage of his indolence and imprudence; and when called to mediate between him and his discontented subjects, instead of urging them to loyalty and obedience, he excited them to rebellion by bribery and intrigue; and at last stripped him of his kingdom and his liberty. In a battle, which decided the fate of Normandy, Robert and the most considerable of his barons were taken prisoners; and this unfortunate prince, deprived of fortune and friends, passed the remainder of his life a prisoner in Cardiff Castle in Wales, where he languished 20 years.

Edgar Atheling, who had accompanied Robert to Jerusalem, and had lived with him ever since his return, was also among the captives in this action; but Henry gave him his freedom and a small pension, and he lived to a good old age, neglected and forgotten among his countrymen.

Henry having now obtained the great point of his ambition, the sovereignty of Normandy, directed his attention to the settlement of his dispute with Anselm. The messengers who had been dispatched to Rome to confer with Pope Pascal II. on the right of the sovereign to confer ecclesiastical benefices, and to receive homage for them, returned with a positive refusal of the king's demands. Henry, however, was determined not to part with his rights so easily; and sent William de Warewelle to negotiate with his Holiness, and to attempt some means of accommodating the affair. During the conference, the English messenger told Pascal, that his master would rather lose his crown, than part with such a valuable privilege; "And I," replied Pascal, "would rather lose my head than allow him to retain it." Matters now grew serious, and the Pope threatened Henry with excommunication, unless he gave up the dispute. But the king still persevered in maintaining his rights; and by his prudence and abilities, at last brought the quarrel to an amicable compromise. He gave up the right of investiture, which consisted in bestowing upon the bishops a ring and crozier as the symbols of their office; and the pope allowed prelates to do homage for their temporal properties and privileges.

From this time, Henry was involved in almost continual war on account of Normandy. William, the son of Duke Robert, after the imprisonment of his father, had been entrusted to the care of Helie de St Saen, a nobleman of strict honour and integrity; and when Henry wished to recover possession of his person, Helie withdrew with his charge to the court of Anjou, and soon after obtained for him the countenance of Louis the Second, King of France. The war which was the consequence, was the cause of many heavy
and arbitrary taxes being imposed upon his English subjects, but was attended by no memorable event. Hostilities on both sides were carried on without energy or decision; and produced only slight and insubstantial skirmishes on the frontiers. Louis, however, finding that he could not prevail by force of arms, endeavoured to interest Pope Calixtus II, in favour of the young prince. He carried William to a general council which was held at Rheims, and represented to them the injustice of Henry in bereaving his nephew of his inheritance, and also of detaining in prison his brother Robert, who, on account of his eminent services against the infidels, was entitled to the protection of the holy see. But Henry employed a more powerful instrument to counteract the intentions of his enemies. He ordered his ambassadors to gain the pope and his favourites, with liberal presents and promises. The cause of William was consequently heard with coldness; and Calixtus, in an interview which he had with Henry, declared, that of all men he was, beyond comparison, the most eloquent and persuasive.

The war in Normandy was again renewed; but Henry being passed over with an army, gave the enemy battle at Breneville. During the conflict, Erquy, a Norman officer, who had followed the fortunes of young William, struck the King of England on the head with such force, that all his armour was covered with blood. Henry, however, no way intimidated, returned the blow, and continued the combat with such resolution, that he brought his antagonist to the ground. His troops were encouraged by his example, and victory declared for the English. A peace was soon after concluded between France and England, and the cause of William was forgotten.

Henry now seemed to have gained the summit of his wishes. Profound tranquility reigned throughout his extensive dominions, both at home and on the continent. He had secured the affections of his English subjects, by restraining the violence and oppression of his barons. These mutinous nobles were kept in awe by the vigour of his government, and his enemies were humbled and discouraged by his invariable good fortune. But an unforeseen misfortune blasted his fondest hopes, and darkened with sorrow the remainder of his days. This was the death of his only son, William, a youth of great promise, who had arrived at his 18th year, and who had been recognised as his successor, and had received the homage of the barons both of England and Normandy. When the king was returning from the latter country with a numerous retinue of the chief nobility, one of the vessels, in which was William and several young noblemen his companions, was carried on a rock, and almost immediately went to pieces. The young prince was put into the boat, and had left the ship, when the cries of his natural sister, the countess of Perche, recalled him to her assistance. Upon the return of the boat, the crew crowded into it in such numbers, that it went to the bottom, and all perished. A butcher of Rouen, who clung to the mast, and was taken up next morning by some fishermen, was the only person saved; and it is said that on this occasion, above a hundred and forty young noblemen of the principal families of England and Normandy were lost. When Henry heard of the disaster, he fainted away, and never laughed after.

The death of William left Henry without a male heir to his crown. His only surviving daughter Matilda, had been betrothed when only eight years of age, to the Emperor of Germany. But he dying without issue, she was afterwards united to Geoffrey of Plantagenet, the eldest son of Fulk, Count of Anjou. The king himself, in hopes of having male heirs, had been induced to marry Adelais, the daughter of the Duke of Lorraine, and the niece of Pope Calixtus. But this princess, who was of an amiable person, brought him no children; and Henry became apprehensive that his nephew William might eventually be enabled to recover the birth-right of his father. But the death of that prince, who was killed in a skirmish with the Langrave of Alsace, put an end to his fears; and his daughter Matilda, having been delivered of a son named Henry, he made the nobility take an oath of succession in her favour. Henry was in Normandy when this event happened, and found such satisfaction in the company of his favourite daughter, who bore successively two other sons, that he determined to spend the remainder of his days in that country. An irruption of the Welsh, however, recalled him to England; but as he was preparing for his journey, he was seized with a sudden illness, caused by eating lampreys, of which he died in the 67th year of his age, and 36th of his reign.

Henry, by his prudence, his talents, and his bravery, would have shone in whatever situation he might have been placed. His great progress in literature procured him the name of Beau-ecire, or the scholar; and his affability of manners encouraged and delighted all who approached his person. He seemed, however, to possess the prejudices of his family against the native English; and during his long reign, none of that nation were ever preferred to any ecclesiastical or civil dignity. Being a foreigner was a recommendation to his protection beyond what any Englishman was supposed to possess; and it was certainly no small evidence of the wisdom and moderation of his government, that the tranquillity of his English dominions was never once disturbed by those conspiracies and insurrections which were so frequent in former reigns.

The death of Henry was followed by many years of tyranny and misery to the defenceless inhabitants of England. This arose not from the character of his successor, but was the consequence of usurped power, which was necessitated to tolerate the violence and oppressions of the nobles by whom it was supported. The oaths of fealty which the barons had taken to Matilda, her son, were only remembered so long as the authority which imposed them was capable of enforcing obedience. These haughty chieftains had been growing in power, and exercised almost absolute dominion over those who held under them. They wished, therefore, for a monarch who should owe to them his exaltation, and who, on that account, would increase and confirm their privileges.

Stephen and Henry, the two youngest sons of the Count of Blois by Adela, daughter of William the Conqueror, had been bred at the court of England, and had received great honours and preferment. Henry had assumed the religious habit, and was created Bishop of Winchester; and Stephen had married the daughter and heiress of the Count of Boulogne, by which alliance he became connected with David, King of Scotland, who was his mother-in-law's brother. The late king had also bestowed upon Stephen rich and extensive possessions both in England and Normandy, for which he had always professed the greatest attachment and gratitude; and along with the other barons, had readily taken the oath of succession in favour of his cousin Matilda. But no sooner had his uncle breathed his last, than these favours, and his own professions, were forgot-
According to his last will, she would have been immediately received as queen. But her claim seems to have been little attended to, both in Normandy and England; and Stephen was scarcely crowned, when he was acknowledged in both kingdoms. Her brother Robert, however, who was a man of honour and abilities, was much attached to her interests, and waited only for a favourable opportunity to assert them. Robert possessed considerable influence in the kingdom, and was supported by numerous friends and retainers. On Stephen's accession to the throne, he had taken the oath of fealty; but with this express condition, that the king should never invade any of his rights or dignities; and thus he reserved for himself a pretence for throwing off his allegiance whenever he thought proper. As soon, therefore, as he had settled the plan of an insurrection, he retired to the continent, renounced his allegiance, and sent the king a defiance; upbraiding him with a breach of those conditions which had been annexed to his oath of allegiance. About the same time, the Scotch wars entered Yorkshire with an army in support of Matilda's claim; but the ravages and massacres which he committed, instead of drawing the nobility to his standard, enraged them against him. They assembled their vassals, and, awaiting his approach at Northallerton, defeated him with great slaughter; and David and his son Henry narrowly escaped falling into the hands of the conquerors. This success overawed the malcontents in England, and might have given stability to Stephen's throne, but he was not engaged in a quarrel with the clergy.

Sensible of the evils which attended the liberty of erecting so many castles throughout the kingdom, which only served as sanctuaries for treason and licentiousness, Stephen resolved to diminish their number, and for this purpose began by destroying those of the clergy. Many of the prelates had acted entirely as barons, and possessed fortified castles, and numerous retainers. Under pretence of a fray which had arisen in the court between the attendants of the Bishop of Salisbury and the Earl of Brittany, the king seized that prelate, and also his nephew, the Bishop of Lincoln, threw them into prison, and obliged them to deliver up the strong castles which they had erected. This bold measure at once excited the whole power of the church against him. Even the Bishop of Winchester, the king's brother, who had received a legati nuncio commission from the Pope, took part with his brethren, and resolved to vindicate their violated privileges. Stephen was sum-
arrived with an army to the relief of his friends. Stephen resolved immediately to give him battle. His troops consisted chiefly of foreign mercenaries, led on by tumultuous barons. After a violent onset, his horse gave way, and were soon followed by the infantry. The king, unaccustomed to fly, was left in the midst of the enemy. He defended himself with great bravery and resolution, till at last his battle-axe and sword being both shivered in pieces, he was compelled to surrender himself to the victors. He was thrown into prison at Gloucester, and loaded with irons.

Matilda is acknowledged as queen.

Matilda was immediately acknowledged as sovereign by most of the nobility and clergy; but she seemed to depend more upon the power of the latter, than of the barons, for the continuance of her authority. She determined to attach the Bishop of Winchester more firmly to her interests, by entrusting him with the entire administration of the government, and placing in his hands the disposal of all vacant bishoprics and abbeys. This unbounded power, accompanied with liberal promises, secured the favour of the legate and the church; and Matilda might have long reigned in tranquillity, had she possessed the policy and prudence to conciliate a turbulent and mortal people. But she disgraced the nation by her pride. She had been the wife of the emperor, and seemed still to retain a consciousness of her dignity. She knew not how to temper a refusal with affability; but rejected the petitions of her subjects in the most peremptory and haughty manner. She refused the petition of the Londoners, to replace the oppressive laws of King Henry by those of King Edward; and imprudently offended the legate, by denying his request to allow his nephew, Eustace, to inherit Boulogne, and Stephen's other patrimonial estates. This refusal was the cause of another revolution; and the prelates resolved to deprive her of a throne, to which she had been chiefly instrumental in raising her. He instigated the Londoners to revolt, and had nearly got possession of the queen's person. But she fled to Oxford, and afterwards to Winchester, where she was besieged by the legate. Being hard pressed by famine, she made her escape, but in the flight her brother Robert was taken prisoner. This nobleman was soon after exchanged for Stephen; and as each was the life of his own party, the contest was carried on for several years with great animosity, but without any decisive advantage on either side.

The death of Earl Robert, however, which happened in 1146, gave a severe blow to the interests of Matilda, and would have been fatal to her cause, had it not been counterbalanced by the imprudence of Stephen, who alienated the affections of many of his friends, by endeavouring to extort from them the surrender of their castles. About the same time, also, Eugenius III. had succeeded to the Papal throne, and had deprived Henry of the legantine commission, which he had conferred upon Theobald, Archbishop of Canterbury, his enemy and rival; and the king, by refusing to submit to some encroachments of that pontiff, was, with his whole party, laid under an interdict. These circumstances encouraged the adherents of Matilda; and Stephen was obliged to conciliate the church, by making proper submissions to the Pope. Both sides, however, were so weakened, that a cessation of hostilities was the consequence; and many of the nobility joined the crusade, which was at this time preached by St. Bernard. Matilda had retired to Normandy with her son Henry, to whom she soon after resigned the government of that duchy.

Young Henry Plantagenet had received the honour of knighthood from his grand-uncle David, King of Scotland; and, while in that country, had displayed such valour, gallantry, and prudence, as raised the hopes of his party in England. By the death of his father Geoffrey, in 1150, he succeeded to the duchies of Anjou and Maine; and by his marriage with Eleanor, daughter and heiress of William, Duke of Guienne, and Earl of Poitou, who had been divorced from Louis VII. King of France, he got possession of those rich provinces as his dowry. His power, added to his great accomplishments, had such an influence in England, that when Stephen was desirous of securing the crown to his son Eustace, and required Theobald, the legate, to assist him in his successor, that prelate refused, and immediately fled to the continent. This event prompted Henry to make an attempt upon England; and having gained some advantages over the royalists at Malmesbury, he proceeded to meet Stephen at Wallingford. But the chiefs of both parties dreading the renewal of bloodshed, compelled the rival princes to settle their differences by a compromise. A treaty was accordingly concluded, by which it was agreed, that Stephen should enjoy the crown of England during his life; that Henry should be acknowledged his successor; and that William, Stephen's second son Eustace being dead, should inherit Boulogne, and his patrimonial estates. Stephen survived this transaction only a year; and his death put his rival in quiet possession of the throne.

Henry II. on his accession to the throne of England, was the most powerful and the ablest sovereign in Europe. Besides his English and Norman dominions, he possessed in right of his father, Anjou, Touraine, and Maine; and in that of his wife, Guienne, Poitou, Anjou, Tongue, Perigord, Angoumois, and the Limousin. To these he soon after annexed Britanny, and the county of Nantz. He thus was master of above a third of the whole French monarchy, and consequently became an object of apprehension to the French king, who, though monarch of a rich and fertile territory, yet had so little control over his vassals, that they were accustomed to make war upon each other without his permission, and sometimes to turn their arms against their sovereign. Louis had remarked, with terror, the rising grandeur of the house of Plantagenet; and, in order to retard its progress, had always endeavoured to support the fortunes of Stephen. But he now saw that it would be in vain to attempt any opposition to Henry's succession, and considered it more prudent to conciliate, than to irritate, so formidable a neighbour.

The English, tired with bloodshed and depredations, and sensible of the noble qualities of their new monarch, received him with acclamations of joy, and all ranks willingly took the oath of allegiance. Conscious that his title to the throne was not only by hereditary right, but by the unanimous voice of the people, Henry began his reign, by resuming those privileges which had been extorted from the weakness of his predecessor. He restored authority to the laws, by demolishing all the castles which had been built since the death of Henry I., except a few which he retained in his own hands, for the protection of the kingdom. He dismissed the mercenary troops; revoked all the grants made by his predecessor; restored the coin, which had been much adulterated, during the former reign, to its proper value and standard; and, by a rigorous execution of justice, curbed the violence and robberies of the
feudal vassals. He gave charters to several towns, by which the citizens held their freedom and privileges from the sovereign himself; and thus, by enlarging the power of the people, he diminished that of the nobility, and was enabled to levy armies independent of the barons.

So far Henry's schemes of reformation were crowned with success; but when he attempted to repress the encroachments of the clergy, he found himself surrounded with difficulties, and involved in danger and disquietude. He had long cherished the design of putting a stop to clerical usurpations, and of maintaining the prerogatives of the crown; but the mild character, and advanced years of Theobald, Archbishop of Canterbury, prevented him from employing any active measures while that prelate lived. On his death, however, he resolved to exert himself, and, for this purpose, raised to the primacy his chancellor Thomas-a-Becket, on whose fidelity and compliance he thought he could entirely depend.

The clergy, during the former reign, had been advancing, with rapid strides, to independence; and such was the height which they had gained, that it was difficult to determine whether the king or the primate was the first man in the kingdom. They had extorted from Stephen new privileges, and immunities wholly inconsistent with the liberty of the subject, or the welfare of the kingdom. They had renounced all immediate subordination to the civil magistrate. They claimed exemption, not only from the usual taxes of the state, but also from its punishments, and pretended that ecclesiastical penalties alone could be inflicted on their offences. Lamentable crimes were the effects of these privileges, and murders, robberies, and rapes, were daily perpetrated with impunity by the lower orders of the church. No less than one hundred murders are said to have been committed, since the king's accession, by ecclesiastics; and holy orders were considered as a sufficient protection for every species of guilt. The first abuse, however, which Henry attempted to remedy, was the commutation of money for penances, which had been inflicted as an atonement for sins. To such an extent had this imposition grown, that more money was drawn from the people in that way, than was produced by all the funds and taxes in the kingdom; and to relieve his subjects, in some degree, from such a heavy and arbitrary burden, Henry required that a civil officer should, for the future, be present in all ecclesiastical courts, to give his consent in every case of a composition for spiritual offences. He next proceeded to the correction of more heinous irregularities, and he soon had an opportunity afforded him of exerting his abilities to the utmost. A clerk in the diocese of Sarum, having debauched a gentleman's daughter, afterwards murdered the father; for which crime he was tried in the archbishop's court, and was punished only with degradation. This circumstance had excited such general indignation, that the king commanded the murderer to be delivered up to the civil magistrate, to receive the punishment of the law. But Becket, who, since his exaltation to the primacy, had broken off all personal intercourse with Henry, and opposed him in all his plans of remedying clerical abuses, (see Becket,) insisted upon the privileges of their order. He asserted that no ecclesiastic could be punished with death; and even hinted to the king, that it did not become him to interfere in the affairs of the church.

Henry was not of a disposition to submit, either to insolence or injustice. He considered this case as a sufficient pretence for bringing, at once, to a decision, those controversies which were daily arising between the civil and ecclesiastical jurisdictions, and to define precisely what were the powers of the civil magistrate. For this purpose he convoked all the prelates of the realm, and demanded of them, whether or not they would submit to the ancient laws and customs of the kingdom: they replied, that they would, saving their own order. Henry, indignant at this evasion, left the assembly; and the bishops were so terrified by his threats, that they all complied except Becket, who, for a time, was inflexible, but who also was induced to yield at the request of the pope's legate.

The king then summoned a general council of the nobility and prelates, at Clarendon, to whom he submitted sixteen propositions, which were immediately agreed to, and which are well known under the title of the Constitutions of Clarendon. Among others, it was enacted, that all suits respecting the advowson and presentation of churches, should be determined in the civil courts; that clergymen, accused of any crime, should be tried by the temporal judges; that no person, particularly no bishop, should leave the kingdom, without the king's license; that no officer of the crown should be excommunicated or suspended, without the sovereign's consent; that no appeal should be carried to the holy see, except with the permission of the king; that all prelates should be regarded as barons of the realm, should possess the privileges, and be subject to the burdens imposed upon that rank; that goods forfeited to the king should not be protected in churches and church-yards; and that the sons of villeins should not receive holy orders, without the consent of their lord. To these, all the bishops, and even Becket himself, after some entreaty, set their seals, and also took an oath to observe the constitutions of Clarendon, legally, with good faith, and without fraud or reserve. The sanction of Pope Alexander III., would now have completed Henry's triumph; but that pontiff, perceiving the tendency of these laws to establish the independence of the civil power on the clergy, rejected them all but six, which were of the least importance, and which he was willing to ratify for the sake of peace. When Becket was informed of Alexander's decision, he expressed the deepest sorrow for his compliance; and even suspended himself from the exercise of all ecclesiastical functions, until he should receive absolution from the pope.

Henry, roused to indignation by the insolence and Henry's quarrels with Becket. Henry pro-obstancy of the primate, resolved to make him feel the weight of his vengeance. He desired the pope to grant a legantine commission to the Archbishop of York. This was sent, but a clause was annexed, forbidding him to execute any act in prejudice of the Archbishop of Canterbury. The king, disappointed in his purpose, returned the commission by the same messenger that brought it. He then instituted an action against him, for some lands which he held in his primacy. Becket excused himself for not appearing personally in court, on account of sickness, but sent four knights to plead his cause. This was construed into a disrespect for the king's court; and for this offence, the primate, in a great council held at Northampton, was punished with the confiscation of all his goods and chattels; and Henry, bishop of Winchester, was compelled, by order of the court, to pronounce the sentence against him. He was next day prosecuted for various small sums, which had passed between him and the king, which he was obliged to pay; and then, as it to crush him at once, Henry demanded of him to give an account of his ad-

The king threatened with excommunication.

History.

administration while chancellor, and estimated his deficiencies, while in that office, at 40,000 marks. To answer such a demand, or even to find sureties for so great a sum, was impracticable. In this emergency, he was advised, by the Bishop of Winchester, to offer 2000 marks in lieu of all demands; but this was rejected by the King. Some exhorted him to resign his see, on condition of receiving an audience: whilst others thought that he should submit himself entirely to the king's mercy. But Becket saw that Henry was determined upon his ruin, which would only be hastened by submission, rejected these timid counsels, and resolved to brave the utmost efforts of royal indignation.

When the king and his court were assembled, the primate, arrayed in his sacred robes, proceeded to the palace, and taking the cross in his hand, as his protection from any violence, he entered the royal apartments. Henry, astonished at such unaccountable behaviour, sent some of the bishops to remonstrate with him on his conduct. But Becket was deaf to all persuasion. He put himself and his see under the protection of the supreme pontiff, and appealed to him against any sentence which the judges might give on the king's claim. He then left the palace, and having requested permission to leave Northampton, he was refused; but afterwards withdrawing in disguise, he escaped to Flanders.

In the prosecution of Becket, Henry seems to have been instigated more by a desire of revenge for his ingratitude and obstinacy, than by a regard to justice, or even prudence. Whatever were the primate's faults, the king certainly took the most effectual method of making these faults be forgotten. His violence and injustice opened the eyes of all men to the motives of his conduct, and Becket soon became the idol of the people, and was hailed by the clergy as a martyr in the cause of the church. He was received by the French king, and Alexander, with every mark of distinction. Louis was jealous of Henry's growing power, and the pope readily embraced a cause in which his own immediate interests were so deeply concerned, and assigned Becket the convent of Pontigny for his residence, where he lived for some years in great magnificence. Henry, in revenge, sequestered the revenues of Canterbury, and banished all the archbishop's domestic and relations. He also prohibited, under severe penalties, all appeals to the pope or primate, and declared it treason to bring from either of them an interdict upon the kingdom, punishable in seculars with the loss of eyes and castration, in regulars with amputation of their feet, and in laymen with death. These measures only tended to widen the breach. Becket had the spiritual thunders at his command, and, in revenge, communicated Henry's ministers by name, and absolved from their oath, all who had signed the constitutions of Clarendon. He even threatened the king with a similar punishment, and suspended it only to give time for submission. The pope acquiesced in all these proceedings, but was prevented from supporting the hostility of Becket, with greater determination, by the fear, that Henry would join the Emperor Frederic, who, at that time, supported the claims of an antipope; and as the means which had already been employed to bring the king of England to submission had not succeeded to his expectation, he had more to fear than hope from the continuance of the dispute. Henry, also, though he at first paid little regard to the fulminations of the Vatican, began to dread the effects which a sentence of excommunication might have upon his subjects, and became equally desirous of a reconciliation. Negotiations were accordingly entered into for this purpose, but were frequently broken off, by their mutual obstinacy and jealousy. At one conference, held in presence of the king of France and the French prelates, Henry said to that monarch, "There have been many kings of England, some of greater, some of less authority than myself. There have been also many archbishops of Canterbury, holy and good men, and entitled to every kind of respect. Let Becket but act towards me with the same submission, which the greatest of his predecessors have paid to the least of mine, and there shall be no controversy between us." This representation of the case made such an impression on the mind of Louis, that he withdrew his friendship from Becket; but his jealousy of the king of England soon led him to a renewal of it.

After many fruitless attempts, the controversy was at last amicably settled. It was agreed that the original dispute should be buried in oblivion; that Becket and his adherents should be restored to all their dignities and livings; and that those who had been promoted to benefices, dependent upon the see of Canterbury, during his absence, should be expelled. and the vacancies filled by the primate Henry, in return for these concessions, had only the satisfaction of seeing his ministers absolved from the sentence of excommunication, and himself relieved from the dread of a similar punishment. But he was anxious that tranquillity should be restored; and, in order to flatter the vanity of the prelate, even stooped, at one time, to hold his stirrup, while he mounted. This condescension on the monarch, however, was only additional fuel to the pride of Becket. Elated with the victory which he had gained over his sovereign, he determined to take advantage of his situation, and to repel every attempt of Henry to set bounds to the usurpations of the clergy.

The King, while the threatened sentence of excommunication was hanging over him, in order to secure the throne in his family, had associated with him his son Prince Henry in the royalty; and the ceremony of coronation was performed by Roger, Archbishop of York. This proceeding gave great offence to Becket, who pretended, that, as Archbishop of Canterbury, he had the sole right of officiating in such a ceremony. He therefore resolved to be revenge on the authors of this affront. The promise of Henry to have the ceremony renewed by the prelate, would not satisfy his vindictive disposition; and when on his arrival in England, he met Roger and the Bishops of London and Salisbury, who were on their way to join the king in Normandy, he intimated to the former the sentence of suspension, and to the two bishops that of excommunication, which at his instance had been passed upon them by the Pope. He was assured of support from Rome; and as he knew that his person and dignity were venerated by the people, he proceeded with the more courage to humble his enemies. He made a solemn progress through Kent, with all the splendour and magnificence of a sovereign pontiff. Wheresoever he passed, he was received with the shouts and acclamations of the populace; and men of all ranks celebrated his triumphal entrance into Southwark with hymns of joy. He then issued sentence of excommunication against some of the principal nobility, who had assisted at the young Prince's coronation, or who had been active in the persecution of the exiled clergy. This haughty and violent conduct was no sooner reported to Henry by the degraded prelates, who implored his protection from the vengeance of their oppressor, than he was so exas-
History.

In the mean time, Henry, with a view to divert the attention of his people from this subject, undertook the conquest of Ireland. He had received a grant of this country from his brother, Richard III, and subdued it with such rapidity, that in a few months he received the submission of the whole island: (See Ireland.) But he was recalled from this conquest by the arrival of the legates in Normandy, who had become impatient of his delay in appearing before them. At the first conference, he found their demands so exorbitant, that the negotiation was broken off; and as the time for taking advantage of Becket's murder was now past, they found themselves under the necessity of lowering their terms, when an accommodation was at last happily effected.

Henry having regained the favour of the church, and established tranquility throughout his extensive dominions, was regarded as the most powerful potentate of Europe. A numerous family gave lustre, and promised stability to his throne, and he looked forward to a peaceful and happy reign. But his happiness was short-lived. His eldest son, Henry, who had married Margaret, daughter of the French king, had been appointed his successor in the kingdom of England, the duchy of Normandy, and the counties of Anjou, Maine, and Touraine; Richard was invested in the duchy of Guienne, and county of Poictou; Geoffrey inherited the duchy of Brittany in right of his wife; and Ireland was destined for John. These arrangements were intended to prevent all jealousy among his sons, and perpetuate the greatness of his family. But he found his government disturbed, and his life imitated, by those very sons whose fortunes he had been so anxious to establish. Young Henry, who was brave, affable, but aspiring and ambitious, being instigated by the king of France, desired his father to resign to him the immediate possession either of England or Normandy. On his receiving a direct refusal, he fled to Louis, and prepared to enforce, by arms, what was denied to his request. He was soon after joined by his brothers Richard and Geoffrey, who had been incited to rebellion by their mother Queen Eleanor; and who had also demanded the government of those territories which had been assigned them. This unnatural combination was openly encouraged and supported by Louis, who engaged the chief vassals of his crown by oath to adhere to the cause of young Henry; and this prince in return bound himself never to desert his French allies. William king of Scotland, with the Counts of Flanders, Boulogne, Blois, and Eu, also entered into the confederacy, and a plan was projected for a general invasion of Henry's dominions. In this emergency, Henry at first recourse to the court of Rome, to reduce his unhappy children to obedience, and he proceeded from the Pope the excommunication of his enemies; but this produced very little effect, and he was at last compelled to take up arms in his own defence. His licentious barons, however, were in general in favour of the young Princes, whose government they knew would be less vigilant and severe than that of their father, and consequently many of them, particularly the Earls of Chester and Leicester, openly declared against their sovereign. Surrounded on every side by enemies, he sought assistance from the Brabançons, or Cottoreaux, a tribe of lawless banditti, who had long disturbed the tranquillity of the continental states by their depredations, and who professed their swords to those who would most freely pay them. With twenty thousand of these, and a few faithful nobles, Henry proceeded to the relief of Verneuil, which had been invested by the enemy. The garrison had engaged to capitulate, if not relieved within three days. On the third day the English army appeared in sight, when Louis, dreading an attack, insidiously demanded a conference, to settle the articles of a general peace. Henry readily consented; but Louis in the meanwhile obliged the garrison to surrender according to agreement, and, having set fire to the place, began to retire with his army. Henry, enraged at such treachery, fell upon the retreating army, and put them to the rout. He then crushed the insurgents in Brittany, and, while victorious, renewed the negotiations. At a conference with the king of France, held between Thie and Gisors, Henry beheld, with sorrow, his three sons in the picture of his enemy; but anxious to bring them to obedience, he proposed to them the most liberal terms. He insisted on retaining the sovereign authority in all his dominions, but offered to Henry half the revenues of England, with some places of surety in that kingdom; or, if he chose to reside in Normandy, half the revenues of that duchy, with all those of Anjou. To Richard, he made a similar offer in Guienne; and he promised to resign all Brittany in favour of Geoffrey. These advantageous offers, however, were rejected; and Henry was recalled to England by an invasion of the Scots.

William had entered Northumberland, and commis-
Henry's penance at Becket's tomb.

William, king of Scotland, defeated and taken prisoner.

A.D. 1175.

Henry being now freed from the toils of war, employed several years of peace in regulating the internal affairs of his kingdom. He made considerable alterations in the trial by water ordeal, which, though condemned by the church, still subsisted. He also moderated the trial by duel, allowing only either of the parties to challenge a trial, by a jury of twelve freeholders. He enacted severe penalties against murder, robbery, false coining, and fire-raising; and having partitioned the kingdom into four districts, he appointed a justice, who was either a prelate or a nobleman, to go the circuit in each division, and decide the causes in the counties. But he was interrupted in the execution of these wise measures, by new dissensions in his family. Philip, king of France, had succeeded his father, while only a youth of sixteen, and had been greatly indebted to the interference of Henry, in composing the quarrels which had arisen in the royal family of France on the death of Louis, and in establishing him upon the throne. But he required these services, by fomenting discord among the children of his benefactor. At this instance, young Henry renewed his demand of the cession of Normandy, and when refused, he found protection at the court of France. Philip, however, not being at that time disposed to support his pretensions, he made submissions to his father, and was reconciled. Richard also, who had received the duchy of Guienne, had refused to do homage for his dominions to young Henry, as he had been agreed upon, which occasioned a war between the two brothers. And this difference was scarcely settled between them, when the king discovered, that his eldest son was again engaged in a conspiracy against himself. His unnatural designs, however, were defeated by his death, which was occasioned by a fever in the 28th year of his age. Before he expired, he expressed great compunction for his unfaithful conduct, and earnestly entreated to see his father; that he might obtain his pardon. Henry, who had been deceived by the pretended repentance of his children, suspected that his sickness was feigned, and would not trust himself in his son's power. But when he heard of his death, he was affected with the deepest sorrow, and reproached himself with hard-heartedness, in refusing the dying request of his son. Young Henry dying without issue, Richard became heir to all his dominions; but not content with what belonged to his brother, he wished also to retain the duchy of Guienne, which Henry had intended for his youngest son John. He even proceeded to take up arms in support of his claim; but dreading an insurrection of the Gascons in favour of his mother, he returned to obedience. Geoffrey, who had been put in possession of Brittany, and who was the most vicious of Henry's children, being known among the people by the name of the Child of Perdition, next demanded that the county of Anjou should be annexed to his territories. This being refused, he prepared for war. But he was soon after killed in a tournament at Paris; and his son Arthur, who was born after his death, was invested in his dominions under the guardianship of his grandfather.

About this time, the attention of all was directed to the progress of the Infidels in Palestine. Saladin, King of Egypt, had spread his conquests over the East; and, through the treachery of the Count of Tripoli, who commanded the Christian army, had reduced Jerusalem, and had almost entirely subdued the kingdom of Antioch. This intelligence filled the Western Christians with sorrow and dismay; and every effort was made to excite the sovereigns of Europe to undertake another crusade for the recovery of the Holy Land. The Arch-bishop of Tyre having procured an interview with Philip and Henry near Gisors, gave such a pathetic description of the sufferings of their fellow Christians in Asia, that they mutually laid aside their animosity, and immediately took the cross. But Richard, pursuing the dictates of ambition rather than of nature, was again seduced from his duty by the King of France, who was still jealous of Henry's power. He entered into an alliance with Philip against his father; and when a negociation was proposed to accommodate their differences, Philip required that Richard should be crowned during the lifetime of Henry, should be invested in all his foreign dominions, and should immediately espouse Alice, Philip's sister, to whom he had formerly been affianced. These proposals were rejected by the king of England.
and open hostilities immediately commenced. As this contest put a stop to the projected crusade, the pope's legate in France excommunicated Richard as the principal cause of discord, and threatened to lay an interdict on Philip's dominions. But these proved entirely ineffectual to restrain the ambition of these princes; and they carried on the war with such vigour, that Henry, after having lost several towns, found himself under the necessity of submitting to very humiliating conditions. It was agreed that Richard should marry the Princess Alice, and should receive the homage and oath of fealty of all his father's subjects; that Henry should pay 20,000 marks to the King of France, to defray the charges of the war; that his own barons should promise, that in case of his violating the treaty, they would join Philip and Richard; and that an indemnity for the past should be offered to all. These terms, rigorous and mortifying as they were, did not affect him so much as the discovery that his favourite son John had been langued with his enemies. When he read his name in the list of those barons to whom he had engaged to grant a pardon for their connection with Richard, he was overwhelmed with grief. He cursed the day that he was born; and bestowed on his ungrateful and undutiful children a malediction, which he never pardoned, and which he always cherished. This last domestic affliction of the spirit, and brought on a lingering fever, of which he died at the castle of Chinon near Saumur, in the 53rd year of his age, and 53rd of his reign. This prince was equally distinguished by his private as well as his public virtues. His greatest blemish was his amour with the fair Rosamond, by whom he had two sons, Richard Longsword, and Geoffrey, afterwards Archbishop of York; and his hypocritical devotion at the shrine of Thomas-a-Becket cannot be justified, even by the emergency of his affairs at the time. By one weak action he cancelled the firmness of his past conduct, and rivetted upon his people those fetters of superstition which, during the former part of his life, he had been attempting to unbend. In his general conduct, however, he displayed the highest qualities of the understanding and the heart. He was the most tender and indulgent of fathers, and though his affections were often torn by the ingratitude and disobedience of his children, his temper always preserved its natural and sensitive path of the spirit, and in the execution of justice he was severe without oppression. In war he possessed bravery and conduct; and perhaps there never was a monarch who extended his dominions and authority so far, with so little violence and injustice.

Richard was no sooner informed of his father's death than he was stung with remorse for the undutiful part which he had acted, and professed his respect for his father's memory, by retaining Henry's ministers and servants in those offices which they had so honourably discharged to their former master; while those who had encouraged and assisted his rebellion, met with neglect and hatred. He immediately restored to liberty Queen Eleanor, who had been long detained in confinement; and profusely bestowed upon his brother John no less than six earldoms, with many opulent and extensive possessions. The commencement of his reign, however, was attended with a very melancholy catastrophe, which, while it shews the bigotry and superstition of the age, proves how ineffectual the authority of the sovereign was to restrain the violence of his subjects. Richard had prohibited any of the Jews from appearing at his coronation; but some of that nation, presuming upon the large presents which they had made to the king, ventured to approach the hall where he dined. As soon as they were discovered, they were exposed to the insults and outrages of the populace; and a rumour was widly spread, that the king had ordered the massacre of all the Jews within the kingdom. London was immediately filled with uproar. The houses of this defenceless people were pillaged and burnt, and they and their families put to death. The houses of wealthy Christians were also attacked and plundered; and so general was the spirit of riot and pillage, that when the king empowered Glanvil, the Justiciary, to inquire into the authors of this enormity, so many of the principal citizens were found to be involved in it, that it was deemed proper to drop the prosecution. At York there were similar disorders, and five hundred Jews, who had retired to the castle for safety, finding themselves unable to defend it against the assaults of the populace, murdered their wives and children, and threw the dead bodies over the walls upon the besiegers; they then set fire to the buildings, and perished in the flames.

This zeal against the enemies of the cross was the The king ruling passion of the times; and Richard, who to this prepares for his crusade, added a love of military glory, was scarcely seated upon his throne, when he began to prepare a crusade. Every other interest and consideration was sacrificed to the success of this pious enterprise. His father had left him above 100,000 marks, and he endeavoured to increase this sum by every expedient. The revenues and manors of the crown, and the offices of greatest trust and power in the kingdom, were exposed to sale. The dignity of chief justiciary was bought by the Bishop of Durham for 1000 marks; and the vassalage of Scotland, together with the fortresses of Berwick and Roxburgh, was sold for 10,000 marks. Exactions and extortion were next employed, and the oppression was felt by all ranks. He was at last enabled to proceed with a well-appointed army to the plains of Vezelay, where he had promised to meet the king of France. There the two monarchs reviewed their forces, and having sworn inviolable friendship, and publicly pledged their faith not to invade each other's dominions during the crusade, they departed for the Holy Land. See CRUSADES.

And set out for Palestine.
A. D. 1190.

Disorders during his absence.
commence hostilities against the dominions of Richard during his absence, yet he endeavoured by every mean secretly to annoy and distract his government. He even detached Prince John from his allegiance, by promising him his sister Alice in marriage, and offering to put him in possession of all his brothers' lands. But the trick was discovered in due time, and that vicious prince was prevented only by the authority of the queen-dowager, and the menaces of the council, from raising a civil war in the kingdom.

Richard was informed of all these machinations of his rival. The ardour of the crusaders had gradually abated; and their numbers being thinned by the sword, by fatigue, and by disease, they now thought of returning home. Richard alone opposed this desire; but he was at last obliged to yield to the general wish, and concluded a truce with Saladin for three years. On his way home, Richard was shipwrecked on the coast of Italy, and, having assumed the disguise of a pilgrim, attempted to pass secretly through Germany. His experiences and liberalties, however, betrayed the dignity of his character, and he was arrested at Vienna, by the Duke of Austria, to whom he had given some disgust at the siege of Acre. This prince delivered him up for a considerable sum to Henry VI., Emperor of Germany, who threw him into a dungeon, and loaded him with irons. This fatal intelligence filled his subjects with grief and consternation. He had secured their affection by his bravery and generosity; and the only traitor in the kingdom was his brother John, who secretly rejoiced in his imprisonment, and joined his influence to that of the king of France to continue his captivity. They entered into negotiations with the emperor to deliver his royal prisoner into the hands of Philip, or to detain him in perpetual confinement; and John, taking advantage of the general confusion, attempted, with the assistance of Philip, to wrest the sceptre from the hand of his unfortunate brother.

The English, however, notwithstanding all these ungenerous efforts, continued faithful to their king; and, when the emperor was at last compelled, by the remonstrances of the German princes, and the threatenings of the pope, to agree to his release for a large ransom, the sum was cheerfully raised by his subjects. One hundred thousand marks were immediately paid, and sixty-seven hostages were delivered for the payment of 50,000 more. Richard's arrival in England was hailed with the utmost exultation; and never did a nation testify such joy at the appearance of its monarch. His splendid victories, the dangers which he had passed, and the sufferings which he had undergone, endeared him to a martial and high-spirited people; and he found all ranks ready to assist him in taking vengeance on the authors of his misfortunes. As soon as he had settled his affairs in England, he hastened to oppose the invasion of Philip in Normandy; but no exploit worthy was recording was the consequence of this war. John deserted the cause of Philip, and implored the forgiveness of his brother. At the intercession of Queen Eleanor, the king forgot the baseness of his conduct, and generously received him into favour. The war with France was several times concluded and renewed, without any advantage being gained on either side. A treaty of peace was at last about to be concluded, by the mediation of the Pope's legate, when the death of Richard put an end to the negotiation. This prince, after a reign of ten years, passed almost in continual hostilities, received his death-wound when besieging one of his vassals in the castle of Chalus, near Limoges, in the 42d year of his age.

Richard possessed the highest military talents; and his intrepidity and personal bravery had acquired him the appellation of Cœur de Lion. With a disposition open, generous, and sincere, he was at the same time ambitious, haughty, and cruel; and had his reign been lengthened, the restlessness of his character would have detached him from the affectionate attachment of his neighbours, or would have led him, as he threatened, to undertake another expedition against the Infidels.

The accession of John to the throne was immediately followed by the revolt of the provinces of Anjou, Maine, and Touraine. They declared in favour of Arthur, the son of Prince Geoffrey, John's elder brother, though only a youth of twelve years of age; and were readily supported by the king of France, who embraced every opportunity of raising commotions in the rival kingdom. John, however, had Richard's will in his favour, and had been acknowledged by the barons of England and Normandy. He therefore prepared to maintain his claim by force of arms; and passing over into France, was enabled, by the assistance of the Earl of Flanders, to defend himself against all the efforts of his enemy. Constantia, the mother of Arthur, in the mean time, becoming jealous of the intriguing character of Philip, and suspecting that he intended to usurp the dominion of the revolted provinces, rather than preserve them for her son, secretly withdrew Arthur from his court, and put him into the hands of John, to whom he did homage for the duchy of Brittany, which he possessed in right of his father. This defection obliged Philip to give up the contest, and a treaty was soon after agreed upon, in which the limits of their territories were properly adjusted, and the interests of their vasals mutually secured. As a token of sincere reconciliation, John gave his niece Blanche of Castile in marriage to Louis, Philip's eldest son, and with her the baronies of Issoudun and Graen, and other fiefs in Berri.

John being now undisputed master of the kingdom, and thinking himself secure on the side of France, began to give reins to his passions, and to expose himself, by his tyranny and weakness, to the hatred and contempt of his subjects. Being deeply enmoured with Isabella, the daughter and heir of the Count of Angouleme, he was determined to possess her at every hazard. She was betrothed to the Count de la Marche, and had been consigned to the care of that nobleman; but John persuaded her father to carry her off from her husband; and having divorced his queen, he married her in spite of the menaces of the Pope, who exclaimed against such conduct. The Count de la Marche, and his brother the Count d'Eu, immediately took up arms, and exiled to insurrection the malcontents of Poictou and Normandy. The king demanded from his English barons a sufficient force to quell the rebels. But these chiefs had begun to feel the influence which they had in the kingdom, when under the government of a weak prince, and unanimously refused, unless he would promise to restore to them their ancient privileges. This was the first symptom of a regular association among the nobles, for curbing the power of the crown. But their plan was not sufficiently matured, and they were obliged to yield to the menaces of their sovereign. John at first overawed the insurgents by his superior arms, but he soon raised up new enemies by his arbitrary and imprudent conduct. It was the custom of those times, that the causes in the Lords Court were chiefly decided by duel; and he carried with him a set of bravos or hired ruffians, whom he intended should fight with his barons, when any controversy was to be decided between him and them. This gave offence to

Marriage of the king.

England.
War with France.

The Duke of Brittany, who had now arrived at man's estate, had also become distrustful of his uncle; and passing over into France, joined the army of Philip, by whom he was treated with great distinction, and received the hand of his daughter Mary.

The allies were everywhere victorious; and so rapid was the progress of their arms, that John was threatened with the loss of his continental possessions. They received a check, however, by the rashness of young Arthur, who, fond of military fame, had entered Poitou with a small army, and laid siege to Mirébeau, where his insurtert enemy Queen Eleanor then resided. John hastened by forced marches to her relief, and coming upon Arthur before he was aware, dispersed his forces and took him prisoner, together with the most considerable of the revolted barons. This good fortune revived for a time his sinking cause; but he soon exposed himself, by his cruelty, to greater danger and danger. Having repelled his nephew the folly of his pretensions, he endeavoured to withdraw him from the French alliance, and to bring him back to a sense of duty. But the young prince, amazed by the presence of his conqueror, boldly asserted his claim, not only to the French provinces, but also to the crown of England. The king finding it vain to reason the matter, determined to rid himself of a rival, by his death. Arthur was accordingly never more heard of; and though the circumstances of his murder were carefully concealed, yet it was universally believed that he fell by his uncle's own hand.

This inhuman deed excited general horror and detestation of the tyrant. The Bretons, enraged at the murder of their prince, laid their complaints before Philip, and demanded justice on his murderer. Philip summoned the king of England to trial, and, upon his non-appearance, adjudged him to forfeit all his fiefs in France. Vigorous efforts were immediately made to put the sentence into execution; and while the king of France was employed in reducing his fortresses, and extending his conquests over his dominions, John was amusing himself at Rouen. When informed of the success of the enemy, he boasted that he would retake in a day, what it had cost the French years to acquire. But notwithstanding his vaunts, Philip proceeded in his career, and laid siege to Chateau Gaillard, the strongest fortress on the frontiers of Normandy. This place was defended by Roger de Laci, a brave and determined officer, and a numerous garrison. For a twelvemonth they bravely repelled every assault; but being at last greatly reduced by famine and fatigue, they were overpowered and made prisoners of war. On the reduction of this bulwark, all Normandy lay open to his arms, and soon submitted to the conqueror. Anjou, Maine, Touraine, and part of Poitou, were also successively reduced; and John was expelled with disgrace from all his foreign dominions. On his arrival in England, he attempted to excuse the cowardice and folly of his conduct, by exclaiming against his barons, who, he pretended, had deserted his standard; and in order to regain his character, he collected a fleet, and summoned his vassals to attend him on a foreign expedition. But his design was several times deferred; and when he at last ventured abroad with a considerable army, he merely took and burnt the town of Angers, but fled on the approach of Philip, and returned to England, loaded with new shame and disgrace. Though despised for his cowardice, and hated for his cruelty, yet he still preserved the prerogatives of his crown; but new affronts awaited him, and having imprudently entered into a contest with the church, he was reduced to the most abject degradation.

On the death of Hubert, archbishop of Canterbury, a dispute arose respecting the election of a new primate. That important privilege belonged to the monks or canons of Christ Church; but some of the juniors of that order had met privately, and had chosen Reginald their sub-prior as Hubert's successor. As no election, however, could be considered as regular without a congé d'elire from the king, and as the suffragan bishops of Canterbury also claimed the right of concurrence in the choice of their primate, John ordered the monks to proceed to a new election, when the Bishop of Norwich was unanimously chosen. The dispute came before the Pope, Innocent III. who, glad of an opportunity of nominating to such a high office, declared both the elections null, and commanded the monks, under pain of excommunication, to choose for their primate Cardinal Langton, an Englishman, but attached to the see of Rome. This attempt to usurp one of the highest prerogatives of his crown, filled John with ungovernable fury. He vented his rage against the monks of Christ Church, whom he expelled from the convent; and when Innocent threatened to lay an interdict upon his kingdom, he swore that he would banish all the bishops and clergy of England, and confiscate their possessions. This idle violence and imprudence encouraged Innocent to persevere in bringing this weak prince to submission, and the interdict was accordingly pronounced. At once the churches were shut; the altars were despoiled of their ornaments; the bells were removed from the steeples; the dead were thrown into ditches, or buried in common fields without any funeral solemnity; marriages were solemnised in the churchyards; the people were forbidden to salute each other, or even to shave their beards; and every deprivation was enforced that was calculated to strike with awe the minds of a superstitious people. John, in revenge, banished the prelates, and confiscated the estates of all the clergy, who obeyed the interdict; but, instead of attempting to secure the interest, or gain the affections of the barons, who alone were able to defend him against these papal usurpations, he seems to have disdained all orders of men by his tyranny and licentiousness.

As John still continued obstinate, the Pope next proceeded to pass a sentence of excommunication against him. No sooner was this known, than many of the bishops and nobility left the kingdom, which so alarmed the king, that he proposed a conference with Langton at Dover, when he offered to receive him as primate, to restore the exiled clergy, and to pay a limited sum as a compensation for the rents of their confiscated estates. The cardinal, however, was not content with these terms, but demanded that full reparation should be made to all the clergy. This exorbitant demand put an end to the conference, and was soon after followed by another papal sentence more terrible than either. The subjects of John were absolved from their oath of fidelity and allegiance; all were declared excommunicated persons, who had any
ENGLAND.

From the barons, was more inclined to favour the weak and submissive John, than these high-spirited nobles, who would embrace the first opportunity to wrest the kingdom from his dominion. He accordingly expressed his disapprobation at the conduct of the barons, but advised the king to grant such demands as were just and reasonable. At Easter the barons assembled at Stamford, attended by 2000 knights, and a considerable number of foot, and advancing to Brackley, where the court then resided, presented a schedule of their demands. The king rejected them with indignation, and the barons immediately proceeded to open war. They besieged the castle of Northampton, occupied Belford, and were received into the capital without opposition. They laid waste the king's parks and palaces, and threatened with their vengeance all the other barons who refused to join them. John finding himself almost completely deserted, was obliged to pretend compliance. He met his barons at Runneymede, between Windsor and Staines; and after a debate of a Magna few days, signed and sealed that famous deed, called Charta the Great Charter, which secured very important liberties and privileges to every order of men in the king- dom; and which is still regarded as the great bulwark of British freedom: (See Magna Charta.) In order to secure the execution of this deed, the city of Lon- don was retained by the barons, and the Tower was con- signed to the custody of the primates. They were also allowed to choose 25 of their own number as conserva- tors of the public liberties. When any of the articles of the charter were infringed, four of these might ad- monish the king to redress the grievance, and upon re- fusal, the council of 25, in conjunction with the great council, were empowered to compel him to observe the charter by force of arms. These men were, in fact, in- vested with the sovereign authority, and all the sub- jects were bound to swear obedience to them under the penalty of confiscation.

John acquiesced, through fear, in all these regula- tions; but he waited only a favourable season to re- tract every promise which he had made. He retired into the Isle of Wight, and, secluded from his courtiers and his nobles, meditated plans for the recovery of his authority. He complained to the Pope of the violence of the barons; and secretly enlisted into his service a numerous body of rapacious Brabançons. Inno- cent, enraged at the presumption of the barons in despising his mandate, issued a bull, in which he an- nulled and abrogated the whole charter; he prohib- ited the barons from exacting the observance of it, and the king from paying any regard to it; and excommuni- cated all who should persever in defending it. John, at the same time, let loose his mercenaries upon the defenceless inhabitants; and, as the barons, trusting to the security given them by charter, had disbanded their forces, he marched from Dover to Berwick without op- position, reducing, wherever he went, the castles and villages to ashes, and filling the whole kingdom with consternation and misery. The barons, in this extrem- ity, being unable to make head against their sovereign, offered the crown to Louis, the son of Philip, if he would protect them from the violence of the tyrant. Philip accepted their submission, and, regardless of the menace of the pope, sent over a small army to their assistance; and soon after Louis arrived and made up several forces. On the appearance of Louis, many of John's foreign troops deserted to the enemy, but both armies committed the most wanton ravages. The French advanced to London, where Louis was solemn-

commerce with him, either in public or in private; and he himself was deposed from his throne, which was offered to the king of France. Philip eagerly embraced the offer, and shewed, by his preparations, how desirous he was to succeed. He collected a fleet of 1700 sail in the ports of Normandy and Picardy, and having summed all the vassals of the crown to attend him, he was in a short time ready to make a descent upon Eng- land. John, though hated and feared by all, was en- abled to advance to Dover at the head of 60,000 men; for the English, however much disposed to submit in matters of religion, would not yield their independence to any tribunal; and had their monarch possessed wisdom and resolution to take advantage of their spirit, and of the natural enmity which subsisted between the two nations, he might have retrieved his situation, and broken for ever the power of the clergy within his dominions. But every thing was to be feared from his cowardice and incapacity. Instead of braving the storm, he bartered his kingdom for his safety; and at a conference with Pandulf, the Pope's legate, he yielded his crown, whereby to the distraction of his dominion. Inno- cent was satisfied with his submission, and commanded Philip to desist from his enterprise. John was now made to feel the insolence of papal power. He was re- quired to resign his kingdom into the hands of the Pope; and to hold it as feudatory of the church of Rome, by the annual tribute of a thousand marks. He then did homage to Pandulf as the Pope's representa- tive: he came disarm'd into his presence, flung himself on his knees before him, and swore fealty. By this abject submission he secured his crown; but he was degraded in the eyes of his people. He next received his barons, and demanded the revenues of his predecessors, particularly those of king Edward, and to maintain justice and right in all his dominions.

John, being now restored to the favour of the church, thought himself secure of tranquillity; and continued to exercise his authority with the most overbearing in- solence and oppression; but he was only reserved for further misfortunes, and still greater degradation. The barons had entered into a confederacy for the restoration of their ancient privileges. They were encouraged and supported in their design by the archbishop of Canterbury, who, being of a generous and liberal spirit, was anxious to promote the real interests of the king- dom. At a numerous meeting of the barons summoned by him at St Edmondsbury, under pretence of devotion, he produced an old charter of Henry I. of which he exhorted them to demand the renewal and observance; and represented in such strong colours the arbitrary conduct of their sovereign, that they all swore before the high altar to support each other, and to make end- less war upon the king, till he should grant their dem- ands. They accordingly assembled in London on an appointed day, and preferred their requests to the king, which were to renew the charter of Henry, and confirm the laws of King Edward. John required some delay to consider of their demands, and promised that he would give them a final answer at the festival of Easter. In the mean time he endeavoured to engage the Pope in his favour, and to draw the clergy to his side by new concessions. But in this case, the interests of the clergy were some measure involved with those of the barons; and the king soon found, that he had to contend against the united strength of these two power- ful bodies. Innocent, who had received also an appli-
ly crowned, and received the homage of the barons and burghers. But the partiality of the new monarch to his own countrymen, and a report, that he had threatened to exterminate the English barons as traitors to their prince, and bestow their estates and dignities on his native subjects, were very prejudicial to his cause. This report was universally credited; and the information was said to have been derived from the Viscount Melun, one of Louis’ courtiers, who revealed it to some of his friends on his death-bed. The Earl of Salisbury, and many other noblemen, jealous of the French influence, returned to their allegiance to John, who was advancing with a considerable army to make one mighty effort for his crown; and the French had every reason to dread a reverse of fortune. But as the king was passing from Lynn, along the sea-shore, and being ignorant of the situation of the place, he lost all his carriages, treasure, and baggage, by the influx of the tide. He was so overwhelmed with grief at this disaster, and the distracted state of his affairs, that he was seized with a fever, which soon after put a period to his existence, in the 49th year of his age, and 18th of his reign.

The character of this prince has been justly held up to general reprobation, as including almost every vice that was mean and odious in our nature; but while we despise his cowardice and detest his baseness, we ought to remember, that it was to his weakness and incapacity, more than to the firmness and generosity of the barons, that we are indebted for the foundation of the British constitution.

The death of John was fatal to the cause of Louis. The resentment of the barons against their sovereign was buried with him in the grave; and the youth of his son Henry, who succeeded him, claimed their pity, rather than enmity. At the head of the opposite party also, was the Earl of Pembroke, an experienced and disinterested statesman, who had maintained, during the whole contest, his fidelity to John unshaken, and who was determined to support, at every hazard, the interests of his son. That nobleman, in a general council of the barons, was chosen protector of the realm; and having crowned the young king at Gloucester, in the presence of Guiso, thelegate, he endeavoured to reconcile all ranks to the government of Henry, by new concessions. The Great Charter, with some alterations and additions, was renewed and confirmed; and new cities were brought near to its present shape; and these concessions were so acceptable to the people, that Louis soon found himself almost without an adherent. The discontented barons hastened to make their submission, to prevent those attainders to which they were exposed by their rebellion; and his cause was rendered still more desperate, by the defeat of his troops near Lincoln, and the destruction of the French fleet, which carried a considerable reinforcement, off the coast of Kent, by Philip d’Albiny, the English commander. He was consequently glad to conclude a peace upon any honourable terms; and stipulated only for his own safety, and an indemnity to his adherents.

The death of the Protector, which happened soon after this accommodation, threw the kingdom into new combinations. It required all the wisdom and valour of that virtuous nobleman, to restrain a licentious and powerful nobility; and though his successor, Hubert de Burgh, possessed both abilities and integrity, he was unable to suppress that spirit of insubordination among the barons, which is the usual attendant of a minority. They held by force the royal castles, and usurped the king’s demesnes. They were continually surrounded by a disorderly retinue, whom they encouraged and protected, in all their outrages and depredations; and the people, as well as the king, suffered by their oppressions. The Earl of Albemarle was particularly distinguished for his violent and illegal proceedings; and Hubert, in order to reduce him to obedience, seized upon Rockingham castle, which he had garrisoned with his adherents. This drove him to more open rebellion; but being excommunicated by Pandulph, the legate, he was deserted by his associates, and obliged to sue for mercy, when he was again restored to his possessions. This restless chief, however, continued for some time to give disturbance to the government. When Henry was declared by the pope to be of full age, and the barons were required to resign into his hands the royal castles and fortresses, Albemarle and some others openly refused. They even attempted to surprise London, and seize the person of the king; and such was the weakness of the executive, that they were considered too formidable to be punished. They were at last, however, through fear of excommunication, forced to comply.

As Henry advanced to man’s estate, he showed himself totally unfit for the government of the kingdom in its present unsettled state. He was gentle and humane, but without activity and vigour; and so fickle and irresolute, that men neither valued his friendship nor dreaded his resentment. Had he been steady to the course of Hubert de Burgh, he might have prolonged and subdued the resentment of his barons; but this able and virtuous minister was displaced, in a fit of caprice, and exposed to the persecution of his enemies. His successor, Peter des Roches, bishop of Winchester, was of a very different character, and by his arbitrary and violent conduct, raised new divisions in the state. He was a Poitevin by birth, and advised the king to invite over a number of his countrymen and other foreigners, whom he pretended could more safely be trusted than his English subjects. Upon these men every place of command and preferment was bestowed to the exclusion of the natives, which occasioned such general discontent, that a combination was formed by the barons to expel the king’s minister from his office. They withdrew from parliament; and when again summoned to attend, they demanded that Henry should dismiss his foreigners, otherwise they would drive him and them out of the kingdom, and put the crown upon a head more worthy to wear it. Peter des Roches, however, found means of disconcerting their schemes. He began to pass laws in favor of the barons, and dispossessed the foreigners, and the more obnoxious barons had their estates confiscated, without legal sentence or trial by peers; and their possessions were profoundly bestowed upon the Poitevins. Edmond, the primate, at last interfered, and threatened the king with excommunication, unless he would dismiss his minister and his associates. Henry was obliged to submit; but the barons found it was only a change of masters. The king having married Eleanor, daughter of the Count of Provence, the kingdom was again inundated with strangers, who were caressed, enriched, and loaded with preferment. The more obnoxious barons had their estates confiscated, without legal sentence or trial by peers; and their possessions were profusely bestowed upon the Poitevins. Edmond, the primate, at last interfered, and threatened the king with excommunication, unless he would dismiss his minister and his associates. Henry was obliged to submit; but the barons found it was only a change of masters. The king having married Eleanor, daughter of the Count of Provence, the kingdom was again inundated with strangers, who were caressed, enriched, and loaded with preferment.

A.D. 1239.
barons; and when complaints were made against their oppressions and violations of the law, they scurried not to deny, "What did the English law signify to them?"

The discontent of the nation was heightened by the failure of the king's expeditions to the continent. In a war with Louis IX., he lost what remained to him of Poictou, and involved himself and his nobility in an enormous debt. But even these grievances of the civil government were less burthensome than the usurpations and exactions of the see of Rome, which the king never failed to countenance and support. Besides the tenth of all ecclesiastical living, the Pope, by his legates, wrested large sums from the prelates and convents. He exacted the revenues of all vacant benefices; he claimed the goods of all interstate clergymen, and levied benevolences upon the people. He filled the chief benefices of the kingdom with Italians, who are said to have possessed, during this reign, living in England to the annual amount of 60,000 marks, and carried his usurpation to such a height, as to claim a right to all ecclesiastical property, which he could dispose of at his pleasure. He next endeavoured to embark Henry in a war with Sicily, in which he himself was engaged; and offered the crown of that kingdom to his brother Richard, who had been created Earl of Cornwall; and who, having amassed immense wealth, would be able to support him in his military operations. Upon the refusal of Richard to enter into such a scheme, it was offered to the king for his second son Edmond, upon the single condition that he would defray the expenses of the conquest. Henry, dazzled by such a present, inconsiderately agreed to the proposal, and gave his Holiness unlimited credit to expend whatever sums were necessary for completing the enterprise. By this foolish bargain, he found himself, before he was aware, involved in a debt of 135,000 marks. In this emergency, he applied to the Parliament, but they unanimously refused to lend their assistance to such a project. The clergy were now his only resource; and, with the aid of the legate, he extorted from them 150,000 marks. This sum, however, was still insufficient. New demands were made by the Pope, and interdicts and excommunications were threatened in case of non-compliance. Henry at last began to discover the cheat, and resigned his claim to a crown, which he could never expect to enjoy.

About the same time, the Earl of Cornwall engaged in an enterprise equally vain and vexatious. On the death of the Emperor Frederic, he was tempted to become a candidate for the Imperial throne. After expending large sums, he was chosen king of the Romans; and proceeding to Germany, he attracted, by his liberality, numerous friends and partizans. But he was soon drained of his wealth by the avidity of the German princes, and returned to England, ashamed of having lavished the savings of a whole life upon the acquisition of an empty dignity.

The barons still continued resolute in refusing supplies, and every application of Henry was met on the part of the parliament with a remonstrance against the oppressions of his favourites, and his violations of the great charter. He at last pretended, that he had taken the vow of a crusade, and demanded their assistance. At this time he made the most humble submissions, and promised a redress of all ecclesiastical and civil grievances. But they had so often experienced the deceitfulness of his submission and promises, that they at first hesitated to comply; but at last consented to grant him a tenth of the ecclesiastical benefices, and a scutage of three marks on each knight's fee, upon condi-

- tion that he would ratify the great charter in a more solemn manner than had hitherto been employed. On this occasion, the prelates and abbots were assembled, each with a burning taper in his hand. The charter was read before them, and sentence of excommunication was denounced against all who should violate it. They then threw their tapers on the ground, and exclaimed—

"May the soul of every one who incurs this sentence so stink and corrupt in hell! To which the king subjoined—"So help me God, I will keep all these articles inviolate, as I am a man, as I am a Christian, as I am a knight, and as I am a king, crowned and anointed."

But Henry, still weak and inconstant, soon forgot his oath; and, again swayed by the counsels of his favourites, returned to his usual extortions and oppressions. Complaints against his government were loud and general. The barons, fatigued with fruitless submissions, and seeing no prospect of obtaining redress at the hands of the king, entered into a confederacy to seize the reins of the state, and compel the fulfilment of those promises which they had so long looked for, but in vain. At the head of this confederacy was Simon de Montfort, Earl of Leicester, a foreigner by birth, but who had succeeded to a large inheritance in England. By insinuation and address, he had acquired a strong interest in the nation, and had gained the affections of all ranks; and being of a violent and ambitious temper, he was capable of the most daring designs. He had alternately experienced the favour and hatred of Henry; but being at last disgraced and banished from court, he resolved to attempt an innovation in the government, and wrest the sceptre from the feeble hands of his sovereign. This spirit of hostility first appeared when Henry had summoned a parliament, in expectation of supplies for the Sicilian war. The barons came to the hall completely armed; and in this hostile attitude expostulated with the king on his imprudent and illegal conduct. That though he had often acknowledged his errors, and promised to give satisfaction to the nation, yet he had still allowed himself to be carried into the same measures; that he must therefore dismiss these faithless counsellors, and confer authority upon those who were more ready and able to redress the public grievances. The king yielded to their demand, and summoned another parliament at Oxford, to prepare such regulations as might be deemed necessary for the reformation of the state. On the day appointed, the barons appeared at Oxford at the head of their vassals; and that assembly, afterwards known by the name of the Model Parliament, appointed 24 commissioners, to whom were entrusted the reformation of abuses. Of these, 12 were chosen from the king's ministers, and 12 from the barons; and the king took an oath, that he would adhere to whatever regulations they should adopt for the welfare of the nation. At the head of this council was Leicester, who directed all their deliberations; and they first ordered that four knights should be elected by each county, to report at next meeting of parliament the grievances which were most felt in their neighbourhood. They then enacted that there should be three sessions of parliament every year; that a sheriff should be annually elected by the votes of the freeholders in each county; that no wards or castles should be entrusted to foreigners; and that no new warrens or forests should be made, nor the revenues of any county or hundred be let to farm. These were the only regulations of the council, from which the public could
derive any advantage. Their future conduct betrayed their selfish and ambitious views; and the object of all their subsequent measures seems to have been, the continuance of their authority, and the aggrandizement of themselves and families. They deposed all the chief officers of the crown, and filled their places with their own creatures. They assumed the custody of all the castles; and even imposed an oath upon all the lieges, that they would execute and obey all the ordinances of the 24 barons. Even Prince Edward, the king's eldest son, and the king of the Romans, after some opposition, were compelled to take this oath. They bound themselves also to stand by each other with their lives and fortunes; and during the interval of the sessions, the whole authority of parliament was vested in a committee of twelve.

These proceedings opened the eyes of the nation to their selfish intentions; and as they had prolonged their authority from time to time, under the pretence that their task was not yet brought to a conclusion, the people became apprehensive that they wished to establish their own power upon the ruins of the royal prerogative, and called loudly for a termination to their intended regulations. The knights of the shires, who seem to have assembled in a separate house, also remonstrated against the slowness of their proceedings; and appealed to Prince Edward to interpose in behalf of the nation. Edward sent a message to the barons, requiring them to hasten the conclusion of their undertaking; as he was determined to resist their usurpations at the hazard of his life. The popular voice was now on the side of the king. The barons had enjoyed the sovereign power nearly three years; but, instead of employing it for the good of the nation, they had openly abused it to the promotion of their own interests. Jealousies and animosities had also crept into the council; and the defection of the Earl of Gloucester, whose moderation ill suited with Leicester's ambitious projects, revived Henry's hopes of regaining his lost power. Leicester, enraged at the opposition he met with even from his own party, had retired to France in disgust.

The barons being thus in a manner disinherited and deprived of their leader, the king took advantage of their quarrels; and having received from the Pope absolution from his oaths and engagements, he resumed his authority. He removed all the officers appointed by the barons; placed new governors in the castles; summoned a new parliament; and offered to refer all the differences between him and the Earl of Leicester to the mediation of Margaret, Queen of France. That bold and turbulent nobleman, however, rejected all interference of a foreign court; and trusting to his influence over the barons, and the unsettled state of Henry's government, meditated an insurrection for the recovery of his power. He had even enticed over to his party Gilbert, the young Earl of Gloucester, and Henry d'Almaine, the son of the King of the Romans; and having entered into a confederacy with the Welsh, who had made an insurrection in England with 30,000 men, he secretly came over from France, and commenced an open rebellion. He was favoured and supported by the Londoners, who broke out into open sedition, and committed the most horrible excesses. He had also seized the person of Prince Edward, who was the very soul of the royal cause; and had assumed such an imposing attitude, that the king was glad to submit to an accommodation. By this treaty, the barons were again reinstated in the sovereignty of the kingdom; and, at a parliament held at Westminster, they insisted that their authority should continue during the lives both of Henry and Edward. These ignominious terms were submitted to by the king, but were rejected by his son, who exerted himself with such success in the defence of his rights, that he prevailed upon many, who had adhered to the barons, to join the royal cause.

Hostilities were again renewed; but the universal clamour of the people for peace was so strong, that both sides agreed to submit the dispute to the arbitration of Louis IX. This prince, instead of availing himself of the distractions of a rival state, to advance his own authority, or to extend his dominions, had, during the whole struggle, acted with the greatest moderation and integrity. Whenever he interposed in the affairs of England, it was with the sincere intention of composing the differences between the king and his nobility, and he always recommended to both parties every peaceable and conciliatory measure. When appealed to by both parties, he declared the impartial and honourable dictates of his mind. He annulled the provisions of Oxford, and re-established the royal authority as it stood before the meeting of the mad parliament; he confirmed the people in all the privileges and liberties which they enjoyed by any former concessions or charters of the crown; and ordered a general amnesty to be granted for all past offences. Though Leicester and his associates had sworn to abide by the award of the French monarch, yet they determined to reject this equitable sentence, and to procure by arms more advantageous terms. The country again became the theatre of a civil war. The king and prince assembled their vassals, and prepared for defence. They were reinforced by some of the bravest barons of the north; and the first advantages were in their favour. Northampton was carried by assault; and Leicester and Nottingham opened their gates at their approach. The rebels, however, were in possession of London, and had laid siege to Rochester. The royalists hastened to its relief, and Leicester fell back upon the capital. But being strongly reinforced, he determined to give battle to the king. The armies met near Lewes, in the county of Sussex. The battle was begun by Prince Edward, by attacking with great fury the Londoners, who composed the van of the rebel army. He drove them off the field with great slaughter; but while he was eagerly pursuing the advantage which he had gained, his father and uncle were defeated by Leicester, and taken prisoners. The prince attempted to retrieve the fortune of the day; but his followers were intimidated, and he was obliged to submit to Leicester's terms. The rebel demanded that the prince and Henry d'Almaine should surrender themselves as pledges in place of the two kings; that all the other prisoners should be set at liberty; and that the final agreement should be settled under the direction of the King of France.

Leicester had no sooner got the royal family into his power, than he forgot his agreement with Edward. He still detained the king as a prisoner, and assumed the sole direction of affairs in the kingdom. He engrossed to himself the ransom of all the prisoners; and seized on the estates of eighteen barons as his share of the spoil in the battle of Lewes. He even treated his confederates with the most wanton insolence; and protected the pirates of the cinque-ports upon condition of receiving a third of their prizes. Knowing that this usurpation of authority could not continue.
without opposition, he endeavoured to increase his popularity, and strengthen his power, by admitting into a share of the government an order of men, which had been hitherto regarded as unworthy of a voice in the councils of the nation. He summoned a new parliament at London; and, besides its usual members, he ordered returns to be made of two knights from each shire, and of deputies from the boroughs. This was the first embryo of the House of Commons,—an institution which, in process of time, proved one of the most useful and powerful members of the British constitution, and which gradually rescued the kingdom from aristocratical, as well as from regal tyranny.

Leicester continued to act in the most arbitrary manner; and, trusting to his popularity, procured to himself all rival to the Earl of among the baronians. He seized the Earl of Derby, whom he threw into prison, and obliged others to leave the kingdom. The Earl of Gloucester even began to dread his authority, and retired to his estates on the borders of Wales. These dissensions revived the hopes of the royalists; and they were farther encouraged by the general wish of the nation for the liberation of the young prince, which Leicester found himself compelled to gratify. That nobleman, however, stipulated for the delivery of all the royal castles, and that the prince should neither leave the kingdom, nor introduce any foreign forces into it during three years. This treaty was of very little advantage to Edward, who, though declared free by the barons, found himself surrounded by the emissaries of Leicester. He at last, however, contrived, by the assistance of Gloucester, to make his escape; which was no sooner known than the royalists flew to arms, and, being joined by many of the discontented barons, presented an opposition, which Leicester was unable to withstand. He had followed the Earl of Gloucester with his army into Hereford; and here he found himself surrounded by his enemies. Edward had cut off all communication with his friends, by destroying the bridges on the Severn; and had also surprised and dispersed an army under his son. Simon de Mountfort, which was hastening to his relief. Ignorant of his son's fate, Leicester had crossed the river in boats, and encamped at Evesham, in expectation of reinforcements. Here he was attacked by Edward, at the head of the royalists, who were inspired by their recent victory. The rebels, who had been weakened by sickness and desertion, defended themselves with great bravery; but at last gave way on all sides, and were pursued with immense slaughter. Leicester, with his eldest son Henry, and about 100 knights, fell in the action. The old king, who had been placed in the front of the rebel army, was wounded, and in great danger of being killed; but, when the blow was falling upon him, he cried out, "I am Henry of Winchester, your king. Saviour." On the slightest show of recrudescence, he was carried to a place of safety. By this decisive victory, Edward at once quelled a rebellion which had lasted for several years, and which had threatened to extirpate his family, and to extinguish the prerogatives of the crown. The rebellion, however, had been so extensive, that the king, on resuming his authority, found it necessary to exercise it with clemency and moderation. No blood was shed on the scaffold; and the only attainders that were fully carried into execution, were those of the Mountfort family.

The Earl of Gloucester, to whom Edward was greatly indebted for the recovery of his liberty and the success of his cause, considering his services undervalued, attempted to renew the flames of rebellion, and excited the Londoners to take up arms. This insurrection was soon suppressed by the activity of the prince; and Gloucester was pardoned, and received into favour, upon his entering into a bond of 20,000 marks, to keep the peace. Edward, however, to relieve himself from all apprehension of disquiet from the formidable power and turbulent disposition of this nobleman, determined to carry him along with him to the Holy Land, whither he had promised to accompany the king of France.

While Edward was reviving among the Saracens the glory of the English name, his father was unable to protect his subjects from the power of the barons, who renewed their oppressions; and committed continual ravages throughout the kingdom. Worn out with age, the feeble Henry could ill manage a sceptre, which in his best days had been wrested from him by a turbulent nobility. After the departure of his son, his health visibly declined, and he expired at St. Edmondsbury, in the 64th year of his age, and 56th of his reign.

Edward had reached Sicily on his return home, when Edward I. he heard of his father's death. His succession, however, being undisputed, and the council having appointed a powerful regency during his absence, he was in no hurry to take possession of his crown, but spent a year in France. He arrived in England after an absence of about three years, and was crowned at Westminster amidst the joyful acclamations of his people.

A prince like Edward, who had already gained the affections of his subjects, and possessed abilities and courage, might easily have extended the prerogatives of the crown as they were enjoyed by his most warlike predecessors; but he was contented with more moderate authority, and set himself to the correction of abuses in the government, and in guarding against those civil commotions which had been so frequent during the reign of his predecessor. His first step was to free the prisoners of the barons, by a strict and impartial administration of justice: He appointed commissioners to inquire into disorders and crimes of all kinds, and rigorously to inflict the punishment of the laws: These were distinct from the ordinary judges, and were confined to the western counties of England, where bands of banditti had become so numerous and powerful as to set all law at defiance. The terror, however, which the severity of the commissioners excited, soon put a stop to their depredations. The corruption of the judges themselves was a more serious evil; and to such an extent did it prevail, that when they were brought to trial before parliament, all of them, except two, who were clergymen, were deposed and severely fined. The king afterwards compelled all the new judges to take an oath that they would receive no bribes.

The Jews were the greatest sufferers in this general renovation of the laws; and as they were hated both by the prince and the people, they were often condemned to death for the slightest information. In London alone, 250 of them were hanged for adulterating the coin; many of the Jews of them had their lands and goods sold and confiscated; and Edward, prompted by his zeal against infidelity, or rather by his rapacity, at last banished them the kingdom, and despoiled them of all their property, except what was sufficient to bear their charges to foreign countries. Having regulated the internal affairs of the kingdom in a manner which promised security to himself and to his people, Edward turned his views to the conquest of Wales.

The Welsh were the only remains of the ancient Britons that had preserved, among their inaccessible mountains, their laws and customs uncontaminated by foreign invasion. Bearing a hereditary enmity against the English, who enjoyed the rich possessions from
which they had been expelled; they seized every opportunity of laying waste their country. They endeavoured to profit by every disturbance among their enemies; and had been deeply engaged in the rebellion of Leicester. Lewellyn, Prince of Wales, on the suppression of that rebellion, had been included in the general accommodation; but dreading the resentment of Edward, he still carried on a secret correspondence with the Mountfort faction, and had even paid his addresses to Leicester's daughter. The discovery of this correspondence furnished Edward with a pretext for war. He marched a numerous army into Wales, and having hemmed in the enemy among the hills of Snowdon, reduced them to submission by famine. Lewellyn and all his barons swore fealty to the crown of England. This humiliation, however, was but of short duration. The Welsh, irritated by the insults and oppressions of their haughty victors, again flew to arms: But it was the signal for their ruin. Edward, well pleased with an opportunity of again going to war, resolved to free himself from all future apprehension of disturbance from that quarter, by making an absolute conquest of the country. He assembled all his military tenants, and entered Wales with an army which rendered resistance vain. Lewellyn was surprized and killed. His brother and successor, David, was driven from one retreat to another, and at last betrayed to the enemy. This prince was tried by Edward as a traitor, and was unjustly ordered to be executed. The Welsh nobility immediately submitted, and the principality received the laws of England. But the barbarous policy of Edward led him to a more inhuman step even than the unjust murder of their sovereign. Sensible how much traditional poetry and music is calculated to keep alive the idea of national valour and glory, he assembled together all the Welsh bards, and ordered them to be put to death.

During an interval of three years of peace, the king resided chiefly on the continent, whither he had been called to accommodate a dispute between the kings of Aragon and France respecting the kingdom of Sicily. On his return, he found his attention arrested by the state of affairs in Scotland. Alexander III. had died without male issue, and had left his kingdom to his grand-daughter Margaret, who was yet an infant. This princess was the daughter of Eric, king of Norway, and Margaret, daughter of Alexander, and is commonly known in history under the name of the Maid of Norway. On the death of her grandmother, she was immediately recognized as sovereign by the states of Scotland, and a regency was appointed to administer the affairs of the kingdom during her minority. Edward, whose mind was continually alive to projects of ambition, was no sooner informed of Alexander's death, than he conceived the design of uniting the whole island into one monarchy, by the marriage of the Maid of Norway with his eldest son Edward. The proposals of the King of England were accepted and approved of by the Scottish parliament, who even agreed that their young sovereign should be educated at the court of Edward. But these flattering prospects were soon dissipated by the death of the young princess, who died on her passage to Scotland. The disputes and disorders which were the consequences of her death, still furnished Edward with a pretext for interfering in the affairs of the neighbouring kingdom; and of at least endeavouring to compel, by force of arms, what he had been prevented from accomplishing in an amicable manner. But these transactions, in which he was chiefly engaged during the remainder of his reign, will be particularly detailed under the article SCOTLAND.

While Edward was intent on the conquest of Scotland, he found himself at the same time embroiled in a war with France. The origin of this war was a quarrel between an English and Norman sailor at Bayonne, in which the Norman was killed. The crew of the Norman vessel to which the deceased sailor belonged, complained to the king of France; but he, without inquiring into the business, bade them revenge themselves, and gave him no more trouble. They accordingly seized an English ship in the channel, and, having hanged several of the crew at the yard-arm, along with some dogs, dismissed the vessel, saying, That was the satisfaction they required for the blood of their countryman slain at Bayonne. This outrage and insult produced retaliations on the ships of France; and, in a short time, the whole navy of both nations were engaged in the quarrel. The sovereigns seemed to take no notice of the depredations which were daily committed against their respective subjects, until, the two fleets having met, an obstinate battle ensued, in which the French were totally routed, with the loss of 15,000 men. The affair had now become too serious to be overlooked; and Philip dispatched an envoy to England to demand reparation. Edward attempted to condescend; and, as he was apprehensive of danger from Scotland, he studiously avoided a rupture with France. Philip pretended, that as it was his honour merely that was interested by the outrages of the Gastons, if Edward would give him possession of Guienne, he would consider himself satisfied, and would immediately restore it. The king was deceived by the artifice, and ordered Guienne to be delivered to Philip, and no sooner got possession, than he threw off the mask, and declared himself sovereign of the province. Edward, enraged more at being thus over-reached, than at the loss of his territory, dispatched a considerable force for its recovery. All his attempts, however, were unsuccessful; and he was, in return, threatened with invasion from France. Philip had entered into a secret treaty with Bariol, king of Scotland; and had even made a descent upon the Kentish coast. His troops took and burnt the town of Dover, but were soon after compelled to retire.

The expenses attending his multiplied wars, obliged Edward to have frequent recourse to parliamentary supplies, and was the means of again introducing the lower orders into a share of the government. The parliament at this time consisted entirely of the great barons and the knights of the shires; for the representatives from the boroughs had never been summoned since the usurpation of Leicester. But as the growth of commerce, and the improvements in agriculture, had given property and consequence to the inhabitants of the towns, they were also called upon to contribute to the support of the state. The king, by his prerogative, had the power of taxing them at pleasure; but he sometimes found it both difficult and inconvenient in enforcing his demands: the taxes could only be levied with the consent of each particular borough; and this consent was often obtained only by solicitations or threatenings. To remedy, therefore, this inconvenience, Edward resolved to summon two deputies from each borough, who should be provided with sufficient powers from their constituents to agree to what he should require of them: "As it is a most equitable rule," said he, "that what concerns all, should be approved of by all; and common dangers be repelled by united efforts."
Above fifty years after, these deputies and the knights of the shires were united in one assembly, with the same rights and privileges, and now constitute the third estate of the realm.

Having procured a liberal supply from his parliament, Edward determined to prosecute the war, both in France and Scotland. He overran the latter kingdom with a numerous army, received the submission of the nobles, and carried Baliol a prisoner with him to London. He sent an army of 7000 men into Guienne, under his brother Edmund; but this prince soon after dying, the command devolved on the Earl of Lincoln, who terminated the campaign without any material advantage. Not discouraged by this failure, he prepared to make a more powerful effort for the recovery of the ancient patrimony of his family. He entered into an alliance with the Earls of Holland and Flanders, and flattered himself that, at the head of the allied forces, he might penetrate to Paris, and compel Philip to purchase peace by the restoration of Guienne. Considerable supplies, however, were requisite for the accomplishment of his plan; and he obtained from the barons and knights a grant of a twelfth of all their moveables; and from the boroughs an eighth. He also applied to the clergy for a fifth of their moveables; but here he met with an opposition, which put a stop, for a time, to his projected expedition.

Pope Boniface VIII had issued a bull, prohibiting any tax being levied upon the clergy without his consent; and the Archbishop of Canterbury told Edward, that they owed obedience to their spiritual, in preference to their temporal sovereign. "If you refuse, then," said the king, "to support the civil government, you are unworthy to receive any benefit from it;" and orders were immediately issued to all the judges, to do every man justice against the clergy, and to do them justice against nobody. Being thus put out of the protection of the laws, they found themselves at the mercy of every ruffian who chose to insult, to plunder, or even to maim them; and they were at last glad to submit to the king's demands, that they might be again admitted under the king's protection.

These supplies, however, were still insufficient for Edward's necessities; and he was obliged to have recourse to arbitrary measures, to complete his preparations. He carried off grain, and cattle, and other commodities necessary for supplying his army, wherever he could find them; for which he merely gave his promise of after-payment: and, in order to recruit his forces, he demanded the attendance of every man possessed of land worth £20 a-year. These oppressive exactions spread general discontent. The barons, jealous of the royal prerogative, and afraid of their own privileges, encouraged the complaints of the people; and, when Edward ordered the Earls of Hereford and Norfolk, the constable and marshall of England, to take the command of the forces to be employed in Gascony, these noblemen both refused, affirming that they were only bound by their office to attend his person in the wars. The king, in a rage, exclaimed to Hereford, the constable, "Sir Earl, by God, you shall either go or hang!"—"By God, Sir King," replied the constable, "I will neither go nor hang!" The king found it prudent not to press the matter; and consequently withdrew the expedition against Guienne: but he soon after embarked, with an army of 50,000 men, for Flanders.

The two ears had gained a strong party among the barons; and, when summoned to attend the parliament, in the king's absence, they came with a large force, and took possession of the capital. They proceeded, however, with moderation. They laid their demands before the council, and only required that the two charters should receive a solemn confirmation: that a clause should be annexed, to secure the nation against all imposition of taxes, without the consent of parliament; and that they and their adherents should be again received into favour. The charters were sent to the king in Flanders, who hesitated for a time to give his consent; but the dangerous consequences of a refusal being represented to him, he at last reluctantly complied. Some time after his return, he gave a more willing and absolute confirmation of the Great Charter, which so completely established its validity, that it was never afterwards formally disputed.

The war in Flanders was carried on with various success. Philip had taken Lisle, St Omer, Courtray, and Ypres; but his career was stopped by the appearance of the English, and his resources being exhaustcd, he had reason to apprehend great famine. Edward, however, had been disappointed of promised assistance from the king of the Romans, whom he had highly subsidised, and was equally desirous of concluding the war. Under the mediation of Boniface, the twonarchies at last came to an accommodation, in which they were both influenced by the most selfish policy. Edward abandoned his ally, the Earl of Flanders; while Philip did the same with the king of Scotland, who was still a prisoner in England; and, by these mutual sacrifices, they were left at liberty to prosecute their particular conquests.

A revolt of the Scots hastened the return of Edward. That unhappy people, under the brave Wallace, struggled for a time with the overwhelming power of England; and, though again subdued, and deprived of their leader, yet they seized the first opportunity of again rising against their oppressors; and, led on by Robert the Bruce, proceeded with a slow but certain step towards the recovery of their independence (Scotland). Edward, enraged at their frequent revolts, assembled an immense force; and was hastening to execute the most dreadful vengeance upon a nation, which had caused him so much trouble and anxiety; when he was suddenly taken ill at Carlisle, and died in the 36th year of his reign, and 69th of his age.

The abilities of this prince shone with equal lustre in the cabinet as in the field. The many wise statutes which he enacted, obtained for him the appellation of the English Justinian; and the improvements which he made in the execution of the laws, gave security and protection to the lowest orders of the people. But, while he took care that his subjects should do justice to each other, he was little solicitous about the rectitude of his own proceedings; and his arbitrary and violent temper, often led him into measures which excited the murmurs of the nation, and sometimes brought them to the very brink of rebellion. But his prudence in stopping in the moment of danger, and his compassion for the innocent, prevented any considerable disturbance during his reign. He tempered the severity of his disposition by the affability of his manners; and few princes have been more revered and respected by their subjects. The conquest of Scotland, which he considered as the greatest enterprise of his life, he left as a legacy to his son, whom he charged, with his last breath, to prosecute the war, and never to desist till he had annexed that kingdom to his dominions.
Edward II, came to the throne with the prepossessions of all ranks in his favour; and, had he possessed but a moderate share of prudence and abilities, he might have preserved inviolate the prerogatives of his crown, and have maintained a respectable name among the sovereigns of his time. But the weakness of his understanding, and the indolence and mildness of his disposition, rendered him totally incapable of wielding the sceptre over a turbulent and high-spirited people. Regardless of the dying commands of his father, he consoled the war in Scotland, disbanded his army, and gave himself up to pleasure and amusement. He recalled from exile his favourite Gaveston, who had formerly ministered to his youthful extravagancies. This Gaveston was the son of a Gascon knight, and had early insinuated himself into the affections of young Edward. He possessed an elegant person, and agreeable manners; but he was vicious and effeminate; and the late king, apprehensive of the ascendency which he had gained over his son, banished him the kingdom, and made the young prince promise never to recall him. Early possibilities L Lancaster, to soon found him in possession of the throne, than he sent for his favourite, and immediately distinguished himself with the highest marks of confidence and friendship. He endowed him with the whole erldom of Cornwall; gave him his own niece in marriage; and seemed happy only as he was enabled to load him with new honours and possessions. But the mind of Gaveston was ill fitted to bear with equanimity the full sunshine of royal favour. Naturally vain-glorious, his pride rose with his fortunes; and he took pleasure in displaying his power and influence, to the mortification of his rivals.

Marriage of the king.

While Edward was in France, espousing the princess Isabella, Gaveston was left guardian of the realm, with more ample powers than had usually been conferred; but, instead of gaining a party in his favour to support his sudden exaltation, he disgusted all ranks by his prodigality and pomp. The haughty nobles could ill brook the neglect of a weak monarch, and the domination of an insolent stranger; and a combination was accordingly formed to expel Gaveston from the kingdom.

At the head of this combination was the Earl of Lancaster, a prince of the blood, and one of the most potent barons in England; and it was also encouraged by the queen, who hated the favourite on account of his ascendency over her husband. The barons, when united, were irresistible. They came to the parliament with an armed retinue, and demanded the banishment of the favourite. Edward was obliged to submit, and immediately dispatched Gaveston to be lord-lieutenant of Ireland.

Unhappy in the absence of his favourite, whose company alone seemed to give him pleasure, the king tried every method of procuring his recall. He softened the opposition of Lancaster, and some of the principal nobility, by raising them to high offices in the government, or by loading them with civilities and promises, and then invited Gaveston to return. The favourite, however, instead of profiting by his past misfortunes, and henceforth enjoying his honours with modesty and moderation, heightened the general discontent, by new insults and injuries. The barons again took up arms, and compelled the timid Edward to devolve the whole authority of the kingdom on twelve commissioners. Their power was to continue only for one year; but whatever ordinances they should think proper to enact, were for ever to have the force of laws. Among other useful regulations, they banished Gaveston for ever from the kingdom, under the penalty of being declared a public enemy, in case of disobedience. The favourite retired to Flanders, but Edward was insupportable for his loss; and removing to York, where he thought himself secure from his enemies, he again recalled him. The barons now saw that the death of Gaveston was the only safeguard against their own ruin. Lancaster hastened to York; but the king had fled with his favourite to Scarborough, and having left him there, with a strong garrison, returned to oppose Lancaster. Scarborough, however, soon after surrendered to the rebels, and the unhappy favourite was put to death without even the form of a trial. The news of Gaveston's murder filled Edward with grief and indignation; and he threatened his utmost vengeance against all who had been concerned in that bloody transaction. But forgetting his feelings in his fears for his own safety, he agreed to an accommodation; and, as the barons were sufficiently satisfied with their revenge, they offered to ask his pardon publicly on their knees, when a general amnesty was immediately subscribed. Tranquillity and union being again restored, the attention of Edward was called to the progress of the Scottish patriots. Ashamed of his former inactivity, and of having allowed the favourable moment to escape, he now determined to execute his father's dying command. He collected, from all quarters, his most warlike vassals, and marched, with an immense army, to the frontiers of Scotland, with the certain hope of finishing, at one blow, the important enterprise which the first Edward had so successfully begun. But the decisive battle of Bannockburn drove him with disgrace from his expected conquest, secured the independence of Scotland, and fixed Robert Bruce upon the throne of that kingdom.

The Scots now retaliated upon their oppressors, and made many successful inroads into England. These disasters, with Edward's inflatuated attachment to favourites, again excited discontent among the barons, and kindled a civil war in the kingdom. Hugh Spencer, the new favourite, was of a noble family, and possessed all those exterior accomplishments which were fitted to make a favourable impression on the weak mind of the king. But he was equally destitute, with Gaveston, of prudence and moderation. He exceeded him in avarice, injustice, and prodigality, and soon became an object of greater hatred than even that unfortunate stranger. The turbulent Lancaster, at the head of the malcontents, entered London with an armed force, and compelled the parliament to pass a sentence of attainder against Spencer and his father. In this, Edward was obliged to acquiesce; but it was only with the intention of reversing it as soon as he had an opportunity; and this opportunity soon arrived.

The queen, who had long been joined by the barons in their hatred against the favourites, while on a pilgrimage to Canterbury, had been denied a night's lodging, by Badlesmere, governor of the castle of Leeds. Irritated by this affront, she persuaded her husband to take vengeance on his insolent vassal. Edward immediately raised an army, and having taken the castle of Leeds, put the governor to death. Being now emboldened with success, he resolved to take advantage of his situation, and to re-establish and confirm his authority, by the destruction of his enemies. He recalled the two Spencers from exile; and marched with his army to the marches of Wales, where the discontented barons chiefly resided. The Earls of Hereford and Lancaster endeavoured to oppose his passage of the Trent; but
A.D. 1326.

A difference having arisen between Edward and Charles the Fair, king of France, respecting the duchy of Guinevere, Isabella was permitted to go over to Paris, in order to adjust matters with her brother. Charles, however, required that the king of England should appear in his court, and do homage for that duchy; but as there were many obstacles to such a journey, the queen proposed that Guinevere should be given to young Edward, and that the prince should come to Paris and do homage to his superior lord. The king, glad of indulging in his indulgence, and in the society of his favourite, willingly consented. The queen, having now got the young prince into her power, was resolved to employ his influence for her own aggrandizement. She had fixed her affections, which had been long estranged from her husband, upon Roger Mortimer, a powerful baron, who, having been engaged in the late rebellion, had escaped into France. At the French court also she met with many English fugitives, the remains of the Lancastrian faction, who were ready to countenance any of her schemes that were likely to be the means of restoring them to their possessions and their country. Being thus supported, and having gained over the Earls of Kent and Norfolk, brothers to the king, as also the Earl of Leicester, brother and heir to Lancaster, and the Archbishop of Canterbury, with many other noblemen and prelates, she landed on the coast of Suffolk, with 8000 foreign troops. She openly declared that her only object was the expulsion of the Spencers from power; but with the ruin of the favourites, she meditated also the dethronement of her husband. As the Spencers were universally hated, the people soon flocked to her standard, and even Robert de Watteville, who was sent by the king to oppose her, joined her with all his forces. Edward endeavoured to rouse the citizens of London in his defence, but in vain; and being in a manner deserted, he fled towards Bristol. Thither he was pursued by the Earl of Kent, and the foreign mercenaries. He then passed over into Wales, leaving the castle of Bristol to the charge of the elder Spencer, who had lately been created Earl of Winchester; but he was by no means there, for the garrison mutinied, and delivered up their governor to the rebellious barons. This venerable nobleman, now in his ninetieth year, was condemned without trial, was hanged upon a gibbet, had his body cut to pieces and thrown to the dogs, and his head sent to Winchester to be exposed to the derision of the populace. His son soon after shared the same fate. The king, disappointed of the expected succours, had attempted to escape into Ireland, but, being driven back by a storm, he fell into the hands of the rebels, and was committed to the castle of Kenilworth, under the custody of the Earl of Leicester. The queen then summoned a parliament at Westminster, in which the king was charged with incapacity for government, and neglecting the public welfare. He was consequently deposed, and was soon after compelled, by menaces, to sign his own resignation. The young prince was then crowned king; but the whole authority of the government fell into the hands of his mother, and her paramour Mortimer. Not content, however, with imprisoning her husband, and her own exaltation, the queen endeavoured to hasten his death, by the most ignominious and cruel treatment. Her criminal correspondence with Mortimer had become apparent to all; and as they became hated for their vices, the dethroned monarch was regarded with pity and veneration. They did not consider themselves as safe while the king lived. He was sent from prison to prison, and made the sport of his mercenary keepers. Every mean was tried to break his spirit. He was kept totally destitute of all the comforts, and almost of the necessities of life. At one time they ordered him to be shaved, in the open fields, with cold and dirty water from a neighbouring ditch; when they refused to change it, he burst into tears, bending low his face, he exclaimed, that, in spite of their cruelty, he should be shaved with clean and warm water. But sorrow and affliction were instruments of murder too tardy for the impatience of his enemies; and Mortimer sent secret orders to his keepers to have him instantly dispatched. The assassins seized him while in bed, and, in order to prevent any outward marks of violence appearing on his person, they held him down with a table which they flung over him, and thrust a pipe up his body, through which they inserted a red hot iron, which consumed his bowels. His agonizing shrieks, and murdered,
Edward, having now taken the sceptre into his own hands, began his reign by correcting the disorders and suppressing the numerous gangs of robbers, which had increased to an alarming degree during the convulsions of the former reign, and the lawless administration of Mortimer. He then directed his attention to Scotland, which was again involved in a civil war by the death of Robert I. and the pretensions of Edward Baliol to the crown. David Bruce was only seven years of age when his father died; and he was soon after deprived of his able guardian, Randolph, Earl of Murray. The loss of this noble warrior and statesman would have been a serious blow to the kingdom of Scots in the present distracted state of the kingdom; it was a death-blow to the cause which he supported; and Baliol, by the assistance of Edward, was raised to the throne. His reign, however, was but of short continuance. His tame subjection to England excited the general indignation of the Scots; and Edward, with all his power, found himself unable to subdue the spirit of that warlike people. But his attention was soon drawn off to more important conquests.

Phllip the Fair left three sons, Louis Hutin, Philip the Long, and Charles the Fair, who were all successively kings of France, but who all died without leaving any male heirs; and one daughter, Isabella Queen of England. On the death of Charles, the male succession to the throne devolved upon Philip de Valois, Charles's cousin-german. Edward, however, whose claims the ambitious mind was always alive to every prospect of aggrandisement, laid claim to the crown of that kingdom in right of his mother; but, as the title of Philip had been universally acknowledged by the French nation, he did not think proper to insist in his pretensions at present, and probably would never have further thought of them, had not some circumstances occurred which kindled a quarrel between the two sovereigns.

Robert d'Artois, who was descended from the blood royal of France, and was married to Philip's sister, had been deprived of the county of Artois by Philip the Fair, and, in attempting to recover it by forgery, was detected, and obliged to fly the kingdom. He found refuge and protection in the court of England, and, being a man of abilities, was soon admitted into the councils and confidence of the king. This excited the resentment of the French monarch, who had also given serious cause of complaint to Edward, by protecting the exiled David Bruce, and encouraging the Scots in all their struggles for independence. Mutual threatenings and recriminations soon led to open hostility. Edward, at an immense expense, had formed alliances in the Low Countries, and on the frontiers of Germany; but it was difficult to bring so many petty sovereigns to act with union and determination. He was at last, however, enabled to appear in France with an army of 50,000 men. Philip opposed him with a force double its strength; but instead of coming to any decisive action, they merely encamped in face of each other, and, after some mutual bravados, Edward was compelled by his exhausted finances to retire into Flanders, and disband his army.

The debts which he incurred in this fruitless expedition, and his preparations for another campaign, obliged him to have recourse to parliament for an extraordinary supply. This was granted upon condition of his confirming the two charters, the charter of the boroughs, and of remedying some lesser abuses. But as Edward had now assumed the title of King of France, and had quelled the arms of France with those of England in his seals and ensigns, the parliament thought it necessary also to declare that they owed him no obedience as King of France; and that, whatever might be the issue of his present enterprise, the two kingdoms must for ever remain distinct and independent. Having equipped a fleet of 250 sail, the king again embarked for the continent; but was met off the Flemish coast by the French fleet, consisting of 400 ships manned with 40,000 seamen. The action was begun by the English, who had gained the wind of the enemy. It was long and fiercely contested; but the Fleming's fleet having descried the battle from their shores, issued from the harbour, and with a considerable force, and decided on the day in favour of Edward. The French in this engagement lost 230 ships and 50,000 men. But this success was followed by no event of importance on shore. Edward took the field with 100,000 men, but was foiled in an attempt upon Tournay; and the only consequence of all his mighty preparations was a truce for twelve months. Disappointed at the unsuccessful issue...
of his plans, and harassed and affronted by his numerous creditors, Edward returned to England discontented with himself and with all around him. He now vented his ill-humour upon his own subjects. Finding, on his arrival, the Tower of London negligently guarded, he imprisoned the constable and all his officers. He then dismissed and punished the officers of the revenue. He displaced and imprisoned the bishops of Chichester and Lincoln, his chancellor and treasurer; as also the keeper of the privy seal, the chief justice, and the mayor of London. Stratford, Archbishop of Canterbury, who had been entrusted with collecting the taxes, fell also under his displeasure; but that prelate being abroad, escaped the immediate effects of his resentment. He was no sooner, however, informed of the king's indignation, than he resolved to maintain the privileges of his character. He issued a general sentence of excommunication against all who should exercise any violence on the persons or the goods of clergymen, and even wrote to Edward that the royal authority was subordinate to the apostolic dignity. The king sought to humble the primate, and, as a mark of disrespect and resentment, sent him no summons to attend the next parliament. Stratford was not discouraged, but repaired to the parliament-house, arrayed in his pontifical robes, and demanded admittance as the first peer of the realm. He was refused for two days, but was at last allowed to take his seat, and was reconciled to the king.

Edward, impelled by his necessities, was obliged, in order to procure money, to aequicere in almost any measures which his parliament might propose; and they, taking advantage of his situation, passed an act, which made considerable encroachments upon the ancient prerogatives of the crown. They required that the great charter should be confirmed anew by the king; and that all the great officers of the state should also take an oath to observe it; that no peer should be punished, but by the award of his peers in parliament; and that the ministers of the crown should be amenable to parliament for their conduct in the discharge of their public duty. Edward consented to this statute; but he had no sooner received the promised supply, than he annulled it; and, about two years after, even prevailed upon the parliament to repeal it.

A.D. 1311.

Affairs on the continent began now to wear an aspect more promising to Edward's ambitious views. The Count of Boulogne seized upon Brittany, to the exclusion of his brother's daughter, who had been invested in the duchy during the lifetime of her father, and had been married to Charles of Blois, nephew to the king of France. Charles was powerfully supported by his uncle in the recovery of his wife's inheritance; while Mountfort strengthened his usurpation by an alliance with the King of England. War was immediately renewed; but, in the very outset of the contest, Mountfort was taken prisoner, and conveyed to Paris. This accident seemed to give a fatal blow to his pretensions. His fortunes, however, were soon retrieved by the magnanimity of his countess, who, having assembled the inhabitants of Rennes, presented to them her infant son, as the only male remaining of their ancient princes, and conjured them, if they had any regard to their ancient liberties, to save them from the dominion of France, by defending the rights of her family. They unanimously declared their resolution to live and die in her cause; and their example was followed by all the fortress of Britany. Having placed the province in a proper state of defence, she shut herself up in the fortress of Hennebont, where she was immediately invested by Charles of Blois. During the siege, she displayed the most heroic courage and indefatigable perseverance. The garrison, animated by her example, performed prodigies of valour; and when their strength was nearly exhausted, she broke through the enemy's line with a small force, retired to Brest, and forced her way back with a reinforcement of 500 cavalry. All her exertions, however, were unable any longer to resist the numbers of the besiegers, and she was upon the point of capitulating, when success from England rescued her from her perilous situation.

After five years of almost constant warfare, in which successes of neither party had gained any material advantage, the memorable battle of Cressy established the fame of England, and secured to Edward a footing in the kingdom of France. Accompanied by his principal nobility, and his eldest son Edward, Prince of Wales, usually denominated the Black Prince, from the colour of his armour, and then only fifteen years of age, the king of England embarked with a strong force for the relief of Guîenne; but the winds proving contrary, he ordered the fleet to steer for the coast of Normandy, and landed his army at La Hague. The French, under the Count d'Eau, constable of France, attempted to oppose his approach to Caen; but they fled at the first onset, and the constable was taken prisoner. The English army, scattered over the country, was destroyed and pillaged wherever they came without opposition, and carried their ravages to the very gates of Paris. Philip, with 100,000 men, advanced to Reuen; but Edward retired before his superior numbers, and hastened by rapid marches towards Flanders. The impatience of Philip, however, to be revenged upon his invaders, who had dared to insult him in his very capital, hurried him forward with such precipitation, that Edward was under the necessity of hazarding an engagement, or of exposing his rear to the attacks of a numerous cavalry. The King of England accordingly halted near the village of Cressy, and, having chosen an advantageous position, disposed his army in three lines, and awaited the approach of the enemy. The first line was entrusted to the Prince of Wales, with the Earls of Warwick and Oxford under him; the Earls of Arundel and Northampton commanded the second; and the king took charge of the third. The French soon after arrived in great disorder, and overpowered with fatigue. They immediately drew up in battle array. The van, consisting of 15,000 Genoese cross-bowmen, was led on by Anthony Doria and Charles Grimaldi; the heavy armed cavalry formed the second division, and were commanded by the Count of Alençon, brother to the king; and Philip himself brought up the rear. The Genoese began the attack, but were soon obliged to give way before the English archers; and, falling back upon their cavalry, threw both lines into confusion. The Prince of Wales perceived the favourable moment, and rushed with his division to the charge. He was followed by the second line; but the French cavalry, recovering themselves, and encouraged by the example of their leader, made such a desperate resistance, that the battle was long and doubtfully contested. The Earl of Warwick, apprehensive of the issue, from the superior numbers of the enemy, sent to entreat Edward to advance to the relief of the prince. The king was viewing the action from an eminence; and asking the messenger if his son was wounded or slain, he was answered in the negative. "Tell my son then," said he, "that I reserve the honour of this day to him. He will be able, without my assistance,
to repel the enemy." This confidence of their monarch inspired the prince and his companions with fresh courage; and young Edward that day performed such feats of valour, as filled even veterans with astonishment. The French cavalry were again thrown into disorder, and their leader slain. Their whole army soon after took to flight, and were pursued without quarter, till darkness saved them from the rage of their enemies. In this battle there fell on the side of the enemy, the Kings of Bohemia and Majorca, the Dukes of Lorraine and Bourbon, the Earls of Flanders, Blois, Vaucluse, and Aumale, with 36,000 combatants; while the loss of the English was very inconsiderable.

Edward followed up his victory by the siege of Calais, which employed him near a twelvemonth. But while he was engaged in this enterprise, the Scots under David Bruce entered Northumberland with an army of 50,000 men, and carried devastation and terror to the gates of Durham. Queen Philippa, in the absence of her husband, undertook the defence of the kingdom, and, with a very inferior force, ventured to give battle to the enemy at Neville's Cross. The Scots were routed with great slaughter, and King David was taken prisoner. The Queen having secured her royal captive in the Tower, proceeded to Calais, and there, by her prudence and humanity, did more for the honour of her husband and of the kingdom, than by the victory which she had so lately won. John of Viennne, the brave governor of Calais, had, during a lengthened siege, resisted all the attempts of the English with the greatest ability and courage. But despairing of relief, and being reduced to the last extremity by famine and fatigue, he offered to surrender the fortress, upon condition that Edward would ensure the lives and liberties of its brave defenders. Edward had been incensed by their stubborn resistance, and had resolved to take exemplary vengeance on them. He was prevailed upon, however, to mitigate his severity; and only insisted that six of the principal citizens should be delivered up to his resentment, with ropes about their necks, and the keys of their city in their hands. These conditions appeared even more hard than their general destruction; and the inhabitants were lost in despair, when Eustace de St Pierre offered himself the first victim for the safety of his friends. Five others soon followed his example; and these heroic men were led like malefactors to the tent of the English monarch. They laid the keys of Calais at his feet, when he gave the barbarous order for their execution. But the treachery of Philippa saved his memory from disgrace. She obtained the pardon of these gallant burgesses, and having entertained them in her own tent, dismissed them with presents. In order to secure the possession of this important fortress, Edward emptied the town of its inhabitants, and repeopled it with English, which was probably the means of preserving this conquest so long to his successors. A truce was soon after concluded between the two sovereigns, and Edward returned in triumph to England. but scarcely had it subsided, when the flames of war again began to rage.

John had succeeded his father Philip in the throne of France, but though possessed of many accomplishments, great personal courage, and the nicest sense of honour, he was deficient in foresight and prudence. His kingdom was torn by intestine commotions, which at last kindled into open rebellion. Edward, ever ready to take advantage of every disturbance in the rival kingdom, determined to support the French malcontents. The Black Prince entered France on the side of Guienne, and ravaged with impunity the whole of Languedoc, while his father, with a numerous army, overran and plundered the open country between Calais and St. Omer. Young Edward, encouraged by his past success, took the field in the following spring with 19,000 men, and attempted to penetrate through France, and join the Duke of Lancaster in Normandy. But finding the bridges on the Loire broken down, he was on the point of returning, when he was intercepted near Poictiers by the French monarch, at the head of an army five times his number. Seeing all retreat impracticable, the Prince chose his ground with the most consummate skill, and prepared for battle. But sensible of his desperate situation, he listened to the mediation of the Cardinal of Perigord, and offered to purchase his retreat, with the cession of all the conquests which he had made in this and the former campaign; and farther, engaged not to serve against France for seven years. John, however, required that he should surrender himself a prisoner, with a hundred of his attendants. Edward indignantly replied, that whatever might be his fate, England should never be obliged to pay his ransom. All hopes of accommodation being thus cut off, both sides left their cause to the decision of the sword. The English army was stationed at the extremity of a narrow defile, covered on each side by hedges, which Edward had lined with archers, through which the enemy must pass before he could take advantage of his numbers. As the French advanced, they were annoyed on each side by the English archers, against whom they were unable to retaliate, and were soon thrown into confusion. An ambush of 600 men under Capitale de Bueche, also attacked them in the rear, which spread such a panic, that the greatest part of their army took to flight. King John with his division alone, maintained his ground, and attempted to retrieve by his valor the fortunes of the day; but being at last deserted by his cavalry, he was overpowered by numbers, and taken prisoner with his youngest son, who had been wounded while fighting valiantly in defence of his father. The French monarch was received with every mark of sympathy and respect. Instead of being puffed up with exultation at his unexpected success, he ascribed his victory not to his own merit, but to a superior Providence, which controls all the efforts and prudence of men; and at a rap- past which he ordered to be prepared for the royal prisoner in his own tent, he stood behind the king's chair as if he had been one of his retainers, and repeatedly refused to take a place at table. Such unassuming modesty and genuine heroism, excited the admiration even of his enemies, and has added more to the glory of his name than all his military achievements. The victory of Poictiers was followed by a truce for two years; and, in the following spring, the Prince of Wales conducted his prisoner to England. They landed at Southwark, and entered the capital amidst an im-

 manganese concourse of spectators. The captive king rode a white charger splendidly caparisoned, while his conqueror attended him upon a black palfrey. John experienced the same generous treatment from the father which he had received from the son; but was led by his misfortunes to submit to a treaty, which would have ruined and dismembered his kingdom. He agreed to restore all the provinces which had been possessed by Henry II. and his two sons, without any obligation of homage or fealty. This pernicious treaty, however, was rejected by the Dauphin, who had assumed the government upon the captivity of his father, and who was resolved to maintain the integrity of his dominions. Edward endeavoured to compel him to submission; and entering France with 100,000 men, laid waste the provinces of Picardy and Champagne, and advanced to the gates of Paris. The prudent Dauphin, sensible of his inability to withstand such a force in the field, had resolved to act upon the defensive. He filled all the considerable towns with proper garrisons and stores, and shut himself up in the capital. Unawed by the presence of the enemy before his gates, he maintained his resolution; and Edward, after desulting the open country, found it prudent to accept more moderate terms of peace. The treaty of Bretigny was accordingly concluded, by which it was stipulated, that King John should pay three millions of crowns of gold for his ransom, about £1,500,000 of our money; that the King of England should for ever renounce all claim to the crown of France, and to the provinces of Normandy, Maine, Touraine, and Anjou, and should receive in return the full sovereignty of Guienne, with the provinces of Poitou, Xaintonge, l'Agenois, Perigort, the Limousin, Quercy, Rouergue, l'Angoumois, and other districts in that quarter, also Calais, Guisnes, Montreuil, and the county of Ponthieu; and that France should renounce all title to feudal jurisdiction or homage, or appeal from them. These terms, though severe and very disadvantageous to France, John, as soon as he had regained his liberty, prepared to execute with the most scrupulous fidelity; but he found considerable difficulty in accomplishing his honourable intentions, from the great reluctance which many of the towns and vassals in the ceded provinces shewed in submitting to the dominion of England. That no endeavours, however, might be wanting on his part, to adjust all differences between the two kings, he resolved to take a journey to England; and when his council endeavoured to dissuade him from this step, and hinted their displeasure at his anxiety to fulfil a treaty which necessity alone had forced him to accept, he made this memorable reply, "That though good faith were banished from the rest of the earth, she ought still to retain her habitation in the breasts of princes." This good prince died while in England, and was succeeded by his son Charles the Wise, who had more political prudence, but less integrity than his father.

Young Edward, who had been invested with the sovereignty of the conquered provinces, under the title of the principality of Aquitaine, had involved himself in debt, by an expedition which he undertook for the restoration of Peter the Cruel to the throne of Castile, and was under the necessity of imposing a heavy tax upon his new subjects. This measure excited general discontent, and some of the nobles even carried their complaints to the King of France. Charles considering this a favourable opportunity of reviving his claim of lord paramount in these provinces, cited the Prince of Wales to appear at Paris, to justify his conduct towards his vassals. The Prince answered that he would come to Paris, but it should be at the head of 60,000 warriors. Hostilities immediately commenced, and the French, aided by the favourable disposition of the inhabitants, and no longer opposed by the abilities of the Black Prince, who was obliged, on account of his infirm state of health, to return to England, made such progress in their conquests, that they soon regained almost all that they had lost by the treaty of Bretigny. Calais, with Bourdeaux and Bayonne, alone remained to Edward of all his vast possessions on the continent.

The Prince of Wales, after a lingering consumption, died at Westminster in the 46th year of his age; and his father survived him only about a twelvemonth. He died at Kew in Surry, in the 65th year of his age, and 51st of his reign. The reign of Edward III. is one of the longest and most glorious in the annals of England. The discontents and dissensions occasioned by the weakness of his predecessor, were forgotten in the domestic tranquillity which succeeded. He curbed the licentious spirits of the nobles, by the prudence and vigour of his administration; and gained their affections by his affability and munificence. He drained the kingdom, however, of its wealth and population, by his foreign wars, which, though they added to his own fame and aggrandizement, were of no real utility to his people. His valour and military talents were only outshone by those of his son, whose name, while it spread terror among his enemies, was hailed among his countrymen with the warmest feelings of enthusiasm and affection. The warlike achievements of young Edward were the least of his praise. He had won all hearts by his affability, kindness, and moderation; and the many eminent virtues for which he was distinguished, would have rendered him an ornament to human nature in any country or age. England had long to regret her loss, in the disturbances and insurrections which distracted the succeeding reigns.

Richard II. the son of the Black Prince, ascended the throne of his grandfather, when only eleven years of age. The administration of the government, which had been in a great measure intrusted by Edward, during his old age, to his second son the Duke of Lancaster, was still retained by that prince, who was supported by the authority of his two brothers, the Dukes of York and Gloucester. As Edward had fixed upon no plan of government during the minority of his grandson, a council of nine peers was appointed by parliament, with full powers to conduct the business of the state for one year. The administration was carried on in the king's name; but the sovereign authority virtually resided in his uncles. These princes kept in obedience the turbulent barons, who were always ready to take advantage of any change in the government, and their opposite characters also served as a check upon each other. Lancaster was reserved and unambitious; York was weak and indolent; but Gloucester possessed considerable abilities, was bold and enterprising, and had besides gained the favour of the people. Richard himself was of a violent temper, and, though young and inexperienced, could not brook the subjection in which he was kept. He was immediate in his expences and pleasures; and often neglected the most important affairs, that he might indulge in indolence or amusement. The wars which his grandfather had left him to finish, had exhausted the treasury, and impoverished his people; and the parliament, in order to relieve his exactions, had recourse to a poll-tax, which was the cause of much discontent. They imposed three groats a head
upon every male and female above fifteen years of age.

This new and oppressive measure met with universal opposition among the lower classes; and their murmurs and complaints were heighted by the harangues of a seditious preacher called Ball, who inculcated the doctrine of liberty and equality, and inveighed against the insolence and injustice of their rulers. Their minds were thus prepared for resistance, and it required only a spark to kindle them into a flame.

This tax was fanned out to tax-gatherers, and was levied with great rigour. One of these men, having demanded payment for a blacksmith's daughter, whom her father asserted to be below the age, was proceeding to indecent familiarities in order to ascertain the fact, when the father, enraged at his insolence, dashed out his brains with his hammer. This resolute action gave courage to his neighbours, and they immediately flew to arms. The spirit of sedition spread rapidly through the kingdom; and, before the government were aware, 100,000 insurgents were assembled. Blasphemy, demanding recourses to grievances. Their leaders had assumed the feigned names of Wat Tyler, Jack Straw, &c., and entering the city, burned the Duke of Lancaster's palace, murdered all the gentry or nobility that fell into their hands, particularly lawyers and attornies, and pillaged the warehouses of the rich merchants. At length the king invited them to a conference, that he might know their demands. They required a general pardon; the abolition of slavery; freedom of commerce in market towns, without toll or impost; and a fixed rent on lands, instead of the services due by villenage. These reasonable requests were complied with, and charters to that purpose were immediately granted. But while the rebels were thus satisfied in one quarter, another party of them under Wat Tyler had entered the Tower, and murdered the Primate, Sir Robert Hakins the treasurer, and some others of the nobility. The king met this tumultuous band in Smithfield, and entered into a conference with their leader. But Tyler, who had grown bold with success, blazoned with pride and insolence, addressing his Majesty, that Walworth, the mayor of London, enraged at his presumption, fell him to the ground with his mace, when he was instantaneously dispatched by others of the king's attendants. The mob seeing their leader fall, were about to sacrifice the king and all his retinue to their resentment, when Richard advanced to them with an intrepid countenance, and asked them, "What, my good people, is the meaning of this disorder? Are you concerned at the loss of your leader? I am your king. Follow me, and I will be your leader." The populace, overawed by his manner, followed him as if mechanically. He led them out of the city into the fields, and there peaceably dismissed them with the same charters that had been granted to their friends. The barons, hearing of the king's danger, soon after joined him with all their retainers, when he found himself at the head of an army that defied all opposition. The concessions that had been made to his people were then revoked by parliament; and several of the leaders of the mob were seized, and severely punished.

The extraordinary presence of mind which the king had shewn on this occasion, gave hopes that he would emulate the glories of his grandfather; but these were soon dissipated by the discovery of his indulgence and incapacity.

Since the death of Edward, the war with France had been carried on without any event of importance. The Duke of Gloucester had traversed from Calais to Brit
framed, and ratified by parliament, by which a council of fourteen persons was appointed, to whom was transferred the sovereign power for one year. In this measure Richard was also obliged to acquiesce; but at the end of the session, he publicly entered a protest, that the prerogatives of the crown should still be deemed entire and unimpaired. He could not, however, but see that he was in a manner dethroned; and his violent temper soon urged him to seek the means of recovering his lost authority. He first endeavoured to gain over the Commons to his interest, by influencing the elections. But this failing, he had recourse to the judges, who encouraged him in resisting the authority of the council. They declared that the late commission was altogether derogatory to the prerogatives of the crown, and that those who supported it were guilty of treason. They also gave it as their opinion, that the king alone has the right of dissolving the parliament at pleasure; that that assembly, when it sits, must first proceed upon the king's business; and that it cannot, without his consent, impeach any of his ministers and judges.

Gloucester at once perceived the king's intentions, and, in order to prevent their execution, he and his adherents assembled their vassals near Highgate, and demanded that those persons who had misled him by pernicious counsels should be delivered up to them. They accused the Archbishop of York, the Duke of Ireland, the Earl of Suffolk, Sir Robert Tresilian, and Sir Nicholas Brembre, as traitors to the king and kingdom. The Duke of Ireland levied some forces, and attempted to relieve his master; but he was defeated by Gloucester, and obliged to fly to the Low Countries. The rest also sought safety in flight; but they were condemned by the parliament as guilty of high treason; and Brembre and Tresilian, who had been discovered and taken, were executed. The other judges, who had given their opinion in favour of the king, were banished to Ireland. But the vengeance of Gloucester was still unsatisfied, and it fell upon Lord Beauchamp of Holt, Sir James Berners, and Sir Simon Burley, who were all condemned and executed. Bursley had been appointed governor to Richard by the late king and the Black Prince, and had attended him from his earliest infancy. He was generally beloved for his many good qualities, but his enemies were jealous of his influence over the king; and though the queen, whose amiable dispositions had acquired her the appellation of the "Good Queen Anne," interested herself in his behalf, and knelt for three hours before Gloucester, begging for his life; yet the tyrant was inexorable. This prince's power, however, which he had so wantonly abused, was but of short continuance. In less than a twelvemonth, Richard was enabled to recover his authority, though by what means is not known, but which he exercised for a time with great moderation. He placed the principal officers of the crown, who had lately been appointed by the opposition; and Gloucester and the Earl of Warwick were also removed, for a time, from the council. He confirmed, by proclamation, the general pardon which had been passed by the parliament; and endeavoured to engage the affections of the people, by remitting some subsidies which had been granted him.

During these domestic convulsions, the French war was scarcely heard of, and the battle of Otterburn was the only event that marked the hostilities with Scotland. This affair, however, proceeded more from a rivalry between the martial families of Percy and Douglas, than from any national quarrel. In this engagement, Douglas was slain, and Percy was taken prisoner; but both sides claimed the victory. A truce was now established with France for twenty-five years; and Richard, who had lost his queen, was allied to Charles' daughter Isabella, now only seven years old.

During this period also, the Duke of Lancaster, with the flower of the English army, had been prosecuting, in Spain, his claim to the crown of Castile; but after a vain and useless effort, he was compelled to resign it, upon receiving a large sum of money. On his return, he was received with great kindness by the king, who employed his authority to counterbalance that of his uncle Gloucester. This turbulent prince, however, still continued to excite divisions and rebellion; and the conduct of Richard tended too much to heighten, rather than to soothe the discontents of the nation. His time was spent chiefly in the company of worthless favourites, and the public treasures were dissipated in low pleasures and unprofitable amusements. The truce with France gave universal dissatisfaction, and Gloucester took advantage of this spirit to inveigh against the measures of government, and the pusillanimity of the king. He inflamed the minds of the people by the recital of their former victories, and compared the glories of the former reign with the indolence and effeminacy of the present. His popularity daily increased, and it was even alleged, that he contemplated the overthrow of the government, and the dethronement of the king. Richard at least was jealous and apprehensive of his popularity, and resolved, by some decisive measure, to counteract his ambitious designs. His impetuous temper would not allow him to deliberate, but he ordered Gloucester to be instantly arrested and conveyed to Calais. The Earls of Arundel and Warwick were seized at the same time, and a parliament was immediately summoned to deliberate upon the conduct of these noblemen. They were accused of high treason, in procuring the illegal commission, and in appearing in arms against their sovereign; to which they pleaded, that their crimes had been committed eight years before, and for which they had received repeated pardons. The defence, however, did not avail them. Arundel was executed, and Warwick was condemned to perpetual banishment in the Isle of Man. A warrant was next issued for bringing over the Duke of Gloucester from Calais, in order to his trial; but the governor returned for answer, that he had died suddenly of an apoplexy. The suspicions which this circumstance excited, were much to the discredit of the king's honour and humanity, for it was generally believed that his uncle was murdered by his orders. Indeed, in the following reign it was incontestibly proved before parliament, that he had been suffocated with pillows, by the command of his nephew.

After the fall of Gloucester and his adherents, Richard endeavoured to attach the opposite party more closely to his interests, by grants and preferments. The principal nobility now seemed devoted to his will; but it was the devotion of fear and interest, not of affection; and they waited only for a favourable opportunity to shake off the restraint under which they were held, and to transfer their submission to a more worthy object. While the king thus believed his government secure from further opposition, a quarrel happened among his friends, which, by his imprudent weakness, was rendered the cause of his future overthrow and destruction. The Duke of Hereford, son of the Duke of Lancaster, accused the Duke of Norfolk before parlia-
ment, of having spoken slanderous words against the
king: Norfolk denied the charge, and offered to prove
his innocence by duel. The challenge was accepted
by Hereford; and the lists were prepared at Coventry
before the king and a committee of parliament. The
combatants appeared in the field, and, after the usual
ceremonies, were about to engage, when Richard inter-
pose, and, without farther enquiry, ordered them both
to leave the kingdom. Norfolk was banished for life,
and Hereford for ten years; the one without being
convicted of any crime, the other without even being
charged with one. This decision produced general
disapprobation. Norfolk was so overwhelmed with grief
and despondence at the judgment awarded against him,
that he died soon after at Venice of a broken heart.
Hereford's conduct was more temperate and submis-
sive; and he behaved with such respect before the
king, that Richard remitted four years of his exile,
and granted him letters patent, by which he could take
possession of any inheritance that might fall to him
during his absence.

Hereford retired to Paris, where he met with a fa-
vourable reception from the French king, and soon
after entered into a treaty of marriage with the cousin
of that monarch, the only daughter of the Duke of
Berry. This alliance, however, excited the jealousy of
Richard, who resolved to prevent it, and dispatched
the Earl of Salisbury to represent the exiled Duke as
a person guilty of treasonable practices, and who would
never be allowed to return to his native country. The
resentment of Hereford, which he had hitherto endeav-
oured to conceal, now burst forth; and it was aggra-
vated by new injuries. On the death of his father, the
Duke of Lancaster, Richard revoked the letters patent
which he had given him, and seized upon his inheri-
tance. This determined the Duke to seek justice, and
attempt the recovery of his possessions by force of
arms; and he now, perhaps for the first time, cherish-
ed the thought of aspiring to the crown of England.
He was generally beloved, both on account of his piety
and valour; and all ranks had exclaimed against his ba-
nishment. He was also possessed of great prudence
and firmness, and was connected by blood or alliance
with the noblest families in England. The king, on
the contrary, was universally hated. His total disor-
der of justice, and of the public welfare, had estranged
from him the affections of his people; and his weak-
ess and effeminacy had excited their contempt. Their
minds were now ripe for a revolution; and while Richard
was indulging himself in careless security, his
throne was tottering to its fall. Unmindful of his pre-
carious situation, he imprudently undertook an expedi-
tion to Ireland, to revenge the death of his cousin the
Earl of Marche, who had been killed in a skirmish with
the native Irish. Hereford, who had now become
Duke of Lancaster, taking advantage of his absence,
came over to England with a few followers; and on his
arrival at Ravenspur in Yorkshire, was immediately
joined by the Earls of Northumberland and Westmore-
land, before whom he took an oath, that his sole object
was to recover the duchy of Lancaster, which had been
so unjustly withheld from him. This reasonable de-
mand was seconded by his numerous friends, and all
the malcontents of the kingdom; and before he reached
the capital, his army had swelled to 60,000 men.

The Duke of York, who had been left guardian of
the realm, and had collected an army of 40,000 men,
found his troops very little disposed to resist the re-
}
enacted, that if any heretic should relapse or refuse to abjure his opinions, he should be delivered over to the civil magistrate by the church, and be committed to the flames before all the people. A statute, for the suppression of heresy, had been surreptitiously obtained by the clergy during the former reign, but as it had never received the consent of the commons, it was never put in execution, and was soon after repealed. But being now supported by the king and a formal statute, they proceeded to gratify their vengeance upon their opponents; and William Saltre, rector of St Osyth's in London, was selected as the first victim, who was made to stand for his erroneous opinions by the penalty of fire.

Henry, however, notwithstanding all his prudence and caution, was involved in numerous inquietudes. The Welsh, led on by Owen Glendour, a name revered among that people even to this day, continued for several years to give disturbance to his government; and the Scots, by their frequent incursions and devastations, kept the northern counties in constant alarm. Henry, in order to chastise those troublesome plunderers, assembled his forces and their retainers, and marched to Edinburgh without meeting with any resistance. He there summoned Robert II., to do homage for his crown; but the Scots were determined neither to submit, nor give him battle; and, satisfied with their useless bravado, he measured back his steps to England. In the following year, the Earl of Douglas passed the borders with 12,000 men, and, after ravaging the country, was returning home with his booty, when he was overtaken by the Percies at Homeldon. A fierce battle ensued, in which the Scots were completely routed, and Douglas, and many of the Scottish nobility, fell into the hands of the victors. As soon as the king was informed of this success, he commanded the Earl of Northumberland not to ransom his prisoners, as he expected, by detaining them in his own power, to make a more advantageous peace with Scotland. This demand was considered by that nobleman not only as an entrenchment upon his right of disposing of his prisoners as he thought best, which was acknowledged by the laws of war in that age, but also as an insult to one, who had been the means of placing him upon the throne. His discontent had also been inflamed by the refusal of Henry, to allow him to treat for the ransom of the young Earl of Marche, to whom he was nearly allied, and who had been taken prisoner by Glendour. These injuries determined him to withdraw his allegiance from Henry, and support the claim of the Earl of Marche, the true heir to the English throne. For this purpose, he entered into an alliance with Glendour, and received assurances of assistance from Douglas, whom he restored to liberty. But just when he was ready to take the field, he was seized with a sudden illness at Berwick. His son Harry Percy, however, took the command of the troops, and marched to Shrewsbury to join the forces of Glendour. The king fortunately had an army in readiness, which he was about to lead against the Scots; but as soon as he received intelligence of the rebellion, he hastened to Shrewsbury before the rebels could form a junction. Percy, impatient to engage, did not wait for the Welsh; and the night before the battle, he sent a manifesto to Henry, wherein, after charging him with perjury, usurpation, and tyranny, he denounced his allegiance, and set the king at defiance. The two armies were nearly equal in numbers, being about 12,000 strong; and their commanders were both renowned for their military at-
chievements. The battle was consequently long and fiercely contested. Henry and his gallant son, then only about fifteen years of age, exposed themselves in the hottest of the fight; and Percy and Douglas outvivelled their former deeds, by their desperate valour in that bloody day. Douglas seemed determined that the king should that day fall by his arm. He sought him all over the field; but as Henry had accosted several of his cap- tains in the royal garb, the sword of the Scottish chief- tain devoured many pretended kings. The death of Percy, however, who fell by an unknown hand, decided the victory in favour of Henry; and Douglas, with many of the rebel leaders, were taken prisoners.

When Northumberland heard of the fate of his army, he disbanded some reinforcements, with which he was hastening to join his son; and came with a small retinue to make his submission to the king at York. He pre- tended that his sole intention in arming, was to mediate between the parties, which Henry thought proper to ac- cept as an apology, and granted him a pardon. The only persons that perished by the hands of the execu- tioner in this rebellion, were the Earl of Worcester and Sir Richard Vernon, who were considered as the chief au- thors of the insurrection. The clemency of Henry, how- ever, could not attach Northumberland to his interests. That nobleman soon after engaged to join another rebellion, headed by the Earl of Nottingham and the Archi- shop of York; but they betook themselves to arms with- out waiting for their more powerful auxiliary. The Earl of Westmoreland, with a small body of royalists, met them at Shipton, and desired a conference between the two armies, persuaded them, by a promise of pardon, and a redress of all their grievances, to disband their forces on the field, which he engaged also to do on his part; but he had secretly given contrary orders to his own men, and when the rebels were dismissed, he seized their leaders, and carried them to the king, who was advan- cing with an army to oppose them. Henry still confined his severity to the heads of the party, and the prelate and Earl were the only persons that suffered. The Earl of Northumberland and Lord Bardolf, upon being informed of this disaster, fled to Scotland; but afterwards returning with some forces, they were defeated at Bram- ham by Sir Thomas Rokesby, and both fell in the ac- tion.

Henry, being now freed from his domestic enemies, began to look abroad to find some employment for the restless and disorderly spirits of his people. The dissen- sions which then agitated the monarchy of France, first invited his attention. During the indisposition of Charles VII, who, though a prince of great spirit and genius, was subject to frequent fits of insanity, which totally incapac- itated him from regularly exercising his authority, the administration of affairs in that kingdom was disputed between the dukes of Orleans and Burgundy. Henry first entered into an alliance with the Duke of Burgundy, and sent him a small body of troops to defend him against his enemies; but he soon after received more ad- vantagous proposals from the Duke of Orleans, which he accepted, and dispatched a greater force to the sup- port of his party. The opposite factions, however, had been brought to a temporary accommodation, when the exertions of the king of England were rendered fruitless and vain; and the declining state of his health prevent- ed him from renewing the attempt.

Though Henry was yet in the flower of his age, his end was visibly approaching; and before his death he became subject to fits, which at times robbed him of his senses. As his constitution decayed, his fears of losing his crown increased; and such was his anxiety, that he always slept with the royal diadem beside him on his pillow. The Prince of Wales, happening one day to enter his fa- ther's chamber, found him in a deep sleep, and supposing him dead, carried off the crown. The king, when he awoke and missed his crown, asked the prince, with marks of great displeasure, if he meant to rob him of his dig- nity before his death? "No," replied his son, "sup- posing your Majesty dead, I took the crown as my law- ful inheritance; but since I see you recovered, I restore it with much more pleasure; and may God grant you many happy days to enjoy it in peace." The king was seized with his last fit while at his devotions before the shrine of Edward the Confessor in Westminster Abbey, and expired in the 46th year of his age, and 13th of his

His death, 20th March, 1413.

Had Henry IV. come to the throne by the right of inheri- tance, he would have been considered one of the great- est monarchs that ever held the sceptre of England. He possessed great military talents, and his political wisdom has seldom been surpassed. Though surrounded with enemies who were continually plotting against his government, yet such was his vigilance in detecting a conspira- cy, and his activity and prudence in suppressing it when it rose to rebellion, that his authority was strength- ened by every effort that was made for its over- throw. His usurpation was certainly in many respects beneficial to the English nation. During his reign, the administration of justice became less arbitrary and less venal; the limitations of the government were more care- fully maintained; the House of Commons assumed powers which it did not before possess, and rose in importance and independence. But while we are pleased with the exer- cise of his authority, we cannot but detest the unjustifiable means by which it was obtained. Rebellion against his sovereign; the deposition and murder of his lawful king; and the exclusion of the rightful heir, are crimes that can never be regarded but with abhorrence. It was these that drew upon him the hatred of his subjects, and from being one of the most popular noblemen in the kingdom, Henry became one of the most unpopular kings that ever sat upon the throne. The intelligence of his death was received without regret, and was im- mediately forgotten in the sincere rejoicings that were made at the accession of his son.

Henry V. came to the throne with the tide of popularity flowing full in his favour. His noviciate in arms, which he performed at the battle of Shrewsbury, gave indica- tions of a great and military genius; and these were strengthened by several advantages which he gained over the brave Glendour in Wales. But his father, who was infected with all the jealousies natural to an usurper, had entertained unreasonable suspicions of the fidelity of his gallant son; and during the latter years of his reign, had excluded him from the command of his armies, and even from all public business whatever. The active and enterprising genius of Henry, being thus restrained from his proper exercise, broke out in the extravagancies of riot and dissipation. Surrounded by a crew of low and profligate companions, he indulged in all their disorderly humours and amusements. When heated with wine, he sometimes encouraged and seconded his associates in attacking and robbing the passengers on the streets and
highways, and enjoyed himself by laughing at the fears and regrets of these delinquent people. In the midst of his excesses, however, the nobleness of his heart often appeared through the clouds which his follies threw over his character; and even when plunged in the extremes of dissoluteness, he displayed such traits of genuine humanity and magnanimity, as gave good reason to cherish the hope of a speedy reformation. An incident is related of him which tended much to encourage that hope, and which shows, that when brought to reflection, he was ashamed of his irregularities and errors. One of his riotous associates had been indicted before Sir William Gascoigne, the chief justice, for some misdemeanour; and Henry appeared with him at the bar, on the day of his trial, to give him countenance, and to overawe the judge. Finding, however, that the criminal was condemned notwithstanding his interference, he was so exasperated, that he proceeded to insult the chief justice upon the bench; but Gascoigne, mindful of the dignity of his office, ordered the prince to be committed to prison for his rude conduct. Henry, as if struck at once with a consciousness of his fault, quietly submitted to his punishment, and acknowledged his errors. When his father was informed of this circumstance, it is said that he exclaimed, in a transport of joy, "Happy is the king who has a magistrate endowed with courage to execute the laws upon such an offender; still more happy in having a son willing to submit to such a chastisement!"

The first actions of Henry's reign confirmed all the hopes that had been entertained in his favour. He assembled his former companions; acquainted them with his intended reformation; forbade them to appear in his presence until they had learned to imitate his example; and dismissed them with liberal presents. The wise ministers of his father were retained in their offices, and received his favour and confidence; even the chief justice, who trembled to approach the royal presence, was applauded for his impartial conduct, and encouraged to persevere in a just and strict execution of the laws. Henry next endeavoured to extinguish the remains of faction, by burying all party distinctions in oblivion, and by exalting to honourable employments in the state, the adherents of either party, who were distinguished by their virtue or abilities. He restored the family of Percy to their fortunes and honours, and treated his competitor, the Earl of Marche, with such singular courtesy and kindness, that this gentle and unambitious nobleman ever after remained sincerely attached to his person and government. Such prudence and magnanimity gained him the affections of all ranks; and the defects of his title to the throne were forgotten in the high esteem and regard in which his personal character was held.

But the mind of Henry, though endowed with the most shining qualities, and sublimest virtues, had not escaped the superstition of the age, and in the religious differences which then agitated the kingdom, he was led to support, with his countenance and authority, the established clergy in all their oppressions. The Lollards had become formidable to the church by their numbers and popularity, and at their head was Sir John Oldcastle, Lord Cobham, a man of valour and abilities, who had been distinguished with the favour both of Henry and his father. The zeal and high character of this nobleman pointed him out to the clergy as a fit object of persecution. His punishment would strike terror into his party, and convince them that the laws enacted during the last reign for their suppression, would be rigorously enforced. The Archbishop of Canterbury, accordingly, applied to Henry for permission to bring Lord Cobham to trial for his heretical opinions; but the generous nature of the king was averse to such violent measures; and he first endeavoured, by a private conversation with that nobleman, to bring him to renounce his errors. Cobham, however, was resolute in maintaining his opinions; and Henry finding him immoveable, gave him up to the fury of his enemies. He was then indicted by the primate, and condemned to suffer death by fire. But he made his escape from the Tower before the execution of his sentence; and provoked by persecution, and stimulated by religious zeal, he was induced to attempt the most criminal enterprises. He endeavoured to rouse his party in defence of their principles, and formed the design of seizing the king's person, and taking vengeance on his enemies. But the attempt was frustrated by the activity of Henry, and the conspirators dispersed. Some of them were taken and executed, but the greater number were paroloned. Cobham, who had made his escape, after undergoing a variety of distresses, was apprehended about four years after. He was first hanged as a traitor, and his body was then burned on the gibbet as a heretic. This insurrection served only to bring discredit upon the reformers, and checked for a time the progress of their party. More severe laws were enacted by parliament against their opinions, which were now regarded as treasonable and dangerous to the state; and all magistrates were obliged to take an oath that they would use their utmost endeavours for the extirpation of heresy.

The ambitious spirit of Henry was now invited to engage in enterprises more congenial to his wishes. The animosities of the rival families of Orleans and Burgundy had broken out afresh, and their hatred became more implacable than ever. The Duke of Burgundy, by an act of the basest treachery, had procured the assassination of his rival in the streets of Paris; and the princes of the blood, combining with young Orleans, rose to avenge the murder of their relative. The civil wars were thus renewed, and consumed the very vitals of the monarchy. The unhappy king, seized sometimes by one party, sometimes by another, transferred alternately to each the appearance of legal authority. Henry resolved to profit by these confusions, and to attempt the recovery of those dominions which had formerly been given up in successive treaties with France. He accordingly sent ambassadors to Paris, demanding Catharine, the French king's daughter, in marriage, with two millions of crowns as her portion; the restitution of Normandy, with all the other provinces that had been wrested from England, together with the superiority of Brittany and Flanders. This message threw the French court into the utmost consternation. They knew the abilities of their enemy, and were conscious of their own desperate condition. They therefore endeavoured to avert the danger by negotiation. They replied that they were willing to give him the princess in marriage, with eight hundred thousand crowns; to resign the full sovereignty of Guienne, and to annex to it the country of Perigord, Rovergne, Xaintonge, the Artois, and other territories. But Henry was deaf to their proposals; and as he could have no expectation of his own demands being complied with, he had been diligently preparing for war. He had assembled a large
Henry invades France. A.D. 1415.

Henry now turned his arms against the Dauphin, who was unable to keep the field. He made himself master of Sens and Montereau, and after an obstinate resistance, took Melun. But the want of supplies obliged him to go over to England. During his absence, the Dauphin had been reinforced by 7000 Scots, under the Earl of Buchan, and had obtained considerable successes in Anjou. At the battle of Baugé, the English, under the Duke of Clarence, the king's brother, were completely defeated; the Duke himself slain, and the Earls of Somerset, Dorset, and Huntingdon, taken prisoners. But the return of Henry with a numerous army, soon restored the fortune of his arms. The Dauphin was compelled to retire before him. The principal fortresses which were held by the adherents of that prince, fell into his hands; and he himself was driven beyond the Loire, and threatened with total destruction. In the midst of these successes, the Queen of England was delivered of a son, which occasioned great rejoicings, both at London and Paris. The infant prince was called by his father's name, and seemed to be universally regarded as the future heir of the two most powerful monarchies in Europe.

But Henry was cut off in the zenith of his glory by the stroke of death. He was seized with a fistula, a disease at that time not sufficiently understood, and sensible that his end was approaching, he proceeded to regulate the government of his kingdom and family. He left the regency of France to his elder brother, the Duke of Bedford; that of England to his younger brother, the Duke of Gloucester; and the care of his son's person to the Earl of Warwick. He advised them never to restore the prisoners taken at Agincourt till his son came of age; and to endeavour, by every means, to maintain the friendship of the Duke of Burgundy, by whose assistance alone they would be enabled to place young Henry upon the throne of France. He also treated them to continue towards his son that fidelity and attachment which he himself had so happily experienced during his lifetime. He then applied himself to his devotions, and expired at the castle of Vincennes in the 34th year of his age, and 10th of his reign.

A.D. 1419.

The general character of this prince, as well as his splendid achievements, endeared him to his subjects, and his memory is still held in reverence by his countrymen. He attached his friends, by his affability and engaging manners; and he overcame his enemies, by his address and clemency. His magnanimous conduct towards the Earl of Marche, who was the rightful heir to the throne, shows his superiority to the petty jealousies which generally influence princes in similar situations; and his character for candour and sincerity must have been firmly established, when his rival could rely so entirely on his
friendship. The exterior figure of Henry was also highly prepossessing. His countenance was beautiful; his limbs graceful and slender, but full of vigour; and his stature somewhat above the middle size.

Henry VI.

Upon the death of Henry, the English parliament proceeded to arrange the administration of the government during the minority of his son. They entirely departed from the will of Henry. They declined the title of regent with regard to England, and appointed the Duke of Bedford protector or guardian of that kingdom. They invested the Duke of Gloucester with the same dignity during his brother's absence, while conducting the war with France; and entrusted the person and education of the young king to his great uncle, the Bishop of Winchester.

The Duke of Bedford continued to prosecute the war in France with the same success which had distinguished the arms of Henry. He had strengthened himself by an alliance with the Duke of Brittany, and had also procured the neutrality of Scotland. But while employed in these negotiations, he at the same time pushed his conquests with such vigour, that the Dauphin, who, on the death of his father, had been crowned at Poictiers by the name of Charles VII, was reduced to the last extremity. The fatal battle of Verneuil had deprived him of the bravest of his nobles, and the flower of his army. He wandered a stranger in his own dominions, without any resources for recruiting or subsisting his troops; without even money sufficient for the decent subsistence of himself and a few followers. The towns which were held by his adherents, though bravely defended, were daily surrendering to the enemy for want of relief or supply; and he had the dismal prospect of being soon stripped of all his patrimonial dominions. But the dissensions of his enemies relieved him from his fears, and restored to him the territories which he had lost. The Duke of Brittany withdrew from the English alliance, and joined himself to Charles, which gave to his affairs a more favourable aspect; and the discomfiture of the English at the siege of Orleans, which was defended by the famous Joan of Arc, was the beginning of disasters, which gradually led to the destruction of the English interest in France. This was hastened by the defection of the Duke of Burgundy, and the death of the Duke of Bedford; and though they continued for several years after to carry on an unequal war, they daily lost ground, and in 1450 were finally expelled from all their conquests in France, except Calais and Guienne. See FRANCE.

While England was sacrificing her best blood and treasure in schemes of foreign aggrandizement, which, had they proved successful, would have degraded her into the rank of a dependent province, the government at home was distracted by intestine disputes. The Cardinal of Winchester, who was a man of abilities, but of an intriguing and aspiring character, had obtained an ascendency in the English council, and employed all his authority in counteracting the designs of his nephew the protector. The Duke of Gloucester, on the other hand, by his generosity and amiable manners, had acquired great and deserved popularity; but his open and hasty temper enabled his rival to gain many advantages over him, and at last to accomplish his destruction. Their sentiments were particularly opposed with regard to affairs in France. The Cardinal had always encouraged every proposal of accommodation, while the high-spirited Gloucester would not relinquish the high pretensions of his brothers, and still entertained hopes of prevailing over the enemy. But he was overruled in all his measures, and the war with France was left to languish through neglect and want of succours; and a truce for twenty-two months was soon after concluded by the influence of the Cardinal. This measure was followed by another still more hostile to the authority of Gloucester.

Henry had now come of age, but had given no indications of a capacity, or even of a desire, to hold the reins of government. It was, therefore, easy to foresee, that his reign would prove a perpetual minority; and the Cardinal taking advantage of the king's situation, resolved to raise up a more powerful opponent to the protector in the person of the queen. For this purpose, he had fixed upon Margaret of Anjou, daughter of Regnier, titular king of Sicily, Naples, and Jerusalem, and niece of the French monarch. She was a princess entirely without fortune, but was highly accomplished both in body and mind. She possessed great resolution and penetration, and was every way qualified to supply the defects and weaknesses of her intended husband. This match was opposed by the Duke of Gloucester, who proposed a daughter of the Count of Armagnac, but he had not sufficient influence to carry his point; and the Earl of Suffolk, after negotiating the truce with France, was empowered by the council to make proposals of marriage to the Sicilian princess. These were immediately accepted; and Suffolk, on his return, was raised to the rank of Duke, and received the thanks of parliament for his services.

The queen at once entered into all the measures of the cardinal and his party; and her first authority was employed in removing Gloucester from the council board. His enemies had taken every opportunity to thwart his opinions, and to wound his happiness. They first endeavoured to render him odious in the eyes of the public, whose favour he possessed in a high degree, by accusing his Duchess of witchcraft. It was pretended that she, in concert with Sir Roger Bolingbroke, a priest, and one Margery Jordan of Eye, a reputed witch, had made a waxen figure of the king, which they melted before a slow fire. As the wax dissolved, the king's strength was supposed to waste, and, upon its total dissolution, his life was to be at an end. This absurd accusation was listened to by the credulous king, and the duchess and her associates were brought to trial. Neither their innocence nor her rank could save them. They were pronounced guilty. The duchess was condemned to public penance, and perpetual imprisonment; Bolingbroke was hanged, and the woman was burnt. The public, however, were sensible that this violence arose entirely from the malice of the Duke's enemies, and, instead of taking part against the perpetrators of these imaginary crimes, as was their usual practice, they pitied the unhappy sufferers, and increased their esteem and affection towards the generous and persecuted Gloucester. The death of this prince was almost a necessary consequence to these proceedings. His enemies knew well, that he could never forgive such cruel injuries, and they had reason to dread the effects of his resentment. They therefore resolved to free themselves from their danger, by his destruction. A parliament was summoned to meet at St Edmondsbury, which was at some distance from the scene of his popularity, where he was accused of treason, and thrown into prison. But on the day appointed for his trial, he was found dead in his bed. Though his enemies en-
ENGLAND.

Stafford was sent with a small force, to quell the insurrection; but he was defeated and slain, in an action with the rebels near Sevenoak; and Cade, advancing with 20,000 followers, encamped on Blackheath. He sent to the court a list of grievances, and demanded the punishment of Lord Say the treasurer, and Cromer, sheriff of Kent, for their malversations. The king retired to Kestworth, and the capital immediately opened its gates to the rebels. Cade at first maintained great order and discipline among his followers, whom he always led out into the fields during the night. But he was obliged to gratify them by the death of Say and Cromer, when they became so unruly, that his orders were unheeded. They broke into the house of a rich citizen, which they plundered; and this act of violence so alarmed the inhabitants, that they shut their gates against them. Cade endeavored to force his way, but was defeated with great slaughter; and the Archbishop of Canterbury, who was then chancellor, having proclaimed a general pardon to the rebels, they retreated to Rochester, and dispersed. Cade was afterwards taken and killed, and many of his followers were executed.

The suppression of this rebellion did not bring quietness and security to the government. The clamours of the people continued as violent as ever; and were supported and encouraged by the appearance of a pretender to the throne. Richard Duke of York was the nearest heir to the house of Mortimer. His mother Anne, Countess of Cambridge, was sister to the last Earl of Marche, who died without issue, and thus he stood plainly in the order of succession to the throne, before the family of Lancaster. Richard had displayed great valour and abilities in his government of France, from which station he had been recalled by the intrigues of the Duke of Somerset. He was then sent to suppress a rebellion in Ireland, and here he was equally distinguished by his conduct and prudence, and had even been able to attach to his person and family that independent people, whom he was sent to subdue. The talents of this nobleman thus made him formidable; but he was rendered still more so by his powerful connections. He possessed immense baronial estates, and was connected by blood or alliance with the most potent and opulent noblemen in England. But with all his abilities and power, he was of a mild and moderate disposition; and his claim to the crown, which had lain so long dormant, would not have been revived by him, had he not been encouraged to do so by the weakness and unpopularity of the present government. He was also in a manner compelled to it, by a regard to his own security. He had become an object of jealousy to the reigning interest, from his pretensions and his power; and he found it necessary to assert his right, in order to maintain his safety. He was even suspected of being concerned in the late discontents and insurrections, and of having secretly instigated Cade to rebellion, that he might ascertain the dispositions of the people towards his title and family. When the government heard that he intended to return from Ireland, they were afraid that he meant to bring a military force along with him, and issued orders to oppose his entrance into England. But he refused the summons of his enemies, by coming only with his ordinary attendants. He could not but see, however, the danger to which he was exposed as a suspected subject, and he therefore endeavored by every mean to strengthen his interest, and to be prepared against every emergency. His partisans were in-

History. 655

Popular discontent.

The murder of Gloucester covered the king and queen with universal odium; and the Duke of Suffolk, who was now raised to the office of prime minister, and was deeply concerned in that crime, partook also of the general hatred attending it. The popular discontent was farther increased by their arbitrary measures. They managed all things with unlimited authority; they disgusted the nobility by their overbearing pride, and the people by their oppressions. The murmurings of the people had become so loud and unequivocal, that Suffolk, sensible that he had become an object of public hatred, endeavored to allay the storm that was gathering around him, by boldly resisting its fury. He rose in his place in the House of Peers, took notice of the public discontent, and complained, that, after his long services both at home and abroad in maintaining the honour of his native country, for which he had been rewarded by his sovereign with the highest honours and distinctions, he should be exposed to its ingratitude and resentment. But this challenge, instead of silencing his enemies, served rather to provoke them; and the commons immediately sent up to the House of Peers an accusation of high treason against him, divided into several articles. These articles, however, were adopted without inquiry, and were founded entirely upon the popular clamours. They consisted chiefly in charging him with having designs upon the crown; and with being the cause of the English losses in France. Such a charge was easily refuted; and the commons themselves soon became sensible of its futility, and sent up a new charge of misdemeanors. They accused him of procuring exorbitant grants from the crown, of embezzling the public money, and of perverting public justice.—charges much more probable, and not so easily eluded. The king, alarmed at the prosecution of a favourite minister, summoned all the peers into his presence, and called upon Suffolk for his defence. That nobleman denied the charge, but submitted to the king's mercy. Henry, in order to allay the public discontent, banished him the kingdom for five years. This irregular proceeding, it was easily seen, was intended to screen the favourite; and, as he still possessed the queen's confidence, it was supposed that he would soon be restored to his former credit and power. But his enemies were determined that he never should return. He was intercepted in his passage to France, his head was struck off on the side of the long boat, and his body cast into the sea.

The Duke of Somerset succeeded to the power of Suffolk, and also to his unpopularity. It was under Somerset's government that the French provinces were lost; and the people, who judge only by the event, repaid him with their animosity and hatred. These passions soon broke out in open insurrections; and one Jack Cade, a low-born Irishman, who had been formerly obliged to fly into France for his crimes, excited a disturbance in Kent, which threatened the most dangerous consequences. He assumed the name of John Mortimer, pretending to be a descendant of that popular family, which drew to his standard a crowd of adherents. Sir Humphrey
structed to discuss his claim in all companies, and to maintain his right by succession, and by the established laws and constitution of the kingdom. The question being thus brought before the public, every one embraced one side or the other, according to his convictions, his feelings, or his interest; and the minds of men were thus insensibly led to cherish all those antipathies and prejudices, which afterwards burst forth with such a dreadful explosion, and which continued to fill the kingdom with slaughter and desolation.

The pretensions of both parties may be shortly stated. The family of Lancaster derived their descent from John of Gaunt, Duke of Lancaster, the third son of Edward III.; while the Duke of York was descended by the female line from Lionel, Duke of Clarence, second son of that monarch. The adherents of the former, while they allowed the advancement of Henry IV. to be irregular, maintained that it was founded upon general consent. It received the sanction of a free people, who were driven from their allegiance by the tyranny of their rulers, and gratefully bestowed the sceptre upon their deliverer; that, though the deposition of Richard II. was perhaps rash and imprudent, yet it was justified by the state of the nation, and it was now too late to remedy the evil; that the crown was entitled upon the family of Henry by reiterated acts of parliament, and were these acts to be now invalidated, the English must be considered not as a free people, who could dispose of their own government, but a nation of slaves, who were implicitly transmitted from one master to another; that the order of succession was established only for the general good, and could never be pleaded for the overthrow of public tranquility; that the nation was bound to the house of Lancaster by their oaths of fealty and allegiance, and were these oaths to be wantonly infringed, it would throw them loose from all principles, and expose them to continued revolutions.

It was replied in favour of the house of York, that it was never too late to correct any pernicious precedent; for, if it were allowed that present possession of power, and continuance in it for a few years, were sufficient to convert usurpers into legal princes, it would throw the throne open to every turbulent innovator; that the deposition of Richard II. and the advancement of Henry IV. were not deliberate acts of the legislature, but proceeded from the levity of the people, or were procured by violence and usurpation; that the maintenance of order in the succession, served to prevent those numberless confusions which must ensue, if no rule were followed but present advantage and convenience; that the restoration of the true order of succession could not be considered as a change which familiarised the people to revolutions, but only the correction of a former abuse, which had itself encouraged the giddy spirit of innovation, rebellion, and disobedience; that as the original title of Lancaster was founded entirely on present convenience, even that principle, unjustifiable as it was, had now gone over to the house of York. A weak king governed by corrupt ministers, or an imperious queen engaged in foreign connections, could never stand in comparison with a prince of approved wisdom and experience, and the lineal heir of the crown, who, by his restoration, would remedy those abuses, of which the nation so justly complained.

These arguments were keenly contested on both sides, and the people were completely divided in their sentiments and affections. Each party was distinguished by a particular symbol. The ensign of the house of Lancaster was a red rose; that of York a white one; and the civil wars which soon after followed, were known throughout Europe under the name of the quarrel between the two roses. This fatal quarrel, which lasted nearly thirty years, was signalized by twelve pitched battles; and eighty princes of the blood are computed to have fallen on the field or on the scaffold.

In a parliament assembled soon after the return of the Duke of York from Ireland, his adherents, encouraged by the general discontent against the administration, obtained a petition from the lower House, which prayed the king to dismiss the Duke of Somerset, the Bishop of Chester, and several others, from his presence and counsels. This request the king hesitated to grant. But it was soon after seconded by the appearance of the Duke himself, who had come to London at the head of 10,000 men, and demanded a reformation in the government, and the removal of the Duke of Somerset from all power and authority. The gates of the city, however, were shut against him; and on his retreating into Kent, he was followed by the king with a superior army. A conference ensued, in which Richard insisted on Somerset's being dismissed, and submitting to trial in parliament. This demand was seemingly complied with, and Somerset was put under arrest; but when Richard came to pay his respects to the king in his tent, and to repeat his accusation against the minister, he was surprised to see that nobleman step from behind the curtain, and offer to maintain his innocence. Richard now found himself in the hands of his enemies; but they judged it prudent to refrain from offering violence to one who was so popular and powerful, and dismissed him upon a promise of obedience. He then retired to his seat of Wigmore, on the borders of Wales.

But new discontenteds drew Richard from his retreat. An attempt was made to recover the province of Gascony from the French, which completely failed. The blame was laid upon the ministry; and Henry having at the same time fallen into a distemper, which rendered him incapable of exercising the royal power, the queen found herself unable to resist the opposite party; and the Duke of York was invited to take upon him the administration of the government. The Duke of Somerset was sent to the Tower, and Richard was appointed lieutenant of the kingdom. The parliament soon after created him protector during pleasure, and the way to the throne thus lay open before him. But Richard had not yet advanced any pretensions to the crown; and was even now irresolute about receiving the power that was offered to him. He desired that it might be recorded in parliament, that this high office was conferred on him without any application on his part; and that all his powers should be specified and defined. This excessive and amiable moderation, however, served only to encourage his enemies; and as soon as Henry had recovered so far as to have the appearance of directing the government, he was dismissed from the protectorship, and Somerset was again raised to the head of affairs.

Richard was sensible of the dangers which threatened him, and had recourse to arms. He still complained, however, only of the king's ministers; but his complaints were answered by the appearance of an army, commanded by Somerset and the king in person. In the battle of St Albans, Somerset was slain with 5000 of his party. Henry was wounded and taken prisoner, but was treated by his enemies with great respect and ten-
...and the attempt victed his described and his The His He was carried back in triumph to London, where the parliament restored the protectorship to Richard but limited its continuance to the period of the Prince of Wales' majority, who was now about three years of age. The queen, whose ambition, supported by her native vigour and perseverance, impelled her to attempt the recovery of her authority, prevailed upon her husband to re-assert his prerogative. She took advantage of the Duke of York's absence from court, and carried Henry to the House of Lords, to whom he signified his intention of resuming the government. This step was so unexpected, that no opposition was made to it; and it was accordingly declared that Richard was not a prince, but that the king was reinstated in the sovereign authority. The Duke even acquiesced in this irregular measure; but soon after, having reason to suspect that designs were formed against his life, he withdrew to his castle of Wingham. Hostilities were again about to be renewed; when the mediation of the Archbishop of Canterbury prevented for a time the eruption of blood. He proposed that the great leaders of both factions should meet in London, and be solemnly reconciled. An outward reconciliation was accordingly effected; and in a solemn procession to St Paul's, the Duke of York led Queen Margaret, and the chiefs of the opposite parties marched hand in hand with each other. But this seeming harmony was but of short continuance; a scuffle which happened between the retainers of the Earl of Warwick, and those of the king, revived their animosity and hatred. The Earl apprehending his life to be aimed at, fled to his government at Calais, and the Yorkists immediately prepared for hostilities. The royalists, under Lord Audley, in a through superior number, were defeated at Bloreheath by the Earl of Salisbury, who was hastening to join the Duke of York at Ludlow. But when a general engagement drew near, a body of veterans, which Warwick had brought over from Calais, deserted to the king, which so dismayed the rebel that they separated without coming to action. The Duke fled to Ireland, and the Earl of Warwick, with some of the chiefs of his party, retired to Calais. This nobleman was the most celebrated general of his age, and had rendered himself extremely popular among the military, by his bravery and munificence. Numerous partisans flocked to his standard, and he soon found himself in a condition again to take the field. He landed in Kent with the Earl of Salisbury, and Edward eldest son of the Duke of York, and was received in London amidst the acclamations of the populace. The royal army hastened from Coventry to give him battle. They met at Northampton, and the action continued for five hours. Both sides fought with the utmost obstinacy, but the desertion of Lord Grey of Ruthin, who commanded the van of the royalists, turned the battle in favour of Warwick, who gained a complete victory. The slaughter fell chiefly on the nobility and gentry; and the Duke of Buckingham, the Earl of Shrewsbury, with the Lords Beaumont and Egremont, were killed in the action or pursuit. Henry was again taken prisoner; but Margaret and her infant son escaped into Scotland. This victory was followed by the arrival of the Duke of York from Ireland, and a parliament was assembled at Westminster to decide upon his claim to the crown. Richard was now at the head of a victorious army, and could have stepped into the throne without resistance; but his moderation and irresolute temper made him averse even to the least appearance of violence. He now, for the first time, openly advanced his claim to the crown, and pleaded his cause before the House of Peers. He stated his title by descent; detailed the cruelties by which the house of Lancaster had paved their way to power; described the calamities which attended the present reign, and called upon them to do justice to the lineal succession. His claim was taken into consideration, and was solemnly debated for several successive days. It was at last decided that his title was certain and indefeasible; but it was also determined that Henry should enjoy the crown during life; that Richard should have the present administration of the government, and should be acknowledged the true and lawful heir to the monarchy, to the utter exclusion of the young son of Wales.

Margaret did not continue long in her retreat. Her spirit rose superior to her misfortunes. She possessed inexhaustible resources in the energies of her own mind. She animated her old friends by her courage and perseverance, and new ones were attracted by compassion for her helpless situation. No time was to be lost, and however unfavourable the present aspect of her interests, she determined again to assert the rights of her family. By her insinuating address, by caresses and promises, she so gained upon the northern barons, that they all armed in support of her cause; and she found herself at the head of an army 20,000 strong, before her enemies were informed of her intentions. The Duke of York hearing of her return, but unacquainted with her force, hastened with 5000 troops to suppress her adherents. But when he came to Wakefield, he was surprised to find himself completely outnumbered. Disregarding, however, the dictates of prudence and experience, he listened only to the suggestions of pride, and the mere chances of political success, was eminent for his personal bravery. He deemed it unworthy of his character and reputation to retire before a woman, and he boldly offered battle to the enemy. His little army was surrounded and cut to pieces: the body of Richard was found among the slain. His head was cut off by order of Margaret, and fixed upon the gates of York with a paper crown upon it, in derision of his title. His second son, the Earl of Rutland, and the Earl of Salisbury, were taken prisoners. Salisbury was immediately beheaded by martial law; the other, a youth only of seventeen, was barbarously murdered in cold blood by the Earl of Clifford, in revenge of his father's death, who fell in the battle of St Albans.

Margaret improved her victory by hastening to London, but weakened her army by sending a detachment under the Earl of Pembroke, against Edward, the new Duke of York. Pembroke was defeated at Mortimer's cross, with the loss of 4000 men. His father, Sir Owen Tudor, was taken prisoner, and immediately beheaded by Edward's orders; and this spirit of revenge, when once begun, continued to actuate both parties during this long protracted contest. On the approach of Margaret, Warwick, who had been left with the command of the Yorkists in London, led out his army, and gave battle to the enemy at St Albans. The Queen was again victorious. Warwick was compelled to fly and take shelter in the capital, which was firmly attached to his party, and the king was left in the hands of the victors. But Margaret was scarcely conscious of her triumphs, when she was threatened by the advance of Edward on the opposite side, with a superior army, and found herself under the necessity of retiring to the north. The young Duke then entered London amidst the shouts of the citizens. The beauty of his person, his youth, his...
bravery, and his amability, had secured their affections; but they were as yet unacquainted with his nature, which was cruel and unrelenting. He was more decided and resolute than his father, but he had none of his mildness and moderation. Aware how prejudicial these estimable qualities were to his father's cause, he resolved to throw aside all reserve; to insist openly on his right to the throne; and to assume at once the title and dignity of a king. He assembled the people in St. John's Fields; and after Warwick had harangued them on the title of Edward, and the tyranny of the rival family, they were asked, whether they would have Henry of Lancaster, or Edward, Duke of York, for their king? The multitude unanimously shouted, "a York!" Upon this, an assembly of bishops, lords, and other persons of distinction, was immediately called at Baynard Castle, which ratified the popular election, and the Duke was next day proclaimed in London by the name of Edward IV.

The new monarch was every way fitted, both by his talents and his dispositions, for the dangerous situation which he had to maintain. Bold and enterprising, vindictive and cruel, he was unawed by danger, and incapable of pity. He seemed to exult in scenes of slaughter and devastation; and, during his reign, the scaffold, as well as the field, incessantly streamed with the blood of England. The first act of his government gave symptoms of his savage disposition. A harmless tradesman, who kept a shop at the sign of the crown, had said, in a punning humour, that he would make his son heir to the crown, which gave such offence to the king, that the poor man paid for his wit with the loss of his head. But Edward was soon called to gratify his savage nature with nobler deeds of cruelty. Margaret, in a few weeks, had collected an army of 60,000 men among her partizans in the north, and was returning to the capital to strike her strongest blow. But she was met at Tounton by 40,000 Yorkists, under Edward and Warwick. Previous to the engagement, a body of Yorkists under Lord Fitzwalter, had been dispatched to secure the passage of the river Arre at Ferrybridge, but they were driven from their post with great slaughter by Lord Clifford, and their leader slain. The disaster at Ferrybridge was revenged by the defeat and death of Clifford by Lord Falconberg, who recovered that important post. This was immediately followed by a general battle, on the issue of which depended the fate of the contending factions. As the Queen's army advanced to the charge, they were blinded by a shower of snow, which blew full in their face; and Lord Falconberg, taking advantage of this circumstance, led out some infantry before the line, and, after discharging a volley of arrows, immediately retired. The Lancastrians imagining that they had come within reach of the opposite army, let fly all their arrows, which fell short of the enemy. Edward then advanced with his main body, and dealt such havoc among the dismayed Lancastrians, that they were totally defeated. As this prince had issued orders to give no quarter, the routed army was pursued with terrible slaughter, and 36,000 men, among which were some of the principal nobility, are computed to have fallen in the battle and pursuit. Margaret, with her son and husband, fled immediately to Scotland, and Edward proceeded to York. He took down, from the gates of that city, the heads of his father and the Earl of Salisbury, which he buried with their bodies, and put in their place the heads of the conquered generals.

On the return of the king to London, a parliament was assembled, which now, overawed by his success, no longer hesitated between the rival families, but immediately recognised his title, and confirmed his authority. They were also ready in their servility to second his revenge against his enemies; and they passed an act of forfeiture and attainder against Henry VII, his queen, and infant son. This act was extended to the principal nobility and gentry, that adhered to their cause, and their estates were vested in the crown. But though the victorious Edward had endeavouring to secure his elevation by the show of legal authority, and by the extirpation of his adversaries; there were many in the kingdom still warmly attached to the House of Lancaster. The Earl of Oxford and his son were detected in a correspondence with Margaret, were tried by martial law, and immediately executed. Sir William Tyrrel and some others suffered in the same arbitrary manner, and for the same crime. The rigours of the government, however, instead of reconciling the discontented to its authority, only increased their animosity, and the people soon discovered that they had exchanged a weak ruler for a tyrannical one.

The battle of Tounton had not extinguished the hopes of Margaret of Scotland. She had engaged the assistance of France and Scotland, by promising to the one the surrender of Calais, and to the other the delivery of the important fortress of Berwick, should her family be again restored to the throne of England. Thus supported, she resolved to make another effort against her enemies, and having received from Louis XII 3000 men as arms, was being farther reinforced by many of her own partizans, and a numerous train of Scottish adventurers, she made an inroad into England. Her ill-fortune, however, still attended her. Her forces received a check at Hedgeley moor, which was soon after followed by a complete defeat, near Hexham, by the Yorkists, under Lord Montague, brother to the Earl of Warwick, and warden of the East Marches. The Duke of Somerset, and the Lords Roos and Hungerford, were taken in the pursuit, and immediately executed. The unfortunate queen, flying with her son from the rage of her enemies, was bennighted in Hexham forest, and fell into the hands of robbers, who regardless, perhaps ignorant, of her quality, stripped her of her rings and jewels, and treated her with great indignity. She, however, found means to escape, while they were quarrelling about the spoil, and retired into the thickest of the wood. Overcome with terror and fatigue, she sunk down in despair, but was suddenly roused by the appearance of a robber, with his sword drawn. Seeing no way of escape, she resolved to trust to his mercy, and boldly advancing, she presented to him the young prince, "Here, my friend," said she, "I commit to your care the safety of your king's son." The man, surprised by the singularity of this adventure, and pleased with the confidence reposed in him, offered her his protection, and gave her every assistance in his power. By his means, she remained concealed for some time in the forest, and then made her escape beyond seas, to her father's court, where she lived for several years in privacy and retirement. Her husband was not so fortunate; for after lying concealed for about a year among his friends in Lancashire, he was discovered, and committed a prisoner to the Tower.

Edward being now firmly fixed upon the throne, and freed from all fears of danger from his enemies, gave loose reins to his libertine disposition, and indulged in all the dissipations and amusements of a luxurious court. His debaucheries and amours became so open and unrestrained, that Warwick, apprehensive that they might spread disaffection among his subjects, advised him to marry; and Edward, in order to give greater security to
his throne, had fixed upon Bona of Savoy, sister to the queen of France. By this alliance, he hoped to ensure the friendship of that power, which alone was able and inclined to give support and assistance to his rival, and he dispatched Warwick to demand Bona in marriage. The proposals were accepted, and the princess was ready to set out for England. But while Warwick was engaged in this negotiation, Edward had found a queen for himself.

Lady Elizabeth Gray, the widow of Sir John Gray of Groby, was remarkable for the grace and beauty of her person, as well as for other amiable accomplishments. Her husband, who was a Lancastrian, was slain in the second battle of St Albans, upon which his estate was confiscated, when his widow went to live with her father Sir Richard Woodville of Grafton. It was here the amorous monarch first beheld Lady Elizabeth, and after having vainly endeavoured to debauch her, he resolved to make her his queen. They were privately married at her father's seat; and when this was communicated to Warwick, that nobleman, deeming himself affronted, returned to England, filled with rage and discontent. Instead of endeavouring to pacify this powerful chief, to whom he owed his throne, Edward heightened his resentment by neglect, and the Earl retired in disgust from a court where his important services seemed to be entirely forgotten. The breach was farther widened by the partiality of kings to the family of Woodville. The queen's father was created Earl of Rivers, and invested with the office of constable for life, and three of her sisters were married to the Duke of Buckingham, and the Earls of Kent and Huntington. The haughty Warwick could not brook to see an upstart family so far surpass him in authority and influence with the king; and in this he was joined by the Duke of Clarence, Edward's brother, and many of the ancient nobility. The Earl's adherents were daily increased by his gracious and popular manners, and a dangerous combination was thus formed against Edward and his ministers.

The king saw the cloud as it was gathering; and in order to secure himself against its effects, entered into an alliance with Charles the Bold, Duke of Burgundy, to whom he gave his sister Margaret in marriage. He, at the same time, concluded a league with the Duke of Burgundy, by which these connections, not only strengthened his power at home, but also enhanced his prospect of foreign conquests. But intestine commotions prevented him from giving disturbance to his neighbours, and confined his attention to more immediate objects. The popular discontent first broke out in Yorkshire, where the inhabitants, complaining of the oppressions which were exercised upon them, in collecting the revenue of St Leonard's hospital, rose in arms, and advanced to the gates of York, in a body of 15,000 strong. They were opposed by Lord Montague, who, having seized Robert Hudlerne his leader, ordered him to be immediately executed. But being afterwards headed by Sir Henry Nevil, and Sir John Coniers, they advanced southward, and their numbers daily increased. The Earl of Pembroke was sent against them with a body of Welsmen, and being joined by the Earl of Devonshire, with 5000 archers, they approached the rebels near Banbury. Sir Henry Nevil was taken prisoner in a skirmish, and put to death; which so enraged his followers, that they fell upon the royalists, routed them with great slaughter, and having seized Pembroke, revenged upon him the death of their leader. This disaster was imputed to the Earl of Devonshire, who, in a quarrel with Pembroke, had retired with his archers before the battle; and the king punished his desertion with death. A part of the rebels then seized the Earl of Rivers, and his son John, at Grafton; and as these noblemen had become objects of envy and dislike, by their sudden exaltation, they were put to death by the orders of Sir John Coniers. The rebels, however, were soon after quieted and dispersed, upon receiving a general pardon.

It does not appear that Warwick or his party were concerned in this insurrection. At the commencement of it he was absent in his government at Calais, and his brother Montague had assisted in repressing it. In another rebellion, however, which soon followed, he took a more active part; and though, perhaps, its origin cannot be justly imputed to him, yet he afterwards encouraged it by his countenance and assistance. It arose in Lincolnshire, and was headed by Sir Robert Welles. The rebels amounted to 30,000 men, and Edward, who entertained no suspicions of the fidelity of Warwick and Clarence, sent these noblemen to raise forces to oppose them; but as soon as they left the court, they levied men in their own name, and issued complaints against the government. In the mean time, however, the king had defeated the rebels, and put their leader to death, which so disconcerted Warwick's measures, that he retired northward, expecting to be joined by his brother Montague, and Lord Stanley, who had married his sister. But these noblemen refused their assistance, and Warwick and Clarence were obliged to disband their troops, and embark for Calais. But the deputy governor, whom the Earl had left in that fortress, seeing him return a fugitive and exile, refused him admittance, upon which he seized some Flemish vessels which were lying off Calais, and proceeded to France.

Louis, whose ambition led him to take every opportunity of giving disturbance to his neighbours, received the banished Warwick with every demonstration of respect, and by his intrigues and promises, brought about a reconciliation between that Earl and his former enemy Margaret of Anjou. The rancorous hatred which had long subsisted between the parties, was overcome by the present distresses of both. Forgetting their former animosity, they now united from common interest; and Louis prepared a fleet to assist them in the possession of England.

But the Duke of Burgundy, enraged at the seizure of his vessels before Calais, had fitted out a superior fleet, in order to intercept Warwick, and had sent information to the king of England of the designs of his enemies. Edward disregarding this intelligence, made no preparation against the threatened danger. He even vauntingly said to Burgundy, that he might spare himself the trouble of watching the enemy, as he wished for nothing more than to see Warwick in England. Edward, in the mean time, had entered into a secret correspondence with his brother Clarence, who promised, on a favourable opportunity, to abandon the cause of Warwick. This act of treachery, however, was balanced on the other side, by the Marquis of Montague, who was in the confidence of Edward, and who engaged, in a similar manner, to turn his arms against his sovereign.

While Edward was engaged in suppressing a rebellion in the north, Warwick, having escaped the Flemish navy, which had been dispersed in a storm, landed at Dartmouth with a small body of troops. His great popularity, however, and the zeal of the Lancastrian party, which had been crushed but not extinguished, drew...
such numbers to his standard, that, in a few days, his army was swelled to 60,000 men. Edward hastened southward to oppose him, and the hostile armies met near Nottingham. The rapidity of Warwick’s march had prevented Clarence from executing his intentions in favour of Edward, and Montague was the first to betray his trust. Having secured his adherents, Montague took arms in the night, and hastened to the king’s quarters.

Edward, alarmed at the Lancastrian cry of war, started from his bed, and being informed of his danger by Lord Hastings, who urged him to make his escape, he fled with a small retinue to Lyne, in Norfolk, where he embarked, and landed in Holland. Such was the precipitation with which he left England, that he had carried nothing of value along with him, and could only reward the captain of the vessel with a robe lined with sables.

The flight of Edward left the kingdom entirely at Warwick’s disposal. That nobleman hastened to London; and summoning a parliament at Westminster, the unfortunate Henry was released from prison, and restored to his throne. Being declared, however, incapable of governing, Warwick and Clarence were entrusted with the regency during the minority of young Edward; and, in failure of that prince’s issue, Clarence was appointed successor to the crown. Many of the Yorkists fled beyond seas, others concealed themselves in London, and the Earl of Worcester was the only nobleman that suffered upon the restoration. But the triumph of the Lancastrians was of short duration, and they were soon compelled in their turn to seek for refuge and protection from the fury of Edward.

The Duke of Burgundy had endeavoured to conciliate the friendship of the reigning party, by refusing all succours to his brother-in-law; but, finding that Warwick had engaged in an alliance with the King of France, and had even sent over 4000 troops to Calais to make inroads into his territories, he resolved to assist Edward in recovering the crown of England. He secretly equipped a small squadron in the ports of Zeeland, in which, with 2000 men, Edward, after an absence of nine months, proceeded to England to try his fortune in the field of war. He landed at Ravenspur in Yorkshire; but, being coldly received, he pretended that he came not to disturb the peace of the kingdom, but merely to claim the inheritance of the house of York. When the adherents of his party flocked to him from all quarters, Warwick having assembled an army at Leicester, hastened to give him battle; but Edward, taking another road, passed him unmolested, and presented himself before the gates of London. Here he was admitted without hesitation, and was even joined by the Archbishop of York, Warwick’s brother. The feeble Warwick was again taken from his throne, and carried back to his old prison in the Tower. Finding himself now in a condition to face the enemy, Edward met Warwick at Barnet, in the neighbourhood of the capital. Warwick had been reinforced by his son-in-law the Duke of Clarence, and his brother the Marquis of Montague; but the former deserted to his brother Edward during the night with 12,000 men. This, however, did not discourage the brave Warwick. He had advanced too far to retreat; and, dismissing all the terms offered him by the enemy, he resolved to stake his fortune upon the issue of a battle. The engagement began early in the morning. The two most renowned generals of the age headed the contending armies, and their example inspired their followers with more than ordinary valour. Victory or death seemed to be the only alternative that was left them; and the battle continued long unabated and doubtful. But owing to a slight mist, the army of Warwick having mistaken a party of their friends for the enemy, fell upon them with such fury, that they drove them off the field. This error turned the fortune of the day; and Warwick having in vain attempted to retrieve the mistake, at last resolved to sell his life as dear as possible, and rushing into the thickest of the enemy, fell covered with wounds. His brother Montague perished with him; and as orders had been given by Edward to give no quarter, the slaughter was dreadful.

On this fatal day, Queen Margaret and the Prince of Wales landed with a small body of French forces; but, instead of meeting with the congratulations which she expected, she was confounded by the intelligence of the death of Warwick, and the captivity of her husband. Her magnanimity, which had formerly supported her under so many trials and disasters, now failed her; and foreseeing the dismal consequences of so fatal a reverse, she took sanctuary in the abbey of Beaumieu. Here, however, her spirits were revived, by the appearance of the Earl of Pembroke, the Duke of Somerset, and other powerful barons, who exhorted her still to hope for success, and offered her their lives and fortunes to support the cause of her family. Yielding to their encouragements, and flattered with the prospect of regaining her authority, she advanced into the heart of the kingdom, while Pembroke went to levy forces in Wales. Her army daily increased as she proceeded; but the determined Edward overtook her at Tewksbury. The Duke of Somerset, a man of valour and abilities, but rash and impetuous, commanded the Lancastrians. He repulsed the first attack of Edward with such vigour, that the Yorkists retired with precipitation; and following up his success, he ordered Lord Wenlock to support him in the charge. But Wenlock disobeyed his commands; and Somerset was overpowered by numbers. Enraged at his loss, and transported with fury at beholding Wenlock still inactive, he ran up to the coward, and with one stroke of his battle-axe dashed out his brains.

About 5000 were slain on the side of the Lancastrians, and Margaret and the Prince of Wales fell into the hands of the victors. Somerset, and about twenty persons of distinction, having taken refuge in a church, were dragged thence, and immediately beheaded. Pembroke, when he heard of the defeat of his friends at Tewksbury, disbanded the troops which he had collected, and fled into Brittany with his nephew, the young Earl of Richmond. When Margaret and her son were brought to Edward, that monarch insultingly demanded of the young prince, how he dared to invade his dominions. That noble youth, then about eighteen years of age, appeared undaunted by the presence of his victorious enemy; but, unmindful of his situation, he boldly replied: “I have entered the dominions of my father, to revenge his injuries, and to redress my own.” Thebarbarous Edward, enraged at his intrepid spirit, struck him on the face with his gauntlet; and his brothers, the Dukes of Clarence and Gloucester, with Lord Hastings and Sir Thomas Gray, taking this as a signal for his death, hurried him into the next apartment, and dispatched him with their daggers. This tragedy was followed by the death of King Henry, who died a few days after in confinement; but it was generally believed, that he was murdered in cold blood by the hand of Gloucester. Margaret was thrown in-

to the Tower; but was ransomed for 50,000 crowns by Louis XI. and died some years after in France, forgotten and neglected.

The principal leaders of the Lancastrian party having perished in the field or on the scaffold, Edward continued to glut his vengeance, by the execution of their meaner adherents; and the gibbet soon finished what the sword had begun. But this relentless monarch, even while his hands were bathed in blood, was immersed in voluptuous pleasures and amusements. He was universally allowed to be the most beautiful man of his time; and his debaucheries, which were open and numerous, were encouraged and imitated by a profligate court. All ranks seemed willing to forget the dismal scenes that were past in the less dangerous exploits of gallantry and intrigue. But the king was roused from his inactivity, by the call of the Duke of Burgundy to unite their arms against France.

A French war was always a popular measure with the English parliament; and they readily granted him a considerable supply, which he increased by levying a benevolence. He then passed over to Calais with 1500 men at arms, and 15,000 archers, attended by his principal nobility. But, instead of being joined by the forces of Burgundy, as he had expected, the Duke was spending his strength on the frontiers of Germany, and against the Duke of Lorraine. This disappointment led Edward to listen to the advances of the French monarch, who, alarmed at the prospect of such a formidable invasion, attempted to avert the danger by negotiation, and to detach him from the alliance of Burgundy. When the King of England dispatched a herald to Louis, to claim the crown of France, and to carry him a defiance in case of refusal, Louis, instead of being irritated by the insult, replied with great moderation, and even gave the herald a considerable present. Louis had also requested the good offices of Lords Stanley and Howard to second his desires for peace; and Edward was soon after brought to conclude a truce, more to the advantage than the honour of Louis. That monarch stipulated to pay 75,000 crowns, upon condition of Edward's withdrawing his army from France; and 50,000 crowns a year during their joint lives. It was also agreed, that the dauphin, when of age, should marry Edward's eldest daughter. The two monarchs had afterwards a private conference at Pequigny, near Amiens, where they interchanged mutual civilities, and confirmed their friendship.

Edvard returned to England, after this fruitless expedition, only to disgust his subjects by his profligacy and cruelty. The Duke of Clarence, since his alliance with the Earl of Warwick, notwithstanding his after services, in assisting him to recover the crown, had never been able to regain the confidence of his brother. His open and hasty temper had also multiplied his enemies, among whom were the queen and his brother the Duke of Gloucester, who united in hastening his destruction. Irritated by the indifference with which he was treated at court, he did not hesitate to express his dissatisfaction, and sometimes indulged in ill-natured invectives. His enemies took advantage of his resentment; and endeavoured to stimulate him to still further resistance, by the persecution of his friends. Thomas Burdet of Arrow, who happened to live in intimacy with the duke, had a favourite buck killed by the king, while hunting in the park of the owner; which so vexed Burdet, that, in a hasty humour, he wished the horns of the deer in the belly of the person who advised the king to do him such an injury. For this ex-
Gloucester, who, by the most profound dissimulation, had been able to conceal a heart deformed by every thing that was mean, cruel, or base, had hitherto lived on good terms with both factions. But as his immediate ambition led him now to look towards the crown, he resolved to attach himself only to those, from whom he might expect least opposition to his views. At the same time, however, he assiduously paid court to the Queen, by professing the greatest zeal and attachment to her family; and thus gained such credit with her, that she for a time trusted implicitly to the sincerity of his friendship.

Young Edward had been committed to the care of his uncle, the Earl of Rivers, the most accomplished nobleman in England, and resided in Ludlow castle, on the borders of Wales. The Queen, desirous of retaining him in her power, wrote to her brother to levy a body of troops, in order to escort the young king to London, and to prevent him from falling into the hands of his enemies. This measure gave great offence to the opposite faction, who, apprehensive of being reduced to subjection by their rivals, declared their resolution of resisting force by force. The wily Gloucester, interposing his authority, and, under pretence of pacifying the dispute, prevailed upon the Queen to bring up no greater retinue than should be necessary to support the state and dignity of the new sovereign. But he himself set out from York, attended by a numerous train of the northern gentry; and at Northampton, was joined by Buckingham with a splendid retinue. Here they waited the approach of the king. Rivers, however, apprehensive that the place would be too small for all their attendants, had sent his charge forward to Stony-Stratford, and came in person to pay his respects to the Regent. He was received with seeming cordiality and friendship; and they all proceeded next day to join their sovereign. But when they were entering Stony-Stratford, Rivers was arrested by order of the Regent, and with Sir Richard Gray, one of the Queen's sons, and Sir Thomas Vaughan, an officer in the king's household, was sent a prisoner to Pontefract castle. Gloucester endeavoured to satisfy the young king with respect to the violence against his relations, but his wishes were unable to dissemble his disappointment and displeasure.

When the queen heard of the fate of her brother, she foresaw that the ruin of herself and family was determined, and took sanctuary with her family in Westminster Abbey. Gloucester now used all his arts to get the Duke of York into his power; but his mother resisted all his solicitations: the council, however, threatened to employ force if she continued obstinate; which induced her to comply. When she took leave of her son, she bade him with her tears, and, as if struck with a presage of his future fate, bade him an eternal adieu. Gloucester then took his nephew in his arms, and, clasping him with feigned affection, declared, that while he lived, the boy should never want a parent. But the hypocritical tyrant was all the while meditating the most bloody designs against the helpless innocent.

Having thus got into his power the principal obstacles to his ambition, Gloucester prepared for more treacherous and bloody deeds. As he was the nearest male of the royal line capable of exercising the government, he was invested by the council with the office of protector, without waiting for the consent of parliament; and the first use he made of his high dignity, was to order the death of Rivers, and the other prisoners in Pontefract Castle. To this tyrannical and sanguinary measure Buckingham and Hastings gave their consent; and the prisoners were beheaded without any form of trial. He next summoned Buckingham respecting his usurpation of the crown; and prevailed upon him, by liberal offers of private advantages, to support him in all his measures. The loyalty of Hastings, however, was proof against every promise and persuasion; and that nobleman determined to maintain unshaken his allegiance and fidelity to the children of Edward. As the tyrant, therefore, dispised of gaining him to his interest, he resolved upon his death. With this design he summoned a council in the Tower. The protector appeared with a cheerful countenance, and, before they entered upon business, conversed with the members with great affability and good humour. He then left the council, as if called away in haste; and in about an hour after returned, but with quite an altered look; his brows knit, and his countenance inclined with rage. Those who knew his savage nature beheld him with horror, expecting some dreadful catastrophe. After a short silence, he asked them, what punishment they deserved who had conspired against his life. Hastings replied, that they desired the punishment of traitors. "See, then," cried the protector, baring his withered arm, "what the sorceress, my queen-sister, and that wretch, Shore's wife, have done by their incantations and witchcrafts; their spells have reduced my arm to this condition; and had they not been timely detected, my whole body would have suffered the same calamity." The council gazed upon one another in much astonishment, knowing that this infirmity had attended him from his infancy; and the silence was again broken by Hastings, who said, "If they have been guilty of these crimes, they merit the severest punishment." "If!" cried Gloucester in a rage; "do you reply to me with your ifs? you are yourself a traitor, and the chief abettor of that witch, Shore; and I swear by St Paul, that I will not dine before your head be brought me." He then struck the table with his hand, and the room was instantly filled with armed men. The council room was now filled with tumult, and one of the guards aimed a blow with his battle-axe at Lord Stanley's head, which the fellow, in all likelihood, had been instructed to do; but that nobleman escaped by shrinking under the table. Hastings was seized, and immediately beheaded on a log of wood which happened to lie in the court of the Tower. Lord Stanley, the Archbishop of York, the Bishop of Ely, and some other counsellors, were afterwards committed prisoners to the Tower; and a proclamation was read to the citizens of London, among whom Hastings was very popular, enumerating his offences, and apologising for his sudden execution, by the suddenness of the discovery. In order to carry on the farce, he ordered Jane Shore to be tried for witchcraft; but as no evidence was produced against her, she was accused of adultery before the spiritual court, and condemned to walk barefoot through the city, and to do penance in St Paul's church in a white sheet, before all the people. This unhappy woman languished out her life in solitude and indignity, neglected and unpitied by those who had formerly been protected by her credit, and had lived upon her bounty.

After the murder of Hastings, Gloucester proceeded openly in his ambitious designs. He endeavoured, by means of Buckingham, to instil into the minds of the people an opinion of the illegitimacy of the late king and his children. He thus had the impertinence to charge his
The Duke of Buckingham was next appointed to harangue an assembly of the citizens, to whom he enumerated the calamities of the preceding reign, and the many virtues of the protector; and endeavoured to convince them of the illegitimacy of the present king. He then asked them whether they would have a bastard prince, or the virtuous protector for their sovereign; but no one answered him. He treated them to speak out their real sentiments, and give him a positive answer; when some of his own servants, who had slipped among the crowd, cried out, "God save King Richard!" which was seconded by a few of the citizens, who had been previously bribed. This feeble cry was interpreted as the voice of the nation; and Buckingham, with the mayor and aldermen, immediately hastened to Baynard's castle, where the Protector then resided, to make him an offer of the crown.

Gloucester, who was a complete master in dissimulation, affected to be surprised at the appearance of Buckingham; and when informed of his intentions, he refused the offer of the crown, and declared his purpose of maintaining his loyalty to the present sovereign. Buckingham appeared displeased with his answers, and told him, that, as the nation were determined to have another king, if he resisted their unanimous wish, they must fix upon some other person who would be more compliant. "I see," cried the Protector with the most hypocritical humility, "that the nation is resolved to load me with pre- ferments unequal to my abilities or my choice; and I graciously accept their petition."

Richard had no sooner obtained the crown, than he resolved to secure it by the death of his nephews; and he gave orders to that purpose to Sir Robert Brakenbury, constable of the Tower. But that gentleman refused to be the instrument of his cruelty. Brakenbury was then commanded to resign the government of the Tower for one night; Sir James Lyric, who, with three associates, Slater, Digton, and Forest, soon accomplished the bloody purposes of the tyrant. They entered the young princes' chamber while they were fast asleep, and suffocated them with the bolster and pillows. They then buried their bodies deep in the ground under the staircase. Their bones were afterwards discovered in the reign of Charles II. and interred under a marble monument in Westminster Abbey.

Richard employed his new acquired authority, in bestowing rewards and preferments upon those who had assisted in his exaltation, and who were best able to support his government. He created Thomas Lord Howard, Duke of Norfolk, and Sir Thomas Howard, his son, Earl of Surrey. He also set Lord Stanley at liberty, and made him Steward of the Household. Buckingham, the chief promoter of his ambition, was loaded with dignity and honours. He was invested with the office of Constable, and received a grant of the estate of Hereford, one of the greatest of the ancient baronies. But while Richard was thus endeavouuring to strengthen his ill-gotten power, he was hated and feared by every man of sense and virtue in the kingdom; and the very accomplices of his crimes were contemplating his overthrow.

The Duke of Buckingham himself soon became disgusted with the new government; but whether this arose from his own restless and turbulent disposition, or from any part of the king's conduct towards him, is not known. It was only, however, a few months after Richard's accession, when this nobleman began to form a conspiracy against him, and to attempt to pull him from the throne, to which he had been so instrumental in raising him. For this purpose he cast his eye towards the young Earl of Richmond, who was the only remaining branch of the house of Lancaster, and who seemed the only person that could free the nation from the tyranny of the usurper. He was encouraged in these sentiments by Morton, Bishop of Ely, a zealous Lancastrian, who had been imprisoned by the king, but who had afterwards been committed to the custody of Buckingham.

Henry Earl of Richmond had been carried into Britain by his uncle, the Earl of Pembroke, immediately after the battle of Tewksbury; and had been detained there in a kind of honourable custody by the reigning duke, at that time the ally of England. Edward IV. after his restoration, had frequently endeavoured to prevail upon his ally, who was a weak but good prince, to deliver the young Earl into his power; and had at last so far succeeded, under a pretence of marrying him to his eldest daughter, that Henry was put into the hands of the English ambassadors, and was on ship-board, when the Duke, suspicious of Edward's real design, recalled his orders, and saved Richmond from destruction. This continued jealousy of Richmond's pretensions to the crown, tended to confirm them in the minds of the people; and the universal detestation in which Richard was held, turned the attention of the nation towards that nobleman. But, in order to unite all parties in a cause which promised to contribute so much to the happiness of the kingdom, by the expulsion of the odious tyrant, Morton suggested the project of uniting the opposite factions, by the marriage of Richmond with the Princess Elizabeth, the eldest daughter of King Edward. This scheme was communicated to the Earl, and also to the queen-dowager. Both entered heartily into the designs of Buckingham. The Queen borrowed a sum of money, and sent it over to Richmond; required him to join and celebrate the marriage on his arrival in England; and promised to join him with all the friends and partizans of the family. But their intention did not escape the vigilant eye of Richard; and Buckingham was suspected of being concerned in the conspiracy. The King resolved to send for the Duke of Buckingham, in order to discover if his suspicions were well founded; but the Duke, well knowing his barbarity and treachery, only answered by taking up arms in Wales, and calling upon his associates every where to join him. But the swelling of the Severn prevented him from marching into England; and detained him so long, that his army, distressed for want of provisions, fell off from him, and left him almost without a follower. In this helpless situation, he put on the disguise of a peasant,
and took shelter in the house of one Bannister, an old servant of his family. A large reward, however, was set upon his head; and the villain Bannister, unable to resist the temptation, betrayed his master; when he was brought to the king at Shrewsbury, and instantly executed. The other conspirators, who had risen in different parts of the kingdom, as soon as they heard of his fate, immediately dispersed. The Marquis of Dorset and the Bishop of Ely fled beyond sea; some of their friends fell into the hands of Richard and were executed, and others contrived to conceal themselves from his vengeance. The Earl of Richmond, in the mean time, had arrived off the coast of England with 5000 troops; but hearing of the dispersion of his friends, he returned to Britany.

Richard, emboldened by his success, now ventured for the first time to call a parliament, which acquiesced in whatever he chose to propose. They approved all his proceedings; confirmed the illegitimacy of Edward's children; attainted the Earl of Richmond and all his adherents; and granted the king the duties of tonnage and poundage for life. He next entered into a negotiation with the Duke ofBritany for delivering up his rival, and had nearly succeeded, through the treachery of Peter Landsais, a corrupt minister of that court, when Richmond, having got timely notice, fled into France. Richard, however, still continued to employ every mean that might give security to his throne; and sensible that his rival was only formidable from his projected marriage with the Princess Elizabeth, the true heir to the crown, he formed the design of espousing that princess himself. He had married Anne, the second daughter of the Earl of Warwick, and the widow of Edward, Prince of Wales, whom he himself had murdered. But, considering her as an invincible obstacle to his designs, he is believed to have carried her off by poison. He then made application to his niece, and paid court to the queen-dowager with such art and address, that thus princess, eager to recover her lost authority, did not scruple to give her consent to this incestuous alliance, and to marry her daughter to the murderer of her three sons and her brother: She even so far joined her interests with those of the usurper, as to desire her son, the Marquis of Dorset, and all her partizans, to withdraw from the Earl of Richmond. But the young princess disdain'd to listen to his vile passion, and treated his addresses with contempt and detestation. While Richard was thrown into perplexity by her unexpected refusal, and before he had time to renew his suite, the Earl of Richmond landed at Milford-haven with a small army of 2000 men. As he advanced, his friends flocked to his standard; but his army, with all his reinforcements, amounted only to 6000 combatants. Richard met him at Bosworth, near Leicester, with a force double the number. This superiority of numbers, however, was rendered of little advantage, by the dissensions which prevailed among them. Lord Stanley had been suspected by Richard of favouring the cause of Henry; and when he empowered him to levy troops, detained his eldest son Lord Strange as a pledge for his fidelity. That nobleman was thus prevented from openly declaring himself, though he had sent secret assurances to Henry of his friendly intentions, and, at the head of 7000 men, posted himself on the flank of the two hostile armies, ready to join either party as occasion should offer. Richard, apprehensive of his design, sent him orders to join him, which Stanley refused; upon which the tyrant was about to take revenge upon his son, but he was persuaded to postpone the execution till after the fight, when, being certain of a victory, he would take ample vengeance upon all his enemies, both open and concealed. The trumpets were then ordered to sound to battle, which began by a flight of arrows; but the ranks soon began to close, when Stanley advanced, and joined the army of Richmond. This circumstance turned the fortune of the day. It inspired Henry's soldiers with unusual courage, while it spread dismay and confusion among Richard's. Richard, enraged to madness by the treachery of Stanley, and sensible of his desperate situation, resolved to finish the battle, either by Henry's death or his own. He rushed into the thickest of the fight, and flew from rank to rank in search of his rival. Richmond himself did not decline the combat; but when they were just within reach of each other, they were separated by the crowd. Richard perceiving his men every where yielding and flying, and giving up all for lost, spurred his horse into the midst of the enemy, and fell covered with slain. His body was found in the field of battle, in the midst of dead enemies, and disfigured with wounds. It was thrown across a horse, and carried to Leicester, where it was interred in the Gray Friars Church. Thus perished Richard III., who waded to the throne through the blood of his nearest relations; who considered no enmity too great, and no action too mean, provided it led him to the object of his ambition. He enjoyed his exaltation little more than two years; and perished by a fate too mild and honourable for his multiplied and detestable crimes. He was of a small stature, hump-backed, with a harsh disagreeable countenance, so that his body and his mind were equally deformed. (?)

The decisive victory gained at Bosworth, was followed by the most important consequences. An ornamental crown, which Richard had worn in battle, having been found among the spoils, was placed upon the head of Richmond; and the whole army, as by one instantaneous movement, shouted aloud, "Long live Henry VII." His title, indeed, to the crown, was in many respects defective. The hereditary right resided in the house of York, of which there were several princes then alive. His own descent from the house of Lancaster proceeded from an illegitimate branch, and though an act of legislation had been passed in the reign of Richard II. yet the very patent which conferred the privilege, excluded the posterity of that line from the crown. But the Lancastrian party had resolved to adopt him as their head; and his solemn engagement to marry the Princess Elizabeth, the representative of the house of York, attached the adherents of that family to his cause. To the expectation of this union he owed much of his past success, and it was hailed by all considerate men as the probable termination of those civil wars, which had raged for thirty years with such destructive violence. He did not, however, deem it expedient to engraft his title upon that of the rival house, but being in possession of the power, he advanced his claim as the heir of Lancaster, while he resolved to prevent the discussion of its validity.

Having refreshed his army a few days at Leicester, he proceeded slowly towards the capital, and at every step of his progress was saluted with the loudest acclamations. He was received by the citizens of London with every expression of satisfaction and respect; but seeming to court popularity, he entered the city in a close chariot, and refused to gratify the people with a sight of their new sovereign. Proceeding directly to St Paul's, he deposited the standards which had been taken at Bosworth, and returned thanks to God for the victory. He hastened to re-
new in public his promise to espouse the Princess Eliza-
Beth; but that he might not seem to derive his claim
from her right, or to depend upon her life for the dura-
tion of his authority, he determined to postpone the alli-
ance till his own coronation should be finished, and his
title recognised by parliament. He was crowned king of
England on the 20th of October 1485, with the usual
pomp and ceremonies; and, to heighten the splendour
of the spectacle, he bestowed the rank of knights banneret
on twelve persons, and conferred peerages on three.

When the parliament assembled in the beginning of
the following month, it was found that many members
of the House of Commons, who were his most zealous
partisans, had been attained in the preceding reign.
These persons he required to abstain from taking their
seats, till an act should be passed to reverse their attain-
der, and thus exhibited a degree of regard to the laws hi-
thero unknown in England. The same parliament,
however, granted the king's ressentment towards the ad-
herents of the York family, by passing an act of attain-
der against the Duke of Norfolk, and thirty other per-
sons who had fought under Richard at Bosworth,—a
measure which could only have been prompted by ava-
rice or revenge, and which excited considerable de-
bates in the House, as well as murmuring among the peo-
ple. At the same time, Henry issued a royal procla-
amation, offering pardon to all who had taken part against
him, upon condition that they submitted by a certain
day, and took the usual oath of allegiance.

Perceiving that the delay of his marriage rendered the
nation more suspicious of his proceedings, and having
been petitioned by parliament to fulfil the wishes of his
people, he espoused the Princess Elizabeth on the 15th of January 1486. The public rejoicings on this occasion,
were greatly superior to those which had taken place at
his own accession and coronation; a circumstance which
Henry regarded with jealously displeasure, as the testimo-
y of general favour to the house of York, and which
gave rise to suspicions in his mind subversive at once of
his own tranquillity, and of that tenderness which he ow-
ed to his amiable consort. Having taken due care to
prolong the continuance of peace abroad, particularly
with the kingdoms of France and of Scotland, he resol-
ved to secure more effectually the internal quiet of his
own dominions. In this view, he set out on a journey
to the northern districts, where the friends of the late
king and of the house of York were most numerous, in
the hope of either swining the malcontents by his pre-

dence, or conciliating them by his censure.

Upon his arrival at York, he received intelligence that
Lord Lovel was approaching at the head of three or four
thousand men, and that Sir Humphrey and Thomas
Stafford had marched with another army to besiege the
city of Worcester. Though in the midst of disaffected
counties, Henry found resources in his own active cou-
rage, and having hastily collected a small body of troops,
he gave the command to his uncle the Duke of Bedford,
with orders, when he approached the rebels, to publish a
general promise of pardon to all who should lay down
their arms. Lovel, dreading the desertion which this
proclamation might produce among his troops, suddenly
withdrew in the night, and made his escape to Flanders.
His army submitted to the king's clemency; and the
other insurgents, intimidated by the surrender of their
confederates, instantly dispersed. The two Staffords
having sought refuge in some obscure church, which had
not sufficient privileges to protect them, were dragged
from the altar, and Humphrey, the elder, was executed
at Tyburn, but the younger, upon the plea of his youth,
received a pardon.

This success was followed by the birth of a son, to
whom Henry gave the name of Arthur, in memory of the
celebrated British king of that name, from whom the
house of Tudor was held to be descended. But neither
the recent triumph over his enemies, nor the acquisition
of a prince, who united all the claims of York and Lan-
caster, could reconcile the hearts of the English to their
sovereign. By a long course of civil war, the people
were become so turbulent and factious, that no king could
please them; and this rooted disposition to insurrection,
was still farther inflamed by Henry's open animosity to
the house of York. The undisguised preference which
he gave on all occasions to the Lancastrians; his frequent
acts of severity against the opposite party; his reported
harsh treatment of the Queen; his refusing her, even
after the birth of a son, the honour of a public coron-
ation; his imprisonment of the young Earl of Warwick
in the Tower; and his own reserved and haughty address,
all conveyed the idea that his prepossessions against the
Yorkists were inveterate, and contributed to render his
government generally unpopular.

In the midst of these discontents, a report was propa-
gated among the people, that Richard Duke of York,
second son of Edward IV. had saved himself from the
cruelty of his uncle Richard III. and was concealed
somewhere in England. This story was received with
great avidity, and suggested to a priest in Oxford, named
Richard Simon, the scheme of raising, upon this ground,
a pretender to the crown. Aided and advised, as has
been generally supposed, by some persons of higher rank,
he fixed upon a youth called Lambert Simnel, about fif-
teen years of age, who was the son of a baker, but who
possessed an understanding and address above his con-
dition, and whom he instructed to personate the son of
Edward, who was now rumoured to be alive. Hearing,
however, a new report, that the young Earl of Warwick
had made his escape from the Tower, and observing that
this was a subject of equally general satisfaction, he chan-
ged the plan of his imposture, and taught Simnel to re-
present that unfortunate prince. Sensible at the same
time that the counterfeit could not stand a very close
inspection, he carried his puppet to Ireland, as the most
proper theatre for opening the scene. In this country,
the people were all devoted to the family of York; and
the whole officers of state appointed in the preceding
regime, had been improvidently allowed to retain their au-
thority. Here the pretender experienced the most fa-
vourable reception from persons of the highest rank,
whose example was eagerly followed by the lower orders;
and Simnel, having been proclaimed king of Ireland,
was lodged with great pomp in the castle of Dublin.

Henry, alarmed by so unexpected a resolution, was at
first inclined to face his enemies in person; but suspect-
ing the conspiracy to have been framed in England, he
directed his own exertions to the discovery of its promo-
ters in that kingdom; while at the same time he did not
fail to provide the most rigorous means of suppressing
the revolt in Ireland. After frequent consultations with
his confidential friends, he commanded the queen-dow-
ger to be seized, and closely confined in the nunery of
Bermondsey; but, unwilling to charge so near a relative
with treason, he assigned, as the cause of this severe-
treatment, her having formerly delivered the Princess Elizabeth and her other daughters into the hands of the late king. He next ordered Warwick to be taken from the Tower, and led through the streets of London in the view of the whole people, directing at the same time several persons of rank, who were attached to the house of York, and well acquainted with the person of the young prince, to approach him, and converse with him. This expedient had the effect of exposing the imposture to his subjects in England; but the people of Ireland still persisted in their rebellion, and charged the King with having exhibited a counterfeit Warwick. John Earl of Lincoln, nephew of Edward IV, who had previously retired to Flanders, being there joined by Lord Lovel, and furnished by the Duchess of Burgundy with 2000 veteran Germans, under the command of Martin Swart, a brave and experienced officer, joined the party of Simnel in Ireland. The Irish, encouraged by this reinforcement, and having first crowned the impostor with great solemnity, proceeded to the invasion of England; and having landed in Lancashire, where they were received by Sir Thomas Broughton, a gentleman of considerable influence in that county; they advanced into Yorkshire, in the expectation of being joined by the inhabitants on their march. But the people in general, convinced of Lambert's imposture, averse to unite with foreign invaders, and awed by the reputation of Henry, either remained in tranquillity, or repaired to the royal army. Lincoln, who commanded the rebels, and whose force amounted to 8000 men, perceiving no hopes but in victory, resolved to bring the matter to a speedy decision. The king, who, upon the news of Simnel's landing, had advanced as far as Coventry, was equally eager for the combat. The hostile armies met at Stoke, near Newark in Nottingham, and, after an obstinate engagement, Henry obtained a complete victory, at the expence of 2000 of his best troops. Lincoln, Lovel, Broughton, Swart, and most of the rebel leaders, with 4000 of their followers, perished in the field of battle. The impostor Simnel, and his tutor Simon, were taken prisoners. The latter being exempted, as a priest, from the power of the civil law, was committed to close custody for life; and the former, being too contemptible an object for the resentment of Henry, was made, first, a scullion in his kitchen, and afterwards advanced to the office of a falconer. Few of the other delinquents were put to death, but many of them were subjected to heavy fines. The proceedings against all who were suspected of having favoured the rebels were sufficiently arbitrary and rigorous; but, on the other hand, the people were gratified, and the principal source of their disaffection removed, by the ceremony of the queen's coronation, which took place on the 25th of November 1487.

Henry, aware of the futility of conquests upon the continent, or, as some authors represent the matter, avverse, through motives of frugality; from all distant expeditions, found it nevertheless necessary, to gratify the warlike temper of his subjects, and to indulge their ancient animosity towards France, by professing a resolution to resist the encroachments which that rival power had recently made upon the province of Brittany. Having summoned a parliament at Westminster, he found no difficulty in persuading them to grant him a considerable subsidy; but, in those days, money was more easily voted than levied in England. The inhabitants of the more northern counties, who had been always disaffected to Henry's government, and who still smarted from his severities after the overthrow of Simnel, resisted the collection of the tax, and put to death the Earl of Northumberland, while he attempted to enforce obedience to the laws. Conceiving themselves too deep in guilt to escape, they proceeded to open rebellion; and, at the instigation of John a Chambré, a sedulous fellow of low birth, they chose Sir John Egremont as their leader, and declared against the king as a tyrant and usurper. As soon as Henry received intelligence of this insurrection, he dispatched a body of troops, under the Earl of Surrey, who dispersed the rebels without much difficulty; and a Chambré, having been taken prisoner, was executed at York, with twelve of his accomplices. Egremont fled for protection to the Duchess of Burgundy; and the greater part of his misguided followers received a pardon.

Henry, disappointed in his wishes to terminate the dispute with France by negociations, found himself under a necessity of adopting more active measures than he had intended; and the distresses of the Bretons became so urgent, that at length, (after receiving possession of two sea port towns from his ally, as security for the payment of his charges,) he sent 6000 men, for ten months, to resist the progress of the French power. These troops, under the command of Lord Willoughby of Break, broker the Bretons for some time masters of the field; but the French, retiring into their garrisons, gave them no opportunity of striking any decisive blow; and when the time of their service had elapsed, they returned home, without having afforded any essential support. The King of England, artfully labouring to avoid the expences of war, and yet to thwart the designs of the French court, became the dupe of his own policy; and, by the marriage of the Duchess of Brittany to the King of France, the province was peaceably annexed to his dominions. The King of England, envious of the schemes defeated, and unwilling to lose his claims of re-imbursement from Brittany, abandoned at length his cautious policy, and resolved to adopt more vigorous measures, when no measures could be of any avail. Upon pretence of a French war, he levied a Reiscntation on his subjects, (a mode of taxation peculiarly odious, as it was made at the discretion of commissioners;) and, lumelling summoned a parliament, vaunted, in a magnificent strain, of his determination to make a conquest of France. The English nobility, seized with military ardour, entered with full cedulity into the orontising schemes of their sovereign. On the 6th of October 1492, Henry landed at Calais with a well equipped army of 25,000 foot, and 1600 horse, and without a moment's delay laid siege to Boulogne. But with all this show of hostility, negociations had actually commenced before the army left England; and, after artfully giving it the appearance of being desired by his nobles, and owing to the delay of his allies, he concluded a peace with France on the third day of November. The principal article of the treaty, was the payment of nearly 745,000 crowns to Henry by the French government, partly as re-imbursement of the sums which he had advanced to Brittany, and partly as arrears of the pension due to Edward IV.; besides the stipulation of 25,000 crowns, as an yearly pension to himself and his heirs.

Before the conclusion of the war, a new pretender to the crown of England had begun to make his appearance. The old Duchess of Burgundy, not discouraged by the
failure of Simnel's imposture, propagated a report that his nephew, Richard Plantagenet, Duke of York, had escaped from the Tower when his brother was murdered; and procured a youth of proper parts to personate the prince. Perkin Oswest or Warbeck, the son of a Flemish Jew, after having been carefully instructed in the character which he was intended to assume, landed in Ireland about the commencement of hostilities with France, and, under the name of Richard Plantagenet, collected a number of partizans in that country. But, being joined by few persons of rank, he accepted an invitation from the King of France, where he was entertained with all the honours due to his supposed quality, and where he succeeded in attaching a number of English gentlemen to his interest. Dismissed from Paris when peace was concluded with Henry, he proceeded to the court of the Duchess of Burgundy, who pretended for some time to treat him as an impostor, but at last avowed her full conviction of his being the son of her brother Edward, and the legitimate heir of the English crown. Perkin, by his prudent conversation and princely deportment, ably supported the fiction of his royal descent; and the English became daily more and more prepossessed in his favour. Many of the nobles, disgusted with Henry's government, which tended to weaken their influence, and some even of his former favourites, who had been most instrumental in raising him to the throne, moved by credulity or ambition, and probably conceiving that their services had not been sufficiently rewarded, meditated a revolt in favour of his enemy. A regular conspiracy was formed against his authority; a correspondence settled between the malcontents in England and the pretender's friends in Flanders; and the whole nation, interested in the event, was held in a state of wonder and suspense as to the issue of the contest. Henry, well informed of all particulars, and conducting himself with his wonted caution and resolution, was actively employed in counteracting the projects of the conspirators. He first took measures to undeceive the people, by ascertaining that the Duke of York was really dead, and by inflicting punishments on those who were convicted of having been his murderers. He next exerted all his talents of policy and penetration, to detect the proofs of Warbeck's imposture; and, by a skilful employment of spies and bribes, he succeeded in developing his whole history, designs, and adherents. He immediately published to the nation the pedigree and adventures of the pretended Duke of York; and when his projects were properly matured, proceeded to inflict punishment upon the principal conspirators. Several men of note were publicly executed, others detained in custody, many pardoned; and, it has been remarked as a commendable feature of Henry's lenity and discrimination in prosecuting conspirators, that, if any one appeared to have been actuated by conscientious adherence to principle, or by affection towards the house of York, he generally experienced the king's clemency; but if he had indicated a restless love of change, or a turbulent opposition to the laws by which he was governed, he was then treated with greater severity.

Perkin, having made an unsuccessful attempt to land on the coast of Kent, proceeded to Ireland; and being there also frustrated in his hopes of support, he bent his course to Scotland. To James IV., who then governed that kingdom, he had been previously recommended by the French monarch, who was dissatisfied with Henry on account of his having joined the confederacy against his attempts upon Italy. This recommendation procured him a favourable reception from the King of Scotland; and his own insinuating address so far imposed upon that youthful and unsuspecting prince, that, in the full belief of his royal birth, he gave him in marriage the daughter of the Earl of Huntley, who was nearly related to himself, and who was one of the most accomplished ladies of her time. He next entered England at the head of a powerful army in support of his pretensions to the throne, but his story had now become stale, even in the view of the populace; and the presence of the Scots aroused the English rather to repel, than to join the invaders. A second inroad in his favour was attended with no better success; and, upon the conclusion of a treaty of peace between the two nations, he was obliged to leave Scotland, and to seek a new protector. His interests in Flanders had been completely overthrown, and his access to that country in a great measure barred, by a treaty of commerce with England. Consulting with his followers, Herne, Skelton, and Astley, three bankrupt tradesmen, he determined, under the name of Richard IV., to try the affections of the inhabitants of Cornwall, who had recently risen against the levying of a tax, and whose mutinous disposition, notwithstanding the lenity of Henry, still subsisted in a degree which seemed to promise him a ready adherence. On his first appearance at Bodmin, he was joined by 3000 of the populace, and immediately laid siege to the city of Exeter. Henry, upon receiving information of his proceedings, prepared with alacrity to meet him in the field; and was seconded with the utmost unanimity by the principal nobility and gentry of the kingdom. Perkin, upon hearing of his approach, though his followers now amounted to 7000, lost all hopes of success, and secretly withdrew to the sanctuary at Beaunieu. His wife, Lady Catharine Gordon, falling into the hands of the conqueror, was treated with the greatest generosity, and placed, with a suitable pension, in a reputable station near the person of the queen. Perkin being persuaded, upon the promise of pardon, to surrender himself into the hands of the king, was conducted through the streets of London, and committed to custody in the Tower. But, impatient of confinement, he soon made his escape, and, finding it impracticable to leave the kingdom, fled to the monastery of Thyne. The prior gave him up to the king, after having again secured his pardon, and he was himself prevailed upon to publish a confession of his imposture. Commit ted once more to the Tower, he soon renewed his attempts to regain his liberty, and contrived to engage in his plot the young Earl of Warwick, who was confined in the same prison. Their designs being detected, they were both condemned and put to death. The impostor had rendered himself unworthy of mercy; but the execution of the last male of the line of Plantagenet, who had been a prisoner from his childhood, and who had merely attempted to escape from oppression, occasioned the greatest discontent among the people, and must be regarded as the darkestblemish in the reign of Henry.

The authority of Henry being now securely established, and his reputation for vigour and sagacity spread over all Europe, his amity and alliance was courted with every demonstration of respect by the most powerful foreign princes. The Princess Margaret, his eldest daughter, was contracted to James the Fourth of Scot-
HENGLAND.

land; but as the royal bride was only in the eleventh year of her age, the marriage was not consummated till three years afterwards. A similar connection, which had long been negotiating between Arthur, Prince of Wales, and the Princess Catherine, third daughter of Ferdinand and Isabella of Spain, was concluded about the same time, and the marriage celebrated with great pomp about the end of the year 1501. These two matches were afterwards productive of the most important events; the former laying the foundation for the future union of the English and Scottish crowns; and the latter proving a remote occasion of the reformation of religion in Christendom. Prince Arthur sickened and died a few months after his marriage; but his father, still desirous to continue his alliance with the royal family of Spain, after procuring the pope’s dispensation, obliged his second son Henry, whom he created Prince of Wales, to be contracted to the infant. During these more prosperous incidents, the queen died in childbirth, and the child survived her only a few days; but, as she had never gained the affections of her husband, though deservedly the favourite of the nation, it was not supposed that her death made much impression upon the king; and he soon after began to lay plans for a second marriage. He first turned his thoughts to the Queen Dowager of Naples; but, hearing that her dower was diminished, he abandoned all further pursuit. In 1506, Philip, Archduke of Austria, who had married Joan, heiress of Castle, having embarked with his consort for Spain, was driven by a storm into the port of Weymouth, and was received by Henry with every possible demonstration of respect. Ever watchful how to draw advantage from every incident, he first prevailed upon Philip to conclude a more favourable commercial treaty, than that which hitherto existed between the English and the Low Countries, and next negotiated a lucrative matrimonial alliance between himself and Philip’s sister, Margaret, Duchess Dowager of Savoy. But the accomplishment of this intended connection was prevented by Henry’s declining health, and by the commencement of a disease which soon terminated in his dissolution. In the view of approaching death, the king applied himself with much earnestness to acts of justice, piety, and mercy; and had recourse to many of those superstitious practices, which were then held most efficacious for conciliating the favour of heaven. He paid the debts of all persons in London who were imprisoned for small sums; and, with the exception of a few of the more aggravated cases, issued a general pardon to all criminals. He directed 2000 masses to be said for his soul within a month after his decease; distributed alms to paupers and prisoners, upon condition that they prayed fervently for his future felicity; and constituted commissioners, to make restitution to all whom he had injured or oppressed. He expired in his favourite palace at Richmond, in the 54th year of his age, and the 24th of his reign.

Henry VII. was, in stature, above the middle size, and though of a slender form, yet strong and active. His deportment was grave and stately; but when any great point was to be gained, he was capable of displaying the most insinuating address. Though not defective in personal courage, and always collected in seasons of danger, he was rather cautious than enterprising in the field. He was indefatigable in public business, and descended to the most minute details; kept his views impenetrably secret, and only prescribed to his ministers the parts which they were to act. His understanding, though not remarkable for acuteness, was sure in its deliberations, and the general success of his measures procured him a very high reputation for political wisdom. He was more deficient in the feelings of the heart than in the faculties of the mind; and was little susceptible of the social and generous affections. An inordinate love of money, and an unrelenting hatred to the house of York, were his ruling passions, and the chief sources of his vices and his vexations. During the latter part of his life, in particular, his strict economy degenerated into absolute avarice, which broke through all restraints; and with the assistance of two rapacious ministers, Empson and Dudley, he committed the most arbitrary exactions upon his subjects. By his frugality and extortions, he accumulated immense wealth, and is said to have possessed, at his death, in ready money, the sum of £1,800,000. But the royal coffers being then the only treasury of the state, he may be said to have saved for the public; and though a few individuals may have suffered from his rapacity, he left the nation wealthy and flourishing. His reign, in a general view, was prosperous at home and honourable abroad; and though not personally the least, he was politically the most useful prince, next to King Alfred, that had hitherto filled the throne of England. He loved peace, without fearing war; and extended his power by wise treaties, rather than expensive victories. It was the uniform tendency of his measures to depress the nobility and clergy, and to raise up and humanise the people. By a law, empowering the nobles to break their entail and alienate their possessions, the overgrown authority and estates of the barons were gradually diminished, while the property and influence of the commons were proportionally increased. By repeated statutes, and a rigorous enforcement of the laws, he prevented the great families from giving livgeries or badges to their dependants and retainers; and thus effectually suppressed those armed bands, maintained around the castle of every baron, and ready for every act of violence or insurrection. He was not so successful in his attempts to abolish the privileges exercised by monasteries, in affording refuge to the most notorious offenders; and all that he was able to accomplish by his influence with the pope, was to procure a regulation, that if any, who were once registered as sanctuary-men, should again sally forth to commit fresh offences, they might be dragged from the place of their refuge, and delivered up to justice. His great efforts were uniformly directed to promote a spirit of industry, and to extend the benefits of commerce among his subjects. In these views he repealed various statutes, which acted as restraints upon manufacturing and mechanical trades; endeavoured to draw the towns from the neighbourhood of strongholds to more commercial situations; and never failed, in his treaties with foreign powers, to secure the commercial interests of the kingdom. He expended fourteen thousand pounds in building one ship, which was called “the Great Harry,” and which may be considered as, in fact, the beginning of the English navy; since the government, before this period, had no other mode of raising a fleet than by hiring or pressing the vessels of merchants. By his prudence and perseverance, in short, he effected a great and beneficial change upon the state of the kingdom; enacted many wise and salutary laws; restored, or rather established commerce; reduced to just subordination a factious and insolent aris-
tocracy; and taught the peaceful arts of civilized life to
a warlike and turbulent people.

Henry VIII, ascended the throne, when he was about
18 years of age, with every advantage that a young
prince could possess, and with the fairest prospects of a
happy reign. Unitiiig in his person the claims of the
houses of Lancaster and of York, his title was indisputed,
and all factions were extingiuished. Beautiful in his form,
expert in every manly exercise, accomplished in all the
literature of the times, and even an adept in school divinity,
he was regarded by his people with indulgent affection
and high expectation. At peace with all Europe,
and in possession of a well-stored public treasury, he
found his subjects advancing in commerce and the arts,
and was himself furnished with the means of contributing
to their power and prosperity. His first measures were
dictated by the wisest policy, and were at the same time
well suited to increase his popularity. He chose as his
ministers, men of eminent abilities and experience; con-
formed, by proclamation, the general pardon granted by
the late king; and renewed the treaties of peace which his
father had concluded with Scotland, France, and Spain.
But, destitute of wisdom to improve his advantages,
and of virtue to prosecute the welfare of his subjects, he be-
came negligent of public affairs; and abandoning himself
to idle dissipation, entrusted the government of the state
to the hands of his ministers. Even in gratifying the
wishes of the nation, he shewed himself more oppressive
than just. Empson and Dudley, the instruments of the
late king's rapacity, were brought to trial; but, as they
could not be impeached for having merely put the laws
in execution in obedience to the will of their sovereign,
and as they had cautiously preserved the royal orders for
all their proceedings, they were charged with a treason-
able design to seize the administration of the govern-
ment upon the decease of their late master, and, by the
weight of popular prejudice and of court influence, with-
out either probability or proof, were condemned and ex-
cuted.

One of the first and most important matters, which
engaged the attention of the council, was the marriage of
the king to his brother's widow, Catherine, the Infanta
of Spain, to whom he had formerly been contracted, and
a dispensation for the union obtained from the Pope.
Though Henry himself was averse to the match, and it
was opposed by Warham, archbishop of Canterbury, as
an incestuous alliance, yet the majority of the council,
for political reasons, recommended the completion of the
contract. The royal nuptials were solemnized at Green-
wich, June 7, 1509, and the ceremony of the coronation
was soon afterwards performed with the most extradi-

tory pomp and magnificence. Engaged in a succession
of expensive amusements, the young king seemed to
think himself born for no other object, than to dissipate
the treasures which his father had amassed; but not con-
tented with his own private extravagance, he proceeded
to involve his people in the heavier burdens of an
meaning and unnecessary war. Suceded by the artifices
of Pope Julius II. and of Ferdinand king of Spain, he
entered into a league with them against Louis XII.
of France. He was flattered with the idea of being the pro-
tector of the church, and of receiving the title of "The
Most Christian King," which the pope had promised
to transfer from the French to the English monarch. He
was so far blinded by vanity and ambition, as even to
announce an intention of conquering France, and annex-
ing it to the English crown. The parliament and the
nation entered with sufficient alacrity into his views, and
granted the most liberal supplies for prosecuting the war.
In 1513, having appointed the queen regent of the king-
don, Henry landed at Calais with a powerful army; and
after an easy victory over the French, a few useless sieges,
and an expensive display of his magnificence at Tournay,
he returned to England, with sufficient honour to his
troops, but with no advantage to his kingdom. His un-
provoked attack upon the French king, had involved him
in a war also with James IV. of Scotland; and, though
his arms were here attended with greater military success,
by the fall of the Scottish king, with the flower of his
nobility, in the memorable battle of Flodden-field; yet
little political benefit accrued to his subjects to compen-
sate the death of his sister's husband, who might have
proved one of his most faithful allies. Discovering,
however, the selfish views of his confederates, who were
severally negotiating secret treaties with the French
king, he readily listened to the overtures of Louis, with
whom he not only concluded a peace, but also formed a
family alliance, by giving him in marriage his youngest
sister, the Princess Mary.

Henry, now left at liberty to indulge his love of ex-

pensive pleasures, soon exhausted all the treasures which
he had inherited from his father, or obtained from his
parliament; and he had found a minister ready to gratify
his most extravagant demands, and to execute his most

in England. 649

Cardinal

Wolsey

minister.

The king's marriage.

The war against France, 511.

Peace with France, August 7, 1514.

Interviews with Charles and Francis, 1520.
but meditated to retrovert the king and the minister in his interests. An offensive alliance was soon after concluded with the pope and emperor against France; and the Princess Mary, Henry's only child, was betrothed to Charles.

The king, strictly attached to the church of Rome, and particularly displeased with the attacks of Luther upon his favourite author, Thomas Aquinas, opposed, with all his influence, the progress of the Reformation; and even wrote a book in Latin against the great reformer, a production which is considered as sufficiently creditable to his talents, and which procured him from Pope Leo, the title of "Defender of the Faith."

An invading army was sent into France in 1522; and in the year following, an expedition was made against Scotland, in order to break the alliance which subsisted between the Scottish and the French governments. But the immense treasures of Henry VII. were now exhausted, by a succession of empty pageants, guilty pleasures, and useless enterprises; and it was necessary to find money, not only for the prosecution of the war, but even for the ordinary charges of the government. Large sums were levied under the name of "a benevolence," which were not granted without loud murmurings on the part of the nation. A parliament and a convocation were summoned; but neither the clergy nor the commons were so easily managed, or so liberal in their grants, as Wolsey had expected, and seven years were suffered to elapse before they were again assembled. Wolsey, attempting to render the king independent of the parliament, first levied in one year what they had granted payable in four; and next proceeded to raise money upon the king's authority alone. The people, at length roused from their long submission by the exorbitancy and the illegality of his exactions, openly opposed the commissioners, and began to threaten a general insurrection. Henry, alarmed by the consequences of his minister's precipitate measures, issued circular letters to all the counties, disavowing the assessment, and declaring that he meant only to apply to his subjects for "a benevolence." But the city of London, hesitating to comply with his demand, and open insurrections breaking out in different parts of the kingdom, the king found it prudent to suspend his meditated usurpations; and the cardinal hastened to make his peace with the sovereign, by presenting him with a magnificent palace at Westminster, which he pretended to have erected, from the first, for his master's use. But a period was now approaching to the exorbitant power of this artful and ambitious prelate; and the same event, which shook his hold of the king's favour, served to overthrow in England the whole system of papal tyranny.

Henry had begun, (at what time and from what motives is not precisely ascertained,) to entertain doubts concerning the legality of his marriage with his brother's widow, Catherine of Spain; and to meditate the design of procuring a divorce. It is certain, that Henry VII. afterwards convinced of the unlawfulness of the match which he had contracted for his son, charged him, upon his death-bed, never to consent to its celebration; and that the states of Castile, when treating respecting the proposal of a marriage between the Emperor Charles and Henry's daughter Mary, had, among other objections, insisted upon the illegitimate birth of that princess. The marriage of Henry and Catherine had been considered by all parties from the beginning as sanctified only by the dispensation of the pope; but, by the progress of the Reformation in England, the authority of such decisions was more freely questioned than in former times. Cardinal Wolsey, and all the English prelates, with only one exception, concurred in declaring that the king's marriage was unlawful; and Henry found it decided by his favourite theologian Aquinas, that, though the pope may dispense with the rules of the church, the laws of God cannot be set aside by any authority, inferior to that by which they were enacted. The decay of Katherine's beauty, and the passion which Henry had conceived for Anne Boleyn, one of the queen's maids of honour, though not perhaps the exciting causes of his scruples, furnished additional motives to his desire of a divorce.

Formal and repeated applications were made to the pope, to annul the king's marriage with Catherine; but his holiness, while he professed his desire to comply with Henry's request, was averse by the power of the emperor; and practised various artifices, to evade the demands of the English monarch. Urged at length by his solicitations, he commissions Cardinal Campegio as his legate to London, who, together with Cardinal Wolsey, should hold a court for trying the validity of the king's marriage; but, when the proceedings were nearly brought to a conclusion, the legate, upon some frivolous pretences, proscribed the court, and the pontiff a few days after adjourned the cause to his own judgment at Rome.

Wolsey had long foreseen, that his ruin would be the consequence of the king's suit for a divorce; and his fall took place more suddenly than could have been anticipated. Solicitous to gratify his royal master, yet fearing to offend the pope, his conduct, throughout the whole course of the affair, was mysterious and temporizing. The king, at last, confident of his minister's talents, or blinded by the ardour of his wishes, suspected his fidelity and zeal in managing the affair. Anne Boleyn, who had been possessed against the cardinal, imputed to him the failure of her hopes; and her influence over Henry contributed to fortify his suspicions against his favourite. Even the queen and her partizans, judging of Wolsey by the part which he had openly acted, expressed the greatest animosity against him; and the most opposite factions seemed to combine for the overthrow of that haughty minister.

Henry, after remaining some time in suspense, at length resolved upon the ruin of Wolsey; required him to deliver up the great seal, and to retire from his palace in London to his country seat near Hampton Court. He next ordered him to be indicted in the star chamber, and abandoned him to all the rigour of the parliament; but though many charges were brought against him, it was found difficult to establish the proof of any crime; and Henry remitted the sentence of forfeiture, which had been pronounced against him, and restored his property which had been seized. Afterwards, however, finding that he stood in the way of his measures against the pope, renewed the prosecution against him; commanded him to be arrested for high treason, and to be brought to London for trial. But by the fatigues of the journey, the agitation of his mind, or, as some have alleged, by the effects of poison which he had taken, he was seized with a violent disorder by the way, and died at Leicester Abbey. See WOLSEY.

Henry, being thus freed from a person whom he regarded as an obstacle to his intentions, resolved, by the
advice of Cranmer, to have the legality of his marriage discussed by all the universities of Europe; and having at length procured their suffrages, as well as the opinions of the Rabbis in his favour, he determined to commence an open resistance to the pope's authority. By the revival of an old statute, which had been employed to ruin Wolsey, and which rendered his exercise of the power of legate unlawful, though it had been done with his own permission, he indicted all those ecclesiastics who had submitted to the legatine court, for having violated the law; reduced them to compound for their offence by a fine of L.118,000; and, at the same time, extorted from them a confession, that "the king was the protector and the supreme head of the church of England." By the strict execution of the old statute above mentioned, much of the profits, and still more of the power, of the church of Rome was cut off; and by several new acts, the usurpations of the pontiff were farther abolished.

Henry, now determined in his own mind, and prepared for all consequences, privately married Anne Boleyn; and upon her becoming pregnant, publicly announced her as his wife, by carrying her in a magnificent procession through the streets of London. His marriage with Catherine having been pronounced invalid by a court held under Archbishop Cranmer, the new queen was publicly crowned with suitable splendour, and was soon afterwards delivered of a daughter, who received the name of Elizabeth. When intelligence of these transactions was conveyed to Rome, the pope immediately issued a sentence, declaring the nullity of Cranmer's decision, and requiring Henry, upon pain of excommunication, to restore Catherine to her place as his only lawful wife. The king, upon receiving information of this decree against him, no longer delayed to execute his long meditated scheme of renouncing the Papal jurisdiction.

A parliament was assembled, which ratified the king's marriage with Anne Boleyn, and appointed the crown to descend to the issue of this connection; declared the king to be the only supreme head on earth of the church of England, and granted him a right to all annates and tythes of benefices, which had hitherto been paid to the see of Rome. The clergy, assembled in convocation, passed a vote, that, by the law of God, the Roman pontiff had no more jurisdiction in England than any other foreign bishop; and the bishops even took out new commissions from the crown, acknowledging all their spiritual and episcopal authority to be derived ultimately from the civil magistrate.

While, however, the king of England threw off the political yoke of the church of Rome, he adhered, with blind obstinacy, to its most pernicious errors; and his subjects were thus brought into a dilemma, which exposed all parties to persecution at his pleasure. It was a capital crime to acknowledge the pope's supremacy; and, on the other hand, it was equally punishable to profess the reformed principles. The Queen, Cromwell, secretary of state, and Archbishop Cranmer, secretly favoured the Protestant tenets; but the Duke of Norfolk, Gardiner bishop of Winchester, and Sir Thomas More, who succeeded Wolsey as chancellor, were zealous supporters of the old religion. The latter, with all his natural gentleness and enlarged mind, acted the part of a furious inquisitor in the prosecution of heresy; and, under his administration, many were put to death for harbouring the reformers, neglecting the fasts of the church, or declining against the vices of the Popish ecclesiastics.

By these severe executions, however, the people were rendered only the more favourable to the new doctrines, and inspired with greater horror of the old; while on the other hand, many eminent individuals, who were friendly to the Romish church, and even instrumental in those cruelties, suffered in their turn whenever they ventured to oppose the king's measures. Fisher, bishop of Rochester, and Sir Thomas More, having refused to take the oath which acknowledged Henry's supremacy as head of the church, and expressed an approbation of his divorce, were thrown into prison, and treated with unusual severity. Archbishop Cranmer, after having failed in his endeavours to persuade them to comply, used all his influence to alleviate their sufferings, and to save them from the fate with which they were threatened. But the king, knowing their attachment to the see of Rome, and the high regard which was paid by all its adherents to their opinion and example, was determined to awe the Papal party by their destruction. They were tried, condemned, and beheaded. (See More.) When their execution was reported at Rome, the utmost indignation was expressed against Henry; and he was denounced by the Italian orators, as worse than Caligula, Nero, Domitian, and all the most unrelenting enemies of the church. Paul III. who had succeeded to the pontificate, summoned the king of England, with all his adherents, to appear at Rome, within ninety days, to answer for his crimes; and should they fail to obey, pronounced the sentence of excommunication, depriving Henry of his crown, laying the kingdom under an interdict, declaring the issue of his second marriage illegitimate, dissolving all his leagues with any Catholic prince, bestowing his dominions upon any invader, absolving his subjects from their oath of allegiance, and declaring it lawful for any one to seize, enslave, and plunder them, as long as they retained their fidelity to his person. But these censures, though passed, were not published, till all agreement with the English monarch should become hopeless, and till the emperor should be in a condition to carry the sentence into execution. Henry, on his part, knowing that he might expect every injury which it might be in the power of Charles to inflict, exerted all his policy to incapacitate his adversary from giving effect to his resentment, renewed his league with Francis, and even made advances to the leaders of the Protestant league in Germany. In the mean time, the decease of Queen Catherine, by removing the foundation of the emperor's principal quarrel with Henry, induced the former to make attempts rather to conciliate his friendship, and to detach him from the interests of France. Thus was the king left at full liberty to exercise the decisive authority which he had acquired over his subjects, and to pursue his schemes for the utter destruction of papal authority in his dominions.

The monks, in their rage against Henry, employed all their influence to inflame the people against his government; and having engaged in various treasonable practices, the king resolved to root them out of his kingdom. Commissioners were appointed to inspect the monasteries; and the greatest disorders having been detected, the parliament was directed to suppress all the smaller religious houses, and to confiscate their goods and revenues for the use of the crown. The reformers gained a further triumph, by a vote passed in convocation, and understood to be directed by the king, for publishing a new translation of the sacred scriptures; but their cause sustained,
about the same time, a severe blow in the fate which held their great patroness Anne Boleyn. Her attachment to the Protestant opinions created her many inveterate enemies, who only waited for a favourable occasion to destroy her influence with the king. Henry’s love to this lady, during the six years which were employed in procuring his divorce from Catherine, seemed to increase by every obstacle which was thrown in the way of his desires; but he had not long obtained possession of his object, when his affection languished, and his heart became estranged from his consort. As she had been delivered of a dead son, which disappointed his extreme desire of male issue, his violent temper was ready to regard her as answerable for the misfortune; and her enemies took occasion, from her levity of behaviour, to inflame the king’s jealousy, by putting the worst construction upon the harmless, but unbecoming liberties to which she was addicted. Her sister-in-law particularly, the Viscountess of Rocheford, a woman of most profligate character, regardless of either truth or humanity, instigated the most cruel suspicions into the mind of Henry; and even went the length of suggesting, that the queen was engaged in a criminal correspondence with her own brother. The king’s jealousy became more unremitting and more ready to lay hold of the slightest circumstance, in consequence of his love being already transferred to another object, Jane Seymour, one of the queen’s maids of honour. The queen’s innocence cannot reasonably be questioned; and even though she had been more guilty, Henry’s own notorious infidelities as a husband might have restrained him from exacting the punishment of death. But his cruelty was as insatiable as his lewdness; and the unhappy object of his rage, being tried for adultery and incest, was condemned, without any legal evidence, to be burned or beheaded at the king’s pleasure. When this dreadful sentence was pronounced, she discovered no emotions of terror; but lifting up her hands towards heaven, she said, “O Father! O Creator! thou who art the way, the truth, and the life, thou knowest that I have not deserved this fate.” She continued to the last to make the most solemn protestations of her innocence; and behaved, at her execution, with the utmost decency and resolution. Henry himself gave the best proof of the queen’s innocence, and of the sentiment by which he had been actuated in her condemnation, by celebrating, on the very day after her execution, his marriage with Jane Seymour; but his new consort died in the following year, after having been delivered of a son, who was named Edward.

Having summoned a parliament and convocation, he found both assemblies completely subservient to all his views; and having acquired, by their enactments, the most absolute authority, he proceeded, without restraint or remorse, to gratify the savage and selfish passions of his heart. The tyrannical nature of his measures, and particularly the destitute condition in which the monks, expelled from the suppressed monasteries, were left to wander about the country, at length excited strong discontent among the people, which in many places broke out into formidable insurrections. These, however, having been repressed, and their principal leaders put to death, his authority at home, and his influence with foreign powers, having been confirmed by the birth of a son, he resolved to seize the present opportunity for accomplishing the entire destruction of the monasteries. To this measure he was impelled, at once by resentment against some of the abbots, who were suspected of having encouraged the recent disturbances, and by his rapacious desires to supply the means of his profusion. In consequence of the king’s unlimited power, and the progress of the Reformation even among those who had taken the vows, his design was so successfully conducted, that, in less than two years, he got possession of all the monastic revenues. He had now suppressed, at different times, 645 monasteries, (of which 28 had abbots possessed of seats in parliament,) 90 colleges, 257 chantries and free chapels, and 110 hospitals. The whole annual revenue of these establishments amounted to £161,100; a sum which, contrary to what has been generally apprehended, did not exceed the twentieth part of the national income. In order to reconcile the people to these severe measures and extensive innovations, the most detestable stories were propagated respecting the immoral lives of the monks; their relics, and other superstitions, were exposed to ridicule; and their pretended miracles openly disclosed: (See Reformation.) The nation was also made to understand, that the king would henceforth have no occasion to levy taxes, but would be able, from the abbey lands alone, to defray, both during peace and war, the whole charges of government; while, at the same time, he interested the higher orders in his measures, by giving in presents, or selling at low prices, the revenues of convents, and even the benefits of the regular clergy, to his favourites and courtiers.

By all these acts of violence, the pope was at length incited to publish the bull which had been passed against the king of England; and having hopes, from the reconciliation which had now taken place between Charles and Francis, that they would unite in the execution of the sentence, he publicly delivered Henry’s soul to the devil, and his dominions to the first invader. Labels were dispersed anew, denouncing him as worse than all preceding persecutors, and particularly reproaching him with his resemblance to the Emperor Julian, whom he was said to have imitated in his learning and apocraypocy, while he was much inferior to him in point of morals. In some of these publications, Henry discovered the pen of his kinsman Cardinal Pole, whom he had originally distinguished with his favour, but who had taken a violent part against the king in support of the papal claims. Several of the nobility were brought to trial, and condemned to death for having joined in a conspiracy with the cardinal, in the design, as was suspected, of raising him to the throne by a marriage with the Princess Mary.

Though Henry had greatly changed the theological sentiments in which he had been educated, he was extremely bigotted and dogmatical in the support of those which he retained; and so much had his native arrogance been inflamed by the flattery of his courtiers, that he thought himself entitled to regulate, by his own private standard, the religious faith of the whole nation. He particularly rested his orthodoxy upon the most absurd of all the popish tenets, namely, the doctrine of transubstantiation; and determined to maintain, in this essential article, the purity of the Catholic faith, he denounced all departure from the belief of this point as heretical and detestable. In his vanity and zeal, he even held a public disputation on the subject with one Lambert, a schoolmaster, who had appealed to the king’s judgment; and who was cruelly burned at the stake, for his opposition to this favourite test. In the parliament a bill was passed, called by the Protestants the “bloody

Statistics, which reduced the essential articles of religion to the number of six, namely, the real presence, communion in one kind, the perpetual obligation of vows of chastity, the edibility of the clergy, the utility of private masses, and the necessity of auricular confession. A denial of any of these points was punishable with death; and, even though recanted, subjected the offender to the forfeiture of his goods, and imprisonment during the king's pleasure: but, in the case of the first, the privilege of recantation was not admitted; which was a degree of severity hitherto unexampled, and even unknown to the inquisition itself. With the most abject servility, the parliament enacted whatever the king and his ministers thought proper to dictate; confirmed the surrender of the monasteries, and secured the property of the abbey lands to the king and his successors for ever; attained of high treason, without any legal evidence or inquiry, but upon a mere suspicion of having aided the insurgents, the Marchioness of Exeter, the Countess of Salisbury, Sir Adrian Fortescue, and Sir Thomas Dingley,—the two last of whom were executed; and at last, in one sweeping act, made an entire surrender of all their civil liberties, by giving to the king's proclamations the same force as a parliamentary statute.

As soon as the act of the six articles had passed, not less than 500 persons, in consequence of the zeal with which the Catholics informed against offenders, were committed to prison; but though Cranmer, Cromwell, and others favourable to the Protestant cause, had not been able to prevent the passing of the act, they found means to evade its execution; and, in consequence of their remonstrating against the cruelty of punishing so many delinquents, they were all set at liberty. The king, at the same time, as if desirous to give each party an opportunity of triumphing in turn, permitted every individual to have in his family a copy of the new translation of the Bible.

In the course of the year which followed the death of Queen Jane, Henry had been engaged in several matrimonial treaties, particularly with the duchess dowager of Milan, and with Mary of Guise, who married James V. of Scotland; but at length, by the advice of Cromwell, he contracted a match with a Protestant princess, Anne of Cleves, of whom a flattering portrait had been shown to him, and whose relations had great weight among the Lutheran leaders. Finding, however, that her beauty did not correspond with the descriptions which he had received, he conceived a strong dislike to her person; and was induced, from mere political motives, to complete the marriage.

A parliament was this year assembled, in which none of the abbots or priors were allowed a place; and the king, after informing them by the mouth of the chancellor, that, in consequence of the great diversity of religions which still prevailed, he had appointed some eminent divines to draw up a list of tenets to which his subjects were to assent, proceeded to make the very unexpected demand of a subsidy, on account of the great expense which he had incurred in putting the kingdom in a proper state of defence. Already had he dissipated the immense sums which he had acquired by the plunder of the church, and he had this very year suppressed the only remaining religious order in England, the Knights of St John of Jerusalem, or "the Knights of Malta," as they are commonly called, whose large revenues formed no contemptible addition to the spoil which he had collected from the monasteries. The commons, though lavish of the liberty and blood of their fellow subjects, were sufficiently frugal of their money; and, had it not been owing to the earnest desire of both the Protestant and the Popish parties to gain the king to their views, he would have found it no easy matter to procure their consent to a demand, which was so contrary to all the expectations which had recently been held out to the public, of a long exemption from supplies to the crown.

These measures, though passed in parliament, excited universal murmurs against the king and his minister, Cromwell. The latter had long been hated by the nobility, on account of his low extraction, and his possession of many offices and honours which they considered as belonging only to persons of illustrious birth; and he was equally obnoxious to the clergy and the people, as the supposed author of Henry's rapacious proceedings. By the Catholics he was regarded as the concealed enemy of their religion; and by the Protestants, he was reproached with the timidity or treachery of his conduct, in giving his countenance to the persecutions by which they were harassed. He had lost all favour with the king, in consequence of his having been the adviser of his late joyless marriage with Anne of Cleves; and, as Henry had now fixed his affections upon Catherine Howard, niece of the Duke of Norfolk, who had long been at enmity with Cromwell, he was easily persuaded, at once to seek a divorce from his queen, and to consent to the ruin of his minister. Cromwell was accused of heresy and treason, and, without examination or evidence, was condemned to death. He made the most humble submission to the king, and wrote to him for mercy in so moving a strain as is said to have drawn tears from his eyes. Archbishop Cranmer interceded earnestly in his behalf, and even went so far as to affirm, that "no king in this realm ever had such a servant." But the charms of Catherine Howard and the importunities of her friends prevailed. Cromwell, one of the wisest and most upright ministers who had ever served in England, and who, in all his exaltation, betrayed no insolence towards his inferiors, and no forgetfulness of his former obligations, fell a sacrifice to the passions of a capricious tyrant, to whom he had been only too obsequious.

The measures for Henry's divorce were carried on at the same time with the bill of attainder against Cromwell. The convocation and parliament readily annulled his marriage, upon his own affirmation, that he had not consented inwardly to the match, and had never consummated the union. Anne herself discovered the utmost indifference in the matter; and, accepting a settlement of L. 3000 a-year, freely consented to the divorce; but, unwilling to return to her own country after sustaining such an affront, she lived and died in England.

The king's marriage with Catherine Howard, which soon followed his divorce from Anne of Cleves, was regarded by the Catholics as a favourable event to their party; and a furious prosecution was commenced against the Protestants who offended against the law of the six articles. Nor did Henry spare the Papists who denied his supremacy; but displayed, with disgusting ostentation, his intemperate oppression of both parties. Three Protestants, Barnes, Jerome, and Gerard, coupled with three Catholics, Abel, Fisherstone, and Powell, were carried to execution at the same time; which gave occasion to a foreigner to remark, that, "in England, those who were against the pope were burned, and those who.
ENGLAND.

In order to quiet the northern districts, and to confer with the king of Scotland, Henry took a journey to the city of York; but James being bribed by his clergy, who dreaded the consequences of this meeting, failed to appear; and his uncle, enraged at this affront, immediately ordered war to be carried on against the Scots by sea and land. Returning to his capital, he experienced a disgrace which touched him much more sensibly. He had openly proclaimed the satisfaction which he enjoyed in his new marriage, and even returned solemn thanks to heaven for his conjugal felicity. On the very next day he received information, too circumstantial and authentic to admit of doubt, that his concert had led a very disgraceful life before marriage, and was strongly suspected of still continuing her licentious indulgences. Two of her paramours having confessed their guilt; the queen herself, while she insisted upon her fidelity to the king's bed, having admitted her former acts of lewdness; and the king being little inclined to make any distinction between these degrees of criminality, she was condemned to death, and beheaded on Tower-hill, along with the infamous Duchess of Rochford, who had conducted her secret amours. At the same time, a bill of attainder for misprision of treason was passed against her grandmother, the old Duchess of Norfolk, her uncle Lord Howard and his lady, the Duchess of Bridgewater, and several other persons of distinction, because they had concealed the queen's vicious course of life; but, probably from reflecting upon the oppressive cruelty of such a proceeding, he afterwards granted a pardon to most of them. In order, however, to guard against the renewal of such misfortunes, he enacted several rigorous and indelicate laws against concealing the incontinence of future queens, which furnished matter of great derision to the people, and which were all repealed in the first year of the following reign.

Henry, in order to enrich his exchequer without endangering a subsidy, took further steps to dissolve colleges, hospitals, and similar institutions; and the parliament, to promote his purpose, annulled all the local statutes of these foundations, which prevented the surrender of their revenues. He proceeded to make inroads also upon the secular clergy, and pillaged several of the wealthier sees of their chapter lands, with which he enriched his parasitical flatterers. While he gratified his rapacity by plundering the church, he continued to indulge his bigotry by persecuting heretics. He engaged the parliament indeed, to mitigate the law of the six articles, as far as regarded those priests who entered into the married state; but he still persisted in maintaining the purity of speculative principles, and enforcing uniformity in religious sentiments. He had appointed a commission, to frame a system of faith for the nation; and the parliament, in the grossness of their servility, had passed a law in 1541, by which they blindly ratified, by anticipation, all the tenets which these divines should afterwards establish with the king's consent. A small volume was at length published, called the Institution of a Christian Man, which may, in fact, be considered as the composition of the king, and which was voted by the convocation to be the standard of sound religion. In all the great points of Christian truth, this production favoured the sentiments of the reformers; but the sacraments, which a few years before had been limited to three, were here again increased to the number of seven, conformably to the opinion of the Catholics. But the king soon after ordered a new book to be composed, called The Condition of a Christian Man, which, without consulting the convocation, but by his own authority and that of the parliament, he published to the nation as the model of their faith, and required them to veer about in their belief at every signal of his inconstancy. He was much perplexed, however, what course to take with the scriptures; and seems to have felt the difficulty of reconciling his requisitions of uniformity with the permission of free enquiry. With the concurrence, therefore, of the parliament, he retracted the concession which had been formerly made, that every person might have the scriptures in his family, and now prohibited all but gentlemen and merchants from perusing them. Even to these classes the permission was granted with evident hesitation and dread of the consequences; for they were allowed to read for themselves, with this cautious proviso, "so it be done quietly, and with good order."

The mass-book also passed under the king's revision; but the principal alterations consisted in striking from the calendar a few fictitious saints, and erasing the name of the pope wherever it occurred. This latter apellation was carefully excluded from every new book that was printed, and blotted out in every old one that was sold, in order, if possible, to abolish the term from the language, and to make the people forget that such a personage existed.

After the death of James V. of Scotland, Henry projected the scheme of uniting that kingdom to his own dominions, by marrying his son Edward to the heiress of the Scottish crown; and a treaty to that effect was actually concluded, by which it was agreed, that the Princess Mary should remain in Scotland till she should be ten years of age; that she should then be sent to England to be educated; and that the kingdom, notwithstanding its union with England, should retain its own laws and privileges. But all these prospects of perpetual amity between the two nations were destroyed by the intrigues of Cardinal Beaton, and the weakness of the Regent James Hamilton, Earl of Arran, and the violent temper of Henry himself, who, upon the first appearance of opposition to his views, precipitated a new war against the Scots. His fleet landed ten thousand men at Leith, who took and pillaged the city of Edinburgh, while another army laid waste the whole country between Berwick and Haddington. By this violent incursion, he only inflamed the passions of the Scots without subsiding their spirit; and, as was commonly observed, did too much if he wished to solicit an alliance, but too little if he intended to make a conquest.

In the mean time, while thus ardently bent upon providing a match for his son, he formed another matrimonial connection for himself; and took as his sixth wife Catherine Parr, widow of Nevil Lord Latimer, a lady who secretly favoured the sentiments of the reformers; but who was obliged to conduct herself with so great caution, that she durst not even intercede for three Protes-
tart gentlemen, and a young lady of her own acquaintance, who were all burnt at Windsor a short time after her marriage. Once indeed she attempted to argue with the king on theological subjects, who complained of her to Bishop Gardiner, and who was instigated, by the advice of that prelate, to proceed against her with the utmost rigour. Articles of impeachment were actually drawn up for her trial, and the hour fixed for her commitment to the Tower; but having received timely intimation of her approaching fate, she found means, by her prudence and address, to pacify her husband, and disappoint her enemies.

The war with Scotland had led to a rupture with France; and in order to support the burdens of this double contest, Henry, instead of demanding a subsidy from his parliament, (which with all his authority he generally found it difficult to control in pecuniary grants,) had recourse to many dishonourable modes of filling his treasury. He required new loans from his subjects, though he had recently enacted laws, which exempted him from the payment of his old debts. He increased the nominal value of gold and silver; and even caused base money to be coined, and to be made current by proclamation. Resolving, in concert with the emperor Charles, to command his army, which was destined for the invasion of France, he thought proper, before his departure, to fix the rule of succession to the crown. By the act passed for this purpose, it was settled, 1. On Edward Prince of Wales, and his lawful issue; 2. On the king's issue by his present or any future queen; 3. On the Princess Mary, and her lawful issue; 4. On the Princess Elizabeth, and her lawful issue; and, failing all these, on such as the king pleased to appoint by letters patent, or by his last will. But, with his usual caprice, while he opened the way to the throne to Mary and Elizabeth, he would not allow those acts to be reversed which had declared them illegitimate, and reserved the power of still excluding them from the succession, if they refused to submit to any conditions which he might be pleased to impose.

Henry having appointed the Queen to the office of Regent during his absence, passed over to Calais with an army of 30,000 men, accompanied by the principal nobles and gentlemen of his kingdom. But, after taking Boulogne, a misunderstanding arose between the allied sovereigns; and the king of England returned home, as in all his military enterprises, with an acquisition of little importance, made at an immense expense. The war with Scotland in the mean time was conducted feebly, and with various success. The commons granted a subsidy, to support the expenses of these two wars; but apprehensive lest more demands should be made upon them, they endeavoured to save themselves, by bestowing on the king all the revenues of the universities, as well as of the free chapels and hospitals. Henry, however, though pleased with a concession which increased his power, took care to acquaint the universities, that he had no intention to deprive learning of its endowments; and it is to his generosity, not to any protection afforded by his prostitute parliament, that these celebrated establishments owe their existence.

Having concluded a peace with France and Scotland, Henry turned his attention to domestic affairs, and particularly to his favourite object of promoting religious uniformity. The hopes of the reformers, who had been rather discouraged by the severe law of the six articles, were revived considerably by some of his measures. He permitted the litany to be celebrated in the vulgar tongue; and added a prayer, to "save us from the tyranny of the Bishop of Rome, and from all his detestable enormities." He protected Cranmer in a very decided manner, from the cabals of his enemies among the Popish party; and entirely withdrew his favour from Gardiner, on account of his malignant attempts to accomplish the destruction of the Queen. His tyrannical disposition, however, irritated and soured by his declining state of health, impelled him to punish, with fresh severities, all who presumed to suffer from himself, especially on the capital point of the real presence. An ulcer broke out in his leg, which occasioned him extreme pain, and which, in addition to his monstrous corpulency, at once threatened his life, and rendered him more than usually passionate and untractable. He became more and more outrageous as his end approached; and the cruelty of his temper seemed to increase, in proportion as his power of exercising it drew nearer to its termination.

The last objects of Henry's cruelty and injustice, were the Duke of Norfolk, and his son the Earl of Surrey; the former the most faithful of the king's ministers, and the latter the most accomplished of the English nobility. Their greatness, and not their guilt, excited the workings of the tyrant's violent and jealous spirit. The great power of Norfolk, his attachment to the ancient religion, and his alliance to the throne, suggested to Henry's mind that, during his son's minority, great danger might arise, both to the public tranquillity, and to the new ecclesiastical system, from the attempts of so potent a subject. These suspicions were increased by some unguarded expressions used by Surrey, when he was recalled from the government of Boulogne, by his refusal of all matrimonial connections that had been proposed to him, and by an apprehension that he entertained the ambitious view of espousing the Princess Mary, as a step to the crown. Disdained also with the whole family, on account of the conduct of Catherine Howard, he yielded the more readily to his vindictive feelings, and, determined upon the ruin of the two noblemen, he gave private orders to arrest and commit them to the Tower on the same day. Surrey, accused of entertaining Italian spies in his family, of holding a secret correspondence with Cardinal Pole, and of manifesting his aim at the crown, by having the annex of Edward the Confessor on his escutcheon, was without proofs, and in defiance of his able defence, condemned and executed for high treason. No greater crime could be discovered against Norfolk, than his once saying, that the king could not hold out long, and that the kingdom was likely to fall into disorders, through the diversity of religious opinions; but a bill of attainder nevertheless was passed against him in the House of Peers, without any species of trial; and the king hastening it through the House of Commons lest his victim should escape, issued the death warrant with all possible expedition. But his own death on the evening preceding the day of execution, procured a reprieve to the noble prisoner; and it was not thought advisable to commence a new reign with the sacrifice of the greatest subject in the kingdom.

Though the king's end had for several days been evidently approaching, none of his attendants dared to inform him of his condition. But Sir Anthony Denny having at length ventured to make the solemn intimation, Henry expressed his resignation, and ordered Cranmer to be brought to him. The king was speechless before

His character.

Henry was very tall, strong, stately in his air, and in 
his youth uncommonly handsome, excelling in all manly 
exercises, fond of magnificence, and full of personal 
courage. He possessed great vigour of mind, and was 
distinguished by an extensive capacity. He was skilled in 
music, and spoke with fluency several foreign languages, 
particularly Latin and French. He was sincere, frank, 
liberal, and capable at least of temporary friendships and 
attachments. But his vices were of the darkest hue, and 
comprehend all the worst qualities of human nature. A 
violent impetuosity of temper, an insatiable love of pleasure, 
and a radical cruelty of disposition, were the distin-
guishing features of his mind, and the sources of his 
greatest crimes, of his profusion, rapacity, injustice, ob-
stacny, arrogance, caprice, bigotry, and tyranny. He 
was filled with an extraordinary conceit of his own supe-
rior wisdom, and fond of flattery; uncontrollable in his 
desires, and inflexible in his purposes; never known to 
yield or to forgive; and never "sparing," as he said of 
himself, "a man in his anger, or a woman in his lust." 
Yet, in spite of his cruelty, extortion, and arbitrary go-
vornment, his exterior qualities so captivated the multi-
tude, that he not only acquired the regard, but in some 
degree possessed to the last the affection of his subjects. 
He had indeed so completely subdued their free spirit, 
that, like eastern slaves, they admired those arts of 
tyranny which degraded themselves; and had he not, by 
promoting their liberation from papal oppression, pro-
duced a corrective for his own despotism, it may be fairly 
questioned, whether the English constitution would ever 
have recovered from the repeated checks which its radical 
principles sustained in his reign.

Accession of Edward VI.

Edward VI. succeeded his father as king of England 
when he was only nine years of age; but, by the will of 
Henry, the government of the kingdom, till the Prince 
should have completed his 18th year, was intrusted to 
sixteen executors, and twelve counsellors, whom he him-
self had expressly nominated, and whom he seems to 
have expected to prove equally obsequious after his 
death as they had been during his life. Their first act, 
however, was to choose a protector of the realm, who 
might represent the royal majesty, and the choice fell upon 
the Earl of Hertford, who was the young king's maternal 
uncle, and naturally interested in his nephew's safety, 
while he himself possessed no claims to the throne, which 
could endanger the Prince's person, or the public tran-
quillity. Created Duke of Somerset, he procured a pa-
tent from the young king, by which he overturned the 
will of Henry VIII. and secured to himself as regent the 
full regal power. He had long been regarded as secret-
ly favourable to the principles of the reformers; and, as 
soon as his authority was established, he openly avowed 
his intention of correcting all the abuses in the former 
system. The alterations, indeed, made by Henry, were 
rather acts of separation from the Pope, than of reforma-
tion from Popery; but now the errors of Rome began to 
be actually removed, and the history of Edward's reign 
becomes rather a detail of the methods employed by his 
governors for reforming religion, than a description of 
political measures, or warlike events.

The protector took care, that all who were entrusted 
with the education of the young king should be attached 
to the principles of the Reformation; and, in all his 
schemes for correcting the errors of popery, he had re-
course to the counsels of Archbishop Cranmer, a person 
of the greatest moderation and prudence. They experi-
cenced considerable opposition from Gardiner, Bishop of 
Winchester, which at length drew upon him the in-
dignation of the council; and he was committed to the 
Fleet-prison, where he was treated, not, indeed, with 
the cruelty of papish persecutors, but with very unbecom-
ing severity. Visitors, consisting of ecclesiastics and laymen 
united, were sent to all the dioceses, with power to cor-
rect the irregularities of the clergy, to abolish ancient 
superstitions, and to bring the worship and discipline of 
the church nearer to the practice of the reformed. Or-
ders were issued to restrain the monks, who had been 
placed in the vacant churches, from preaching in defence 
of the old abuses; and twelve homilies were published, 
which the clergy were enjoined to read to the people, 
instead of addressing them in discourses of their own 
production. The protector, having made due provision 
for the stability of affairs at home, resolved to prosecute 
the war with Scotland, in order to accomplish the pro-
ject of the late king, for uniting the two kingdoms by 
the marriage of Edward and Mary; and, with an army of 
18,000 men, attended by a fleet of sixty sail, he ad-
vanced within sight of the Scottish capital. Having routed 
the army of the Scots at Pinkie with great slaughter, 
and appointed commissioners at Berwick to treat of a 
peace, he returned to London, with that increase of pop-
ularity and power, which a conqueror, it has been ob-
served, is always sure to acquire with the English na-
tion. To this character, however, he added more esti-
mate and amiable virtues; was humble, affable, and ac-
cessible to the meanest subject; and was obviously in-
fluenced in his general conduct by the principles of reli-
gion and honour. Having summoned a parliament, he 
abated the rigour of many former statutes, and particu-
larly abolished the law, by which the king's proclama-
tion was made of equal force with an act of parliament. 
The dawn, both of civil and religious liberty, began to 
rise upon the English nation; and the gradual refor-
mation of papal corruptions, continued to be carried on 
with prudent perseverance. Various superstitious prac-
tices were abolished; all images removed from the 
churches; private masses prohibited; and auricular con-
fession, hitherto accounted an indispensable duty, and 
always one of the most powerful engines of a corrupted 
church, was pronounced a matter of indifferenc, which 
the people might observe or omit, according to their own 
choice. The government of the kingdom became in a 
great measure aristocratical, in consequence of the late in-
crease of possessions which the nobles had acquired; and 
great distractions prevailed in the state. Lord Seymour, 
a man of insatiable ambition, and possessed of distin-
guished abilities, had recently married the queen dow-
ager, and by this alliance became the rival in power of 
his brother the protector. A contest between their wives, 
on the subject of precedence, created a breach be-
tween them, and the whole court and kingdom were di-
vided by their opposite cabals and pretensions. Sey-

Cabals and execution of Lord Seymour.

mour discovered his intriguing spirit and ambitious 
views, by the most rash and criminal conduct, by using 
unwarrantable means, during the protector's absence 
in Scotland, to captivate the affections of the young 
monarch, by making a direct attack upon his bro-
 ther's authority as unconstitutional, in as much as he
if an universal conspiracy had been formed, rose at once in several parts of the kingdom. It was only in Devonshire and Norfolk that they assumed the appearance of a regular army, and became formidable by their numbers. In the former county, one thousand rebels were cut to pieces by Lord Russel, and two thousand in the latter by the Earl of Warwick. Their leaders were tried and executed at London, and many of the inferior class put to death by martial law. Those that escaped, threw down their arms upon the offer of pardon; and a general indemnity was soon after published by the protector.

But while these tumultuary insurgents were thus quickly subdued, the factions in the council, under the artful management of Warwick, became daily more formidable to the protector. Somerset, rated with his high dignity, had paid too little attention to the opinions of the other executioners and counsellors, and discovered a disposition to govern every thing according to his own views. The nobility and gentry were in general displeased with the preference which he seemed, in the late commotions, to have given to the claims of the people. The people themselves, being much influenced by the Catholic party, and ascribing many of their distresses to the Reformation, of which he was the open patron, were not heartily affected to his authority. His interest being at length overpowered by the increasing power and influence of one of his immediate predecessors, and to submit to the most humiliating conditions; Warwick, the new protector, having made peace with Scotland and France, gave full scope to his aspiring and avaricious disposition. Finding that the principles of the Reformation had sunk too deep into the mind of Edward to be easily eradicated, he resolved to comply with the prince's inclinations, and pushed the cause of the Protestants with more zeal and violence than had ever been done by his predecessor. Many of the bishops, who favoured the Catholic tenets, were treated with great severity; several of them deprived of their sees, and others obliged to secure protection, by sacrificing the most considerable part of their revenues. An order was issued by the council for purging the libraries at Westminster and Oxford of all superstitious volumes; and much useless devastation was committed in the execution of these instructions. The council, however, were not inattentive to the interests of the public; and, by their wise regulations, excited a spirit of industry and commerce, hitherto unknown in England. But the ungovernable ambition of Warwick again involved the kingdom in domestic troubles. He procured for himself the title and ample possessions of the Duke of Northumberland. He found means to accomplish the condemnation and death of Somerset, and many of his friends, as the chief obstacles in his career. He summoned a new parliament, and took care, by the most arbitrary interference, to have such members returned as were obsequious to his will. He brought about a marriage between Lady Jane Gray and his fourth son, Lord Guilford Dudley; and, at the same time, fortified his family by other powerful alliances. He then proceeded, with his last project, to prevail with the young king, whose health was declining fast, to make such a change in the succession as would have brought forward his own daughter-in-law, Lady Jane, as next heir to the crown. The prince, accustomed to submit to his views, and anxious to secure a Protestant successor, agreed to refer the matter to the council; and at length, after many ob-
the intrigues and menaces of Northumberland prevailed.

After this settlement of the crown upon the heirs of the Duchess of Suffolk, the young king’s health visibly declined every day. By the advice of Northumberland, supported by an act of the council, his physicians were dismissed, and an ignorant old woman entrusted with the care of his health. Under her management, his worst symptoms rapidly increased, and he expired at Greenwich, in the 16th year of his age, and the 7th of his reign. He possessed great mildness of disposition, united with a sagacity far above his years; and had made attainments in learning which astonished all with whom he conversed. Amidst the struggles for power among his ministers, he was merely the instrument of their mutual resentment and intrigues; but he never signed the orders of execution against any party, without tears in his eyes. His young mind was deeply tinctured with the principles of sound religion; and his many virtues rendered him an object of tender affection to his subjects, who had soon reason to lament the short duration of his promising reign.

By the decease of Edward, there were four female claimants to the crown; Mary, the eldest daughter of Henry VIII. by Catherine of Spain, and the first in succession by her father’s will; but whose illegitimacy had never been repealed; Elizabeth, Henry’s second daughter by Anne Boleyn, who had also been declared illegitimate, but whose attachment to Protestant principles might otherwise have rendered her more acceptable to the nation; Mary, Queen of Scotland, descended from Henry’s eldest sister, whose legitimacy could not be questioned, but who had been passed over in Henry’s will; and Jane Grey, the daughter of Henry’s youngest sister, whose mother, by that monarch’s will, came next to her own daughter, and who, by the will of the late king, had been preferred before them on the ground of their illegitimacy. The title of Mary, however, always esteemed the most natural and just, had been by her father’s will rendered legal and parliamentary; and during the whole of Edward’s reign, she had been uniformly regarded as his lawful successor. The Protestants, indeed, had reason to dread the effects of her religious prejudices; but the general hatred entertained against the Dudleys, counterbalanced this ground of objection. Mary, also, had the policy to promise to her adherents, that she would make no change in the laws of Edward respecting religion; and her pretensions were thus the more readily admitted by the nation at large. Northumberland, nevertheless, resolved to enforce the will of the late king in favour of his daughter-in-law; and having failed in his schemes to bring the two elder princesses into his power, caused Lady Jane to be proclaimed queen. Ignorant of the previous political transactions, attached to elegant literature, and satisfied with enjoying the affections of a husband deserving of her esteem, her heart had never opened to the allurements of ambition, and she resisted, as criminal and hazardous, her proposed elevation to the throne; but, overcome by the intrigues of her relations, she submitted at length, in opposition to her own judgment and wishes. In the mean time, the partisans of Mary were daily increasing. Lord Hastings, who had been sent to oppose her claims, revolted to her side with 4000 men; Northumberland himself was deserted by his soldiers on their march; and the council, whom he had treated as his prisoners, hastened, upon his departure from London, to declare against him. Suffolk, who commanded in the Tower, finding resistance fruitless, opened the gates to the friends of Mary; and Lady Jane Grey, resigning the crown, which she had held only ten days, gladly returned to that private station which she had never desired to leave. Northumberland, despairing of success, joined with apparent satisfaction in the proclamation of Mary at Cambridge; and she soon entered London with the most sensible expressions of loyal attachment on the part of her subjects. Northumberland was immediately arrested, capitaly convicted, and soon after executed, together with Sir John Gates and Sir Thomas Palmer, two infamous instruments of his ambitious and tyrannical measures. Sentence was, at the same time, pronounced against Lady Jane Grey and her husband Lord Guilford; but, without any present view of putting it in execution. Their youth and innocence (neither of them having reached their 17th year) pleased sufficiently in their behalf; and Mary was desirous, in the beginning of her reign, to acquire popularity by the appearance of clemency. No other blood was at this time shed; and a general pardon, with a few exceptions, was granted to those who had been concerned in the late enterprise against the rights of the sovereign. But the joy arising from the succession of Mary was inexpressible. Her excellent and gracious demeanour of the queen in her first proceedings, was soon clouded by apprehensions of her hostile designs against the reformed religion. Gardiner, Bonner, Tonstal, and the other bishops, who had been imprisoned in the last reign, were reinstated in their sees; and Holgate, Archbishop of York, Bishops Coverdale, Ridley, Hooper, and Latimer, were thrown into prison. On pretense of discouraging controversy, all the preachers were silenced, except such as should receive a particular license, which, it was clearly foreseen, would be granted only to the Catholics. Cranmer having published, in strong terms, a contradiction of a report that he had promised to read the mass before the Queen, was thrown into prison, and condemned for high treason in having concurred with the friends of Lady Jane Grey; but he was reserved for a more cruel punishment. The foreign Protestants hastened to leave the kingdom; and many useful arts and manufactures which they had introduced, were lost to the nation. A parliament was assembled, in which those who hesitated to comply with the court religion declined to serve, and which consisted therefore of members favourable to Mary’s designs. Their jealousy, however, was excited by her proposed marriage with Philip, King of Spain; and, having remonstrated in strong terms against so dangerous a measure as a foreign alliance, for this act of presumption they were instantly dissolved. The new laws regarding religion were in the mean time openly put in execution by the government. The mass was every where established; the marriages of the clergy prohibited; and nearly one half of their number deprived of their livings. In addition to the discontent excited by these violent and sudden changes, the intended Spanish match produced a more general apprehension for the liberty and independence of the nation. To obviate all objections, the articles of marriage were drawn as favourable as possible for the interest and security of England; but as it was naturally concluded that all conditions would soon be violated whenever it suited the emperor’s views, the publication of them gave no satisfaction to the people. The nation became so alarmed by the terror of Spanish tyranny, that a general rebellion was threatened; and there needed only encouragement from some foreign power, or the ap-
England.

The appearance of some person of rank as a leader, to overturn the authority of Mary. A partial insurrection broke out in Kent, headed by Sir Thomas Wyatt, a Roman Catholic, who issued a declaration against the Spanish match, and the queen's evil counsellors, without making any mention of religion, and marched to London with a body of 4000 men. But he suffered the critical season to elapse; and his partizans, upon discovering that he was not joined by any person of note, deserted rapidly from his standard. Obliged to surrender at discretion, he was tried and executed. Great cruelty was exercised against his followers. Four hundred and nineteen of them were hanged, drawn, and quartered, and many of the executioners; and the same number were conducted before the queen, with ropes about their necks, to receive a pardon on their knees. The Princess Elizabeth, and her lover the Earl of Devonshire, were committed to the Tower, upon suspicion of having been concerned in the plot; but as Wyatt had acquitted them by a solemn declaration upon the scaffold, of all share in his rebellion, it was found impracticable to proceed farther against them, except to retain them both in custody. The Duke of Suffolk having made an unsuccessful attempt, at the same time with Wyatt, to raise the midland counties, his daughter, Lady Jane Grey, and her husband, who still remained under the sentence formerly pronounced against them, were ordered to prepare for death; and the council, dreading the compassion which their youth, beauty, innocence, and noble birth might excite in the hearts of the people, gave directions that they should be beheaded within the limits of the Tower. The Duke of Suffolk was soon after brought to the scaffold. Lord Thomas Grey, Sir John Throckmorton, and many of the persons of distinction, suffered on the same account. The late rebellion furnished the queen with a pretence for exercising the native cruelty of her disposition; and her vengeance was directed against many of the nobility and gentry, more on account of their interest with the nation, than any appearance of their guilt. Finding that she had become the object of universal hatred to her subjects, she determined to disable them from future resistance, and ordered them to be mustered in different parts of the kingdom, and to be deprived of their arms.

The authority of Mary was much increased by the suppression of Wyatt's rebellion; the emporer had sent 400,000 crowns to be distributed, in bribes and pensions, among the members of parliament; and the queen had removed all alarm regarding the restoration of the church lands, by assuming the title of supreme head of the church, which she had dropped some time before. But while the parliament readily ratified the articles of marriage, which were drawn so favourably for England, they refused to pass a preamble, by the chancellor, investing the queen with a power of disposing of the crown, and appointing her successor; but, on the contrary, made such enactments, as effectually precluded Philip from possessing any authority in the government of the kingdom. They refused also to revive the law of the six articles, and to pass certain bills against heresy; and the queen finding that they would not sufficiently serve all her purposes, finished the session by dissolving them.

Mary's whole thoughts were now occupied with the completion of her marriage with Philip; and she discovered all the impatience of the youngest and fondest lover for his arrival. Her health, and even her understanding, were visibly impaired, by her extreme anxiety; and she at last became apprehensive, lest her person should be so injured by time and sickness, as to become disagreeable to her future consort. News at length were brought of his arrival at Southampton, and they were married a few days after at Westminster. They made a pompous entry into London, where Philip displayed his wealth with great ostentation; but his cold and haughty manners were ill calculated to remove the prejudices of the English nation against him. Mary soon found that his ruling passion was ambition; and that the only way of securing his affections was to render him master of England. Ready to sacrifice to his pleasure the interest and liberty of her people, she summoned a new parliament; and the influence of Spanish gold, the zeal of the Catholics, the powers of the prerogative, procured a House of Commons sufficiently compliant. Both houses, upon the representation of Cardinal Pole, who had come to England in the capacity of legate, addressed the King and Queen, professing their desire to be reconciled to the apostolical see, and requesting their intercession with the holy father for their absolution. Their request was easily granted, and the parliament and kingdom were formally re-admitted into the bosom of the church. But while they repealed all former statutes enacted against the Pope's authority in England, they took special care to secure the plunder which they had made from the ecclesiastics, and to retain possession of all the abbey and church lands. Having thus made provision for the safety of their own estates, they became very indifferent about the interests of religion, or the lives of their countrymen; and readily revived all the old sanguinary laws against heretics, placing the national religion nearly on the same footing as at the death of Henry VIII. But, with all their submission, they still preserved a regard to national independence; and resisted all proposals to put the administration into the hands of Philip, to declare him presumptive heir of the crown, or even to assist his father by subsidies in his war against France. The Queen, however, in her extreme desire to have issue, mistaking the commencement of a dropsey for a state of pregnancy, great rejoicings were made in the prospect of an heir to the throne; and the parliament passed a law, which, in case of the Queen's decease, appointed Philip protector during the minority; but, resisting all farther concessions in his favour, they were unexpectedly dissolved.

It was now frequently debated in the council, whether the laws, lately revived against heretics, should be put in execution, or merely employed by way of terror, as a restraint upon the more turbulent and obtrusive. Cardinal Pole, though firmly attached to the Catholic tenets, strongly recommended a toleration of the Protestants; but Gardiner, though suspected of less sincerity in his religious principles, keenly contended for the expediency of a violent persecution.

The arguments of the latter being more agreeable to the cruel bigotry of Mary and Philip, it was determined to enforce the laws in all their rigour against the reformed religion; and England was for three years filled with scenes of horror, which disgraced human nature, and rendered the Catholic system an object of general detestation. It has been computed, that, during the above mentioned period, 277 persons were brought to the stake; besides those who were punished by imprisonment, fines, and confiscation. Among those who suffered by fire, were 5 bishops, 21 clergymen, 8 lay gentlemen, 84 tradesmen, 100 servants and labourers, 55 women, and 4 children. Those persons,
too, were not convicted of publicly teaching tenets contrary to the established religion; but were seized upon suspicion of heresy, required to subscribe the Roman articles of faith, and were generally condemned for refusing to acknowledge the doctrine of the real presence. Among the chief sufferers, were Hooper, Bishop of Gloucester; Rogers, Prebendary of St. Paul's; Ridley, Bishop of London; Ferrar, Bishop of St. David's; Latimer, Bishop of Worcester; and Cranmer, Archbishop of Canterbury. The principal agent in these barbarities was Bonner, Bishop of London, upon whom Gardiner had devolved the invidious office; a man of profligate manners and brutal disposition, who seemed to rejoice in the torments of the unhappy sufferers, and who frequently applied the most cruel punishments with his own hands. Repeated orders were sent from the council, to quicken the diligence of the magistrates in searching out heretics; and, in some places, the entry were constrained to countenance, by their presence, the barbarous proceedings against the unhappy victims. An attempt even was made to introduce the inquisition into the country. But all those instances of cruelty and oppression were so abhorrent to the feelings of the English nation, that they produced the very opposite effect of what was intended; rendered the Spanish government daily more odious; and forwarded, instead of checking, the progress of the new opinions.

The effects of the public discontent appeared even in the next parliament that was summoned; and the Queen's application for a subsidy, and for additional enforcements of persecution, was resolutely rejected. Philip, in the mean time, finding his authority in England extremely limited, sensible of the general hatred which he had incurred, and tired by the Queen's impertinent love and jealousy, went over to Flanders, where he continued to spend most of his time, and seldom took any notice of his consort's fond epistles, except when he had occasion to demand a supply of money. In order to gratify his wishes, Mary had recourse to all the violent and irregular expedients of loans, levies, and similar extortions; and, at the same time, engaged the council, not, however, without the most vehement importunity and menace, to declare war in aid of Spain against France. This measure involved the nation in new difficulties; and the town of Calais, which had been held by England above 200 years, having been taken by the French, the whole kingdom was filled with murmurs and complaints against the improvidence of the Queen and her councillors. The Queen herself, who had been long in a declining state of health, conscious of being hated by her subjects, deplored the loss of Calais, apprehensive, in the prospect of Elizabeth's succession, for the safety of the Catholic faith, and overwhelmed with grief on account of her husband's determination to reside in Spain during the remainder of his life, fell into a lingering fever, which terminated her days in the 43d year of her age, and the sixth of her reign. She possessed few qualities, that were either estimable or amiable; and her person was as little engaging as her mind. She was cruel from natural disposition, and bigotted from a narrow understanding; and, excepting the single virtue of sincerity, her character was a complication of the most odious vices, of obstinacy, tyranny, malignity, and revenge.

After the death of Mary, the Princess Elizabeth ascended the throne, in the 25th year of her age, not only without opposition, but with the joyful acclamations of the whole nation. During the reign of her sister, she had been treated with great severity, and exposed to the most imminent dangers. Mary and the Popish bishops, well aware that, upon coming to the throne, she would instantly overturn that religion, which they were using such extreme means to establish, only waited for some new insurrection, or other favourable pretext, to take away her life. Compassion for her situation rendered her an object of interest to the nation; and the difficult part which she had to act, insured her to that exercise of prudence which qualified her to reign. Debarring also, by her confinement, from seeking amusement abroad, she applied herself to the pursuit of knowledge at home; and improved her understanding by the study of languages and science. She entered London amidst crowds of people, who strove with each other to give her the strongest testimonies of their affection; and when she reached the Tower, where she had formerly been exposed to all the bigotted malignity of her enemies, she gave thanks on her knees to the Almighty, for her deliverance from bloody persecutors; but this was the only instance in which she testified her recollection of past injuries, and with a magnanimity truly laudable, she received, with affability, even those who had treated her with the greatest malignity. When the bishops, however, came to explain their hommage, she turned aside from Bonner as from a man polluted with blood, and as it just object of horror to every friend of humanity. Immediately after her accession, she received proposals of marriage from Philip of Spain, who still hoped to obtain, by her means, that dominion over England, of which he had been disappointed in espousing Mary. But Elizabeth, neither attached to the person nor to the religion of her admirer, and sensible of the aversion which her subjects entertained to the Spanish influence, declined his addresses; yet in such an evasive manner, that for some time she retained hopes of success, and even took measures for procuring a dispensation from the Pope for the match.

The young queen, who had formed a determination, even amidst the restraints of a prison, to reform the church, upon her coming to the throne, proceeded without delay, in conjunction with Sir William Cecil, her secretary of state, to concert measures for restoring the Protestant religion; and as the cruelties exercised in the last reign had completely alienated the people from the ancient faith, it became a very easy matter to accomplish this object. Resolved, however, to proceed by secure and gradual steps, she checked the furious attacks of the Protestant teachers on the Romish superstitions, by prohibiting all preaching without a special licence, and by exempting from this restriction only the more moderate and judicious of her own party; and made no other innovations in the form of worship, except to forbid the elevation of the host, and to cause the greater part of the service to be read in English. At the same time, she clearly indicated her intentions of supporting the Reformation, by recalling the Protestant exiles, and setting at liberty all prisoners who were confined on account of religion; but delayed the entire change of the national faith till the meeting of the parliament, which was summoned to assemble, and in the elections for which the Catholics scarcely struggled for the superiority. After recognizing the queen's title to the throne, they annexed the supremacy of the church to the crown; confirmed all the statutes enacted in King Edward's reign with regard to religion; and, in one session, without violence or clamour, altered the whole public system of religion, nearly to the very state in
which it is at present established. Thus did England change its religious tenets four times in the space of 92 years; but, in this last instance alone, without compulsion. The people were now Protestants from inclination, chiefly in consequence of the persecutions under Mary; and out of 9400 benefited clergymen throughout the kingdom, only 14 bishops, 12 archdeacons, 15 heads of colleges, and about 80 of the parochial clergy, quitted their preferments on account of the Reformation.

Elizabeth, now seated on a Protestant throne, found all the neighbouring states, France, Scotland, Spain, and the Pope, openly or secretly combined against her; and having thus no friend to aid in her emergencies, she sought her great resource in the affection of her subjects, and the wisdom of her administration. To make herself beloved by the people, and at the same time feared by her courtiers, became therefore the governing maxims of her conduct. By frugal management of the national treasure, and by the most gracious affability in her public appearances, she acquired a degree of popularity, which no other English sovereign ever attained; and by a sparing distribution of gifts to her favourites, together with strict impartiality in dispensing rewards or punishments, she kept the great in sufficient subjection. Her chief minister was Robert Dudley, son of the late Duke of Northumberland, to whom she cherished an attachment, for which, as he had neither great abilities nor virtues, it is not easy to account; but, to make amends for his incapacity, the two favourites next in power were Bacon and Cecil, men of the highest talents and most indefatigable application, who regulated the finances of the kingdom, and directed all the great political measures of her reign.

While measures were pursuing for settling the public religion at home, negotiations were, at the same time, going on for peace with France; and a treaty was at length concluded, by which it was stipulated, that the French monarch should restore Calais at the end of eight years; that, in case of failure, he should pay 500,000 crown; and the queen of Scots still retains; and that, if Elizabeth broke the peace with France or Scotland during the interval, she should forfeit all claims to Calais; and that if the king of France made war on England during that time, he should be bound immediately to restore that fortress. A peace with Scotland was the natural consequence of that with France; but a serious ground of quarrel soon arose between the English and Scottish queens, which was attended with the most important consequences, and which was removed only by the death of the latter. The birth of Elizabeth was liable to the charge of illegitimacy, and the next heir of blood to the English throne was the queen of Scots, now married to the dauphin of France. The French king had been secretly soliciting at Rome, a ball of excommunication against the daughter of Anne Boleyn; and Mary had been persuaded to assume openly the arms and title of England. This was vindicated by her descent from the blood royal, and by the example of other princes; but, as it had not been done during the reign of Mary, Elizabeth considered it as indicating an intention to dispute, on the first opportunity, the legitimacy of her birth, and the validity of her title to the crown. Hence, she conceived a violent jealousy against the queen of Scots, as at once her most formidable rival and mortal enemy. Determined, as far as possible, to incapacitate her opponents from executing any project against her, she readily listened to an application from the Scottish reformers, for assistance against the French party in that kingdom; and by the most prompt and powerful succours, soon secured an honourable and advantageous treaty for herself and her friends. It was stipulated, that the French should evacuate Scotland, and that the queen of Scots should abate from bearing the royal arms of England; while, at the same time, by procuring favourable terms for the Scottish Protestants, she continued to possess a stronger influence over them, than their native sovereign was ever able to acquire. But Mary, afterwards refusing to ratified the treaty, and thus to make a formal renunciation of her pretensions, unless she was declared to be next in the succession to the English crown, and Elizabeth determined never to assist in any respect in strengthening the claims of so formidable a rival, the two queens, amidst all the appearance of cordial friendship, continued to entertain a perpetual jealousy of each other's intentions.

In the mean time, Elizabeth, leaving the queen of Scots, sufficiently occupied with domestic concerns, turned her attention to regulate the affairs of her own kingdom, and to promote the prosperity of her subjects. She adopted measures for paying off the debts of the crown, and reformed the coin which her predecessors had debased; furnished her armies with military stores, and provided for the general defence of her dominions; encouraged agriculture and commerce, by wise regulations; and particularly exerted her endeavours to increase the naval power of the kingdom. She bestowed great encouragement also upon the seminaries of learning; and set an example of moderation and justice to the Catholic party, by providing for the more faithful payment of the pensions, which had been granted to the dispossessed monks, but which had hitherto been in a great measure neglected. Powerful at home, and respected abroad, she received numerous proposals of marriage, both from surrounding princes, and from the more eminent of her own subjects. The Arch duke Charles, second son of the Emperor; Casimir, son of the Elector Palatine; Eric, King of Sweden; Adolph, Duke of Holstein; the Earl of Arran, heir to the crown of Scotland; the Earl of Arundel, distinguished by his nobility and wealth; Sir William Pickering, a man much esteemed for his personal merit; and, above all, Robert Dudley, Earl of Leicester, were all competitors for her hand; but, while she publicly declared her resolution to lead a single life, she gave to all her suitors such gentle refusals, as generally encouraged them to persevere in the pursuit; and this she has been supposed to have done partly from motives of policy, to keep them more attached to her interests, and partly from taking pleasure, as a woman, in receiving professions of love. While thus apparently determined to have no heir of her own body, and avoiding carefully to fix any successor to the crown, she seems to have also resolved, either from policy or malignity, to prevent every one, who had pretensions to the throne, from having either heirs or successors. Lady Catherine Grey, youngest sister of Lady Jane, and now the nearest claimant, after the queen of Scots, to the throne of England, having privately married the Earl of Hertford, without the consent of Elizabeth, they were both committed to the Tower in separate prisons, where they suffered ten years of severe confinement; till the death of the lady, by removing the unrelenting jealousy of the queen, procured the liberty of her husband. A similar anxiety to prevent the marriage of the queen of

Elizabeth's wise and vigorous administration.
Scots, excited new contests with that rival princess, in which the treachery and cruelty of Elizabeth's prince cannot be justified; though it must be admitted, that the fears which impelled her proceedings were not without foundation, and were too often alarmed by the rashness of Mary's friends. During her illness, and consequence of the small-pox, when little hopes were entertained of her recovery, the partizans of the Scottish princess, and those of the House of Suffolk, already divided the nation into such violent factions, that the controversy, it was evident, in case of the queen's decease, would be terminated only by the sword. The commons, therefore, as soon as her health was restored, earnestly entreated her to put an end to such apprehensions, either by choosing a husband, or by naming her successor. Elizabeth, however, afraid to declare against Mary, who clearly possessed the right of blood, and who would instantly have become her avowed enemy; and, on the other hand, unwilling, by a settlement in her rival's favour, to establish pretensions which might be enforced even during her reign, she resolved to keep both parties in awe, by an ambiguous conduct and evasive answers; and chose rather that her subjects should run the risk of a civil war at her death, than that her throne should be endangered during her life. She continued, with all her vigour and policy, to avert such attempts on the part of the Popish interest, by giving her enemies employment at home; and afforded every necessary succour, both to the Hugonots in France, and to the Reformers in Scotland. An event, however, happened, which placed the person and the fate of her rival entirely at her disposal; and effectually precluded all farther danger from her pretensions. Mary, queen of Scots, having been reduced, by her imprudence, if not by her guilt, to take refuge in England, and to seek the protection of Elizabeth against her own subjects, was allured, by the most plausible professions of friendship, to admit the queen of England as umpire in her cause; and being at length required either voluntarily to resign her crown, or to associate her son with her in the government, leaving the administration of affairs in the hands of the Earl of Murray, she was, upon her refusal to make such a submission, unjustly detained as a prisoner in England. Various insurrections and conspiracies, chiefly on her account, and sometimes with her concurrence; an attempt by the Duke of Norfolk, (for which he suffered on the scaffold,) to espouse and to deliver the royal captive; the open interference of the Pope, who excommunicated Elizabeth, and freed her subjects from their allegiance to her person; and particularly, a plot conducted by the Catholics to assassinate the Queen, to which Mary, irritated by confinement, and anxious for liberty, had become a party; these occurrences, and a multitude of other political considerations, induced Elizabeth to bring her unhappy prisoner to a trial, and to hasten the ruin of a competitor, whom she had never ceased to dread or to hate. Mary, who had now lingered 16 years in confinement, was accordingly condemned for high treason against the Queen of England, and beheaded in one of the rooms of her prison:—a transaction, in the course of which Elizabeth was guilty of the grossest dissimulation and most cruel injustice; and which, whatever were the crimes of the sufferer, must remain an inimitable stain upon the memory of her oppressor.

While Elizabeth was engaged in plotting the destruction of her rival, she was carrying on a treaty of marriage with the young Duke of Anjou; and, after long struggling between ambition and inclination, she was on the point of yielding to the latter, and of subjecting herself and her people to a foreign and a Catholic prince, when all her favourite attendants and ministers united in deprecating so imprudent an alliance. A letter, particularly written to her on the subject by the celebrated Sir Philip Sydney, and distinguished by unusual elegance of expression, as well as force of reasoning, is understood to have raised her to reflection; and, after spending several nights in restless anxiety, she finally determined against the match, and dismissed her lover, with proper apologies for her breach of engagement.

While Philip of Spain had been actively intriguing with the malefactors in England and Ireland in the cause of the Queen of Scots and of the Catholics, Elizabeth had been rendering powerful aid to the insurgents against his authority in the Low Countries. In retaliation for this interference, he sent, under the name of the pope, a body of 700 Spaniards and Italians into Ireland, where the inhabitants, discontented with the English government, were ready to join any invader; but by the active measures of the Earl of Ormond, they were soon reduced to the necessity of surrendering at discretion. The queen of England, on the other hand, countenanced the predatory attacks of Sir Francis Drake upon the Spanish settlements in South America; and, by those mutual aggravations, the two nations were at length brought to an open rupture. Elizabeth, in the view of an approaching war with so powerful an antagonist, concluded a league of mutual defence with the king of Scotland; and hearing that Philip was secretly preparing an immense fleet for the invasion of her kingdom, she resolved to strike the first blow, and to brave his boasted naval force in his own harbours. Sir Francis Drake was immediately dispatched with a strong squadron, which the London merchants had assisted to equip, in the hopes of sharing the plunder; and, sailing direct to Cadiz, he destroyed about a hundred vessels laden with ammunition and stores. By this short expedition, the intended invasion of England was retarded a whole twelvemonth; and the English seamen were taught to despise those unwieldy vessels of the enemy, which were threatening to spread terror along their coasts. The preparations of Philip, who meditated nothing short of the entire conquest of England, were carried on with redoubled vigour; and the Spaniards, confident of success, had already denominated their navy the Invincible Armada. Elizabeth, on her part, exerted her utmost prudence and vigour to resist the danger with which she was threatened; and employed all the resources which her domestic situation, or her foreign alliances, could afford. By all the Protestants of Europe, the enterprise was considered as decisive of their fate; and those who could give no assistance, contemplated, with anxious interest, the approaching struggle. The people of England, animated by the spirited example of their sovereign, manifested the most determined resolution to defend their religion and their liberties; and even the Catholic subjects, treated by the queen with generous moderation, forgetting for the present all party concerns, united with one heart in defence of the common cause. The armada at length set sail from Lisbon, and entered the Channel in the form of a crescent, which extended its two extremities to the distance of seven miles; but, completely baffled in its first attempts by the skill and courage of the English navy, gradually weakened by their daring and repeated attacks, and finally overtaken by a dreadful storm when passing the Orkneys, this mighty armament was so ut-
terly discomfited, that not one half of its ships returned
to Spain, and nothing but want of ammunition in the
English fleet saved it from total destruction: (See the
article ARMADA.) This defeat of the armada inspired
the English nation with a kind of enthusiastic passion
for enterprises against Spain; and scarcely a single year
was suffered to elapse without some successful attack
being directed against the dominions of Philip. In
1596, particularly, a powerful expedition was fitted out
against Cadiz, which defeated the Spanish fleet in the
bay, took the city by storm, and destroyed in the har-
bour a fleet of merchant ships of immense value. It
was in this reign, and by these enterprises, that the
English navy began to acquire that irresistible superior-
y which it has never ceased to maintain, and that
many of its most able and adventurous commanders
were produced. In this reign, also, notwithstanding
the imperious character of the sovereign, the spirit of
liberty, following the progress of reformation in reli-
gion, presumed to show itself in the proceedings of the
English parliament. Elizabeth, indeed, was sufficiently
tenacious of all her prerogatives, and frequently exercis-
et them with a degree of despotism unequalled by
many of her predecessors. She repeatedly discharged
the House of Commons from discussing, without her
permission, any matters relating either to the church or
the state; defined their liberty of speech to extend no
further than aye or no; and, without hesitation, com-
mited to the Tower every member who presumed to
press any topic contrary to her wishes. But amidst
the tamest submissions and most fulsome flatteries from
successive parliaments, a few resolute individuals, (who
have generally been branded with the contemptuous
name of Puritans, while they deserve to be revered as
the fathers of British freedom,) persisted, without dis-
may, in ascertaining public grievances, and asserting par-
lamentary privileges, whenever they could procure
the smallest support; and so far at length did their spi-
rit and numbers increase, that, in the last parliament
which Elizabeth assembled, she found it necessary,
while she held the most absolute tone in her messages,
to abandon, in a great measure, the oppressive system
of monopolies, which she was accustomed to grant as
rewards to her courtiers, and which the Commons had
brought in a bill to abolish.

Though the signal advantages gained by the arms of
Elizabeth over the Spaniards, and the uncontrolled
authority which she exercised over her own subjects,
gave complete security to her throne, she continued
to regard her heir, the king of Scotland, with the
same malignant jealousy which had influenced her
conduct towards the unhappy Mary. James had, in-
deed, succeeded to all the claims of his mother; but,
as a Protestant prince, he did not possess the fa-
vour of the Catholics, which could render his preten-
sions dangerous; and his indolent, unambitious dispo-
sition, sufficiently secured her from any disturbance in
the possession of the crown. Still, however, she cau-
tiously abstained from satisfying the nation by any de-
claration in favour of his title; and was as anxious to
prevent every circumstance which might augment his
credit or power, as if he had been her immediate com-
petitor for the kingdom.

The authority of the English in Ireland had been hi-
thero little more than nominal; and the complete sub-
jugation of that country had been always deferred, by
the necessity of watching the more formidable powers
of the continent. But the rebellion in that kingdom
having now risen, under the conduct of the Earl of
Tyrone, to a more alarming height than at any former
period, and the Spaniards having exerted themselves, as
the most effectual mode of diverting the power of the
English from their coast, in sending succours to the
natives, it was therefore resolved to push the war in
that quarter with more vigorous measures; and the
young Earl of Essex, who had succeeded, since the
death of the Earl of Leicester, to the queen’s favour,
obtained the government of Ireland, and the command
of the army destined for its reduction. Having disgust-
et the queen by his ill success and insolent behaviour,
he returned suddenly to England to make his peace at
court; but Lord Mountjoy, who was then appointed as
deputy-governor to the command, by his able and
indefatigable exertions, defeated the rebels in every quar-
ter, and at length compelled Tyrone to make an absol-
ute surrender of his life and fortunes to the queen’s
mercy.

Essex, in the mean time, who had long possessed a
powerful hold of Elizabeth’s affections, but whose un-
governable spirit she found it requisite to humble, was
brought to trial before the privy-council, and condem-
ed to retirement in his own house, till the queen should
be pleased to restore him to office. He expressed in
his defence the most dutiful submission to his sovereign’s
pleasure; and, as Elizabeth herself had openly declared,
that her severity was intended to correct and not to ruin
him, it was generally expected that he would soon re-
gain all his ascendancy over her mind, and reappear a
greater favourite than ever. Persuaded, however, by
his enemies, that his lofty spirit was far from being sub-
dued, she pushed her rigorous treatment to a degree
which impressed him with a belief that she was alto-
gether inexorable, and drove his impatient temper to the
most fatal extremities. He threw off all appearance of
duty and respect, and even indulged himself in great
liberties of speech, respecting the queen’s advanced age
and decayed beauty. He used every art to increase his
popularity, which was already greater than what any
other subject enjoyed; and he entered into a secret cor-
respondence with the King of Scotland, whose right of
succession he proposed to compel Elizabeth to acknow-
ledge. Having formed a strong party of malecontents,
and trusting chiefly to his great authority with the
population, he formed at length the desperate attempt
of seizing the queen’s person, removing his enemies from
office, and settling, with the advice of his partizans, a
new plan of government. Finding, however, that his
designs were suspected, and the queen upon her guard,
yet determined to make some open effort before they
should be completely discovered, he adopted the wild
project of raising the city of London in his favour; and
madly imagined, that by the mere good will of the mul-
titude, he should be able to over turn the wise and well-
established government of Elizabeth. Sallying forth
in the full blaze of day, he exclaimed, ‘Tyrone, as a
queen! for the queen! a plot is laid for my life!’ he
proceeded to the house of the sheriff, upon whose aid
he placed great reliance. The citizens, in the mean-
time, flocked around him in amazement, but discovered
no disposition to join him in arms. Observing their
coldness, and hearing that he was proclaimed a traitor,
he began to despair of success, and to think of retreat-
ing to his own house. Attempting to force his way
through the streets, which were now barricaded and
watched, he was beaten back and wounded in the
thigh; but at length, by putting his followers on board
of small boats, he escaped down the river to his house,
which he proceeded to fortify in the best manner that:
he could, and proposed to defend to the last extremity.  He was soon compelled to surrender at discretion, brought to immediate trial, clearly convicted of high treason, and condemned to capital punishment. Elizabeth hesitated long between love and resentment, compassion for her favourite, and the care of her own safety. She signed the warrant for his execution; then countermanded the order; again commanded it to proceed, and again yielded to a return of tenderness in his favour. But, hardened against him at last, chiefly by his supposed obstinacy in making no application to her for mercy, she finally consented to his death. His proud heart having been humbled in the solitude of prison, not by fear, but by sentiments of religion, he made a full confession of his disloyalty, acknowledged the justice of his sentence, and testified on the scaffold the most suitable symptoms of penitence and piety.

The vigour of Elizabeth's mind and the happiness of her life seemed to expire with her favourite; and, though she went through the business of the state by habit, she took little interest in any public measure or event. She sunk at last into a profound melancholy, which nothing could alleviate, and for which various reasons have been assigned. Some ascribe this depression of mind to remorse for having been persuaded to pardon the rebel Tyrone, or for some other actions of her life; others to a discovery which she had made of the correspondence maintained by her courtiers with her successor, the King of Scotland; others to the neglect which, on account of her old age and infirmities, she now imagined that she experienced; others, to a mere decay of her faculties, in consequence of long and severe exertion of mind; and others, with more probability, to a revival of her regret for the death of Essex, whom she had given up entirely in resentment for his invincible obstinacy, but who, she now discovered, had actually thrown himself upon her clemency, while his enemies had found means to conceal his application. From the moment of making this discovery, she resigned herself to the deepest despondency, refused all sustenance and consolation, rejected all advice from her physicians, and remained sullen and immovable on the floor, venting her grief in sighs and groans. In this situation she continued for ten days and nights, leaning upon cushions which her maid brought to her; and, as her end was visibly approaching, the council sent the Secretary and Lord Admiral to know her will respecting her successor. She faintly replied, that, as she had held a regal sceptre, she wished a king to succeed her, and that her heir, therefore, could be no other than her near kinsman the King of Scots. Being then exhorted by the Archbishop of Canterbury to fix her thoughts upon God, she answered, that her mind did not in the least wander from him. She soon after fell into a lethargic slumber, which continued for some hours, and then expired without any further struggle, in the 70th year of her age, and the 45th of her reign.

The character of Queen Elizabeth varied considerably with the circumstances in which she was placed. At the commencement of her reign, she was humble and moderate; and, ascending the throne in highly difficult circumstances, she conducted the government with unsurpassed felicity and success. But she after-wards became more haughty and severe; and frequently exerted the powers of her prerogative in the most violent and oppressive manner. She possessed, indeed, the most singular talents for government; and, in point of vigour, steadiness, penetration, vigilance, magnanimity, and address, may stand a comparison with any sovereign in any period of the world. In the choice of her favourites, she was often guided by unworthy and capricious motives; but her able ministers and commanders, to whom she owed so much of the glory of her reign, if not always selected by her own discernment, were at least advanced and supported by the constancy of her friendship. Her economy was very remarkable, and enabled her, with a small revenue and few supplies from her people, to execute the greatest undertakings; but it was a virtue which she practised more from natural disposition, and a desire of being independent of parliamentary aid, than from any tender concern for her subjects. She was great, in short, as a public character; and all her stronger qualities were preserved in due subordination by her own self-command. But, in private life, she was less to be admired; and had many infirmities, which all her excellent sense and strength of mind could not overcome, and which made her most disliked and feared by those who were placed nearest to her person. Deficient in sincerity and sympathy; vain of her beauty, which she only could discover; delighted with the praise of her charms, even at the age of sixty-five; jealous of every female competitor, to a degree which the youngest and silliest of her sex might despise; and subject to sallies of anger, which no sense of dignity could restrain, her character adds one more to the many instances which occur in human life, and which are calculated to subdue human pride, of the greatest moral weaknesses united with the highest intellectual superiority. But whatever was the merit of the sovereign, the progress of the English nation in arts, arms, commerce, agriculture, and literature, during the reign of Elizabeth, is unparalleled in history. The genius of the people, if not the wisdom of the government, surmounted every obstacle; and a kingdom, formerly unsettled and stormy like the element by which it is encompassed, successively sinking under foreign invasion, or torn by domestic disputes, became industrious, enterprising, polite, powerful, secure at home, and formidable abroad. Its external commerce, by the exertions of its adventurous navigators, was pushed to the most distant quarters of the globe; and its internal manufactures, aided by the Flemish artists, who were driven from their own country by the oppressive measures of Spain, flourished beyond all precedent in every district of the country, in spite of the oppressive monopolies granted by the crown. By the progress of religious enquiries, and the perusal of the scriptures in the amended translation, the people were improved in taste as well as in morals; and though the queen herself was more vain of shining by her own learning, than liberal in the encouragement of genius, many of the nobles and higher clergy, both by their patronage and example, contributed so essentially to the improvement of the English language, that many writers have been disposed to fix its Augustan age to that period. Liberty, indeed, still continued to depend upon the pleasure of the government; but, though Elizabeth often stretched her power to actual despotism, yet the people were less absolutely submissive than in former reigns; and even under her imperious sway, those noble principles of freedom, which at length pervaded the British soil, began to spring up, and to find a shelter beneath the fostering protection of enlightened religious zeal.

Elizabeth was succeeded by James VI. of Scotland, and I. of England; and from the period of his accession, the history of both kingdoms is comprehended under the article Britain. (9)
PART II. STATISTICS.

Although an admeasurement of the maps of England and Wales, even inaccurately constructed as they were at this period, might have been sufficient to prove that the areas assigned by tradition and by Malines, were far below the truth; yet Sir William Petty, in his calculation of the extent of South Britain, reduces the number of acres, considering them as amounting only to 28,000,000. But Sir William Petty in this, as in too many other instances of political arithmetic, was satisfied with vague and loose conjecture, where he might at least have gained a near approach to truth and accuracy. It may, indeed, have happened, that Sir William Petty calculated by 60 miles to a degree of latitude; in which case, the number of acres that he assigns to South Britain will agree very nearly with Morden's map, which was the best that had been published when he wrote.

Gregory King, Lancaster herald, who published "Natural and political observations and conclusions upon the state and condition of England, 1696," which work is praised and garbled by Davenant, and has been lately republished entire by Mr George Chalmers,—calculates that England and Wales contain 99,000,000 acres; of which 12,000,000 consisted of heaths, moors, mountains, barren lands, rivers, lakes, meres, and ponds; roads, ways, and waste lands; or were occupied by houses, homesteads, gardens, orchards, churches, and churchyards. The same author calculates, that England and Wales are in proportion to the globe of the earth and seas, as one to 3,500:—to the known habitable world, as one to 600;—to Europe (including Muscovy) as one to 43;—to France, as one to three and a quarter;—to Holland, as nine to two; and to France and Holland, as one to three and a half.

It is evident, that in all these calculations of Malines, Sir William Petty, and Gregory King, political arithmetic had derived no assistance from the more sure and accurate sciences, but had been suffered to range unenlightened and uncontrolled, either by geography or geometry. At length, Dr Edmund Halley, in consequence of the earnest desire of his industrious and inquisitive friend Mr Houghton, author of the Collections for the improvement of Husbandry and Trade, made a most elaborate calculation with respect to the contents of England and Wales, which he found to contain in the gross—that is, taking the whole from a single map,—38,660,000 acres; and on a strict computation of the several counties, each separately examined, he computed the total to be 39,938,500 acres; and as these sums, attainted to by these two different methods, so nearly approached each other, he concluded that neither of them could be very wide from the truth. He adds, that, in his judgment, England and Wales might be esteemed the 3000th part of the whole globe of the earth, and the 1500th part of the inhabited world. Dr Halley's own account of his calculations is given in vol. i. p. 69, of Houghton's Collections. Besides the source of error to which the calculations of Dr Halley were exposed, from the inaccuracy of the maps of England, which existed in his time (a circumstance which will be afterwards more particularly noticed,) his estimate was rendered erroneous, by his having used (as most of our geographers still do)
ENGLAND.

Mr. Norwood's measure of a degree of latitude, instead of the true measure; or sixty-nine miles and a half, instead of sixty-nine and one fifth: had he used the latter measure of a degree of latitude, the total would have been reduced about $70,000 acres, which would have nearly coincided with the area of South Britain, as given by Morden's map, when measured according to the true length of the successive degrees of latitude and longitude;—the single map, from which Dr Halley took the gross amount, was Adam's, and the map from which he took the several counties, was the six-sheet map of Saxton's.

In the Philosophical Transactions for the year 1711, (No. 380, page 266.) are given the calculations of Dr Nehemiah Grew on this subject, and the result of these calculations. According to him, South Britain contains 72,000 statute miles, and consequently 46,005,000 statute acres. As Dr Grew was at the trouble to obtain a wheel measure of those roads, which were necessary to supply him with what he conceived to be sufficient data on which to found his calculations, it might be supposed that the area he assigns to South Britain would approach very nearly to the truth; but he unaccountably forgot, that roads are not always straight or smooth; and assuming, on the contrary, that the wheel measure of them gave him a straight line, he makes the length of South Britain, from Newhaven, in Sussex, to Berwick, 395 miles; and its breadth, from the South Foreland to Kent, to the Land's End, he makes 367 miles; both, as we shall afterwards see, considerably above the truth. Nor was this mistake respecting the roads the only source of his error; for he very carelessly and inaccurately conjectures, that a right-lined triangle, formed by uniting the South Foreland and the Land's End with Berwick, is commensurate with the space contained by the irregular outline of the country. This error would have given less than the real area to South Britain, had the sides of the triangle corresponded with the actual distances, though the amount was not sufficient to destroy the error arising from making these sides too long.

The next calculation respecting the area of South Britain, was given to the world by Mr Thomas Templeman of Bury, in his work entitled a New Survey of the Globe. According to him, it contains 49,445 square miles, or 31,648,000 statute acres. This extent, much more below the truth than the calculation of Dr Grew raised it above it, Mr Templeman obtained, by adopting a mode of computation that is progressively more erroneous, as it is applied to countries more distant from the equator. Mr Arthur Young seems to have been the first who objected to the accuracy of Templeman's calculation; but not perceiving the source from which the error of this author took its rise, he endeavours to correct it on improper grounds; and supposing that the error would be rectified by taking 694 miles instead of 60 miles to a degree, and moreover supposing, that Templeman erred as much in his calculation respecting the area of England, as the calculation of Necker respecting the area of France proved he had done with regard to that kingdom; Mr Young assigns to England and Wales 46,915,883 acres.

Amidst this uncertainty of calculation and opinion on this subject, the trigonometrical survey of England was begun; and, in its progress, it was abundantly and clearly proved, that the geography of this country, in many respects, was very erroneous. Indeed, before it was commenced, it had been discovered, that in the older maps the counties in the vicinity of the metropolis were erroneously laid down, both with respect to the general amount of their area, and with respect to the particular areas of each; so that the distance from the South Foreland in Kent, to the Land's End, was ascertained to be less by about half a degree than had been formerly laid down.

For all the purposes of political arithmetic, however, it is not necessary to have recourse to that minute accuracy which trigonometrical surveys afford. A sufficient degree of accuracy will be afforded by a mode of computation, ingenious, easy, and satisfactory, which was published by Dr Becke, in his Observations on the Produce of the Income Tax. He was naturally led to the consideration of the subject of the extent of South Britain, by the computation of the income of Great Britain, as stated by Mr Pitt in the House of Commons. This statesman had assumed the truth of Mr Young's calculation respecting the area of England, (to which Mr Middleton, in his Survey of Middlesex, had also lent the authority of his name,) and, consequently, had rated the income of this county, much too high. Dr Becke formed a scale, which is given below, the construction of which depends on the length of the degrees of latitude and longitude, according to their situation on the surface of the earth. In this scale, the number of acres and decimal parts in every successive four-sided figure, or trapezoid, are given; these trapezoids being formed by the intersection of lines, or circles of longitude and latitude, whose distance from one another is a minute, or the sixtieth part of a degree. The length of the degree of latitude and longitude, according to their situation, by which the following scale is calculated, is taken from the recent observations and measurements for that purpose, in this country, as they are detailed at large in the Philosophical Transactions.

A trapezoid, formed by drawing parallel lines across a map from east to west, and others from south to north, at the distance of the sixtieth part of a degree, contains, on an average of every ten minutes successively, the following number of acres and decimal parts.

From 40° 50' to 50° 0' 550.09 Acres.
From 50 0 to 50 10 548.88.
From 50 10 to 50 20 546.95.
From 50 20 to 50 30 545.07.
From 50 30 to 50 40 543.19.
From 50 40 to 50 50 541.31.
From 50 50 to 51 0 539.43.
From 51 0 to 51 10 537.52.
From 51 10 to 51 20 535.62.
From 51 20 to 51 30 533.72.
From 51 30 to 51 40 531.82.
From 51 40 to 51 50 529.92.
From 51 50 to 52 0 528.02.
From 52 0 to 52 10 526.09.
From 52 10 to 52 20 524.15.
From 52 20 to 52 30 522.23.
From 52 30 to 52 40 520.30.
From 52 40 to 52 50 518.37.
From 52 50 to 53 0 516.44.
From 53 0 to 53 10 514.50.
From 53 10 to 53 20 512.55.
From 53 20 to 53 30 510.60.
From 53 30 to 53 40 508.65.
From 53 40 to 53 50 506.70.
From 53 50 to 54 0 504.75.
From 54 0 to 54 10 502.78.
soils, which predominate on the eastern side of the kingdom, the increase of surface, from its irregularity or unevenness, does not amount to much more than the 1000th part; that in the hilly and chalky counties, it scarcely exceeds the 400th part; and that, making a greater allowance for Wales, Westmoreland, and other very mountainous districts, it will not collectively amount to more, at most, than between 120,000, and 150,000 acres.

The progressive geography of England and Wales. Progressive geography may be classed under four periods, which will supply us with the divisions of this country, at the time when the Romans invaded it; during their abode here; during the Saxon heptarchy; and at present.

At the period of the invasion of the Romans, the Daunamone inhabited the counties of Cornwall and Devonshire; the Durotriges, Dorsetshire; the Belgae, Somerset, Wiltshire, and the northern part of Hampshire; the Atrebati, Berkshire; the Regni, Surre, Sussex, and the south part of Hampshire; the Cantii inhabited the county of Kent; the Trinobantes, Middlesex and Essex; the Iceni, Suffolk, Norfolk, Cambridgeshire, and Huntingdonshire; the Catueuculani, Buckinghamshire, Hertfordshire, and Bedfordshire; the Dobuni, Gloucestershire, and Oxfordshire; the Silures, Herefordshire, Monmouthshire, Radnorshire, Brecknockshire, and Glamorganshire; the Dimetis, Caernarvonshire, Pembrokeshire, and Cardiganshire; the Ordovices, Flintshire, Denbighshire, Merionethshire, Montgomeryshire, Caernarvonshire, and the Isle of Anglesey; the Cornovii, Cheshire, Salop, Staffordshire, Warwickshire, and Worcestershire; the Coritani, Lincolnshire, Nottinghamshire, Derbyshire, Leicestershire, Rutland, and Northamptonshire; the Brigantes, Yorkshire, Lancashire, Westmoreland, Cumberland, and Durham; and the Ottodanes, Northumberland.

During the Roman period, England was divided into the following large provinces, the extent and boundaries of which are not, however, exactly ascertained; Britannia Prima, which comprehended the whole southern part of England, as far as the mouths of the Severn and the Thames; Britannia Secunda, which comprised modern Wales; Flavia Cesariana, which comprehended the middle of England, from the Thames to the Humber; Maxima Cesariana, in which were included a part of the northern counties, from the Humber to the Tyne, on the east side, and from the Mersey to the Solway Frith, on the west side of the kingdom. The province of Valentia seems to have comprised the remainder of the northern counties, and to have been formed and named when the province of Vespasiana, which included part of the south of Scotland, was reconquered.

During the Saxon period of the history of England, this country formed a heptarchy, or seven kingdoms, which were divided in the following manner:

Kent, comprehended the county of Kent; it was founded by Hengist, in the year 454, and terminated in the year 823.

Sussex, or the kingdom of the South Saxons, comprehended the counties of Sussex and Surrey: it was founded by Ella, in the year 491, and ended in the year 885.

The East Angles comprehended the counties of Norfolk, Suffolk, Cambridgeshire, and the isle of Ely: it was founded by Uffa, in the year 566, and terminated in the year 792.

Wessex, or the kingdom of the West Saxons, comprehended the counties of Cornwall, Devonshire, Dor-
England.

In the 10th of Edward I. the statute of Rhuddlan was passed, by which it was declared, that the territory of Wales, with its inhabitants, which had been formerly subject to the king by feudal right, was entirely annexed to the crown of the kingdom of England, as part of that monarchy. Notwithstanding this statute, however, Wales retained many of its peculiar privileges and immunities, which were not abolished till the reign of Henry VIII. By the statute 27th of that monarch, chapter 26, A.D. 1535, entitled, an “act for laws and justice to be ministered in Wales, in like form as it is in this realm,” it is enacted, that the dominion of Wales shall be for ever united to the kingdom of England;—that all Welshmen born, shall have the same privileges and liberties as the rest of the king’s subjects;—that lands in Wales shall be inheritable, according to the English tenures and rules of descent;—(before the passing of this act, their lands were divided equally among all the male issue, and did not descend to the eldest son alone);—that the laws of England, and no other, shall be used in Wales; besides several other regulations and enactments of inferior moment and interest.

Henry VIII. also passed another statute in the 34th year of his reign, chapter 26, by which the statute already mentioned was confirmed, and further regulations added: by this statute, some peculiar privileges were granted to the Welsh, particularly that there should be courts within the principality itself, independent of the process of Westminster Hall. But this statute claims our attention, at present, in a more direct and especial manner, as being that which gave to the counties of Wales, and to the adjoining counties of England, the names and extent which they still retain. By this act the marches, or intermediate lands between England and Wales, were divided into new counties, or annexed to old counties. The new counties that were now formed, were Monmouth, which was declared an English county, Brecknockshire, Denbighshire, Montgomeryshire, and Radnorshire in Wales. The English counties which were augmented by annexation, were Gloucestershire, Herefordshire, and Shropshire. The Welsh counties which were augmented, were Cardiganshire, Caernarthsire, Glamorganshire, Merionethshire, and Pembrokeshire.

The next inferior division of the territory of England is into trethings, trithings, or tridings; lathes, and rapes. Trething, trithing, or triding, is an appellation evidently derived from the circumstance that the county to which it is applied, is divided into three parts; this appellation is now corrupted into riding, and occurs only in Yorkshire. The terms lathes and rapes are not of such evident and certain etymology or meaning; though there can be no doubt, that though not exactly synonymous with trethings, or the third part of a county, they signify a larger division of it than hundreds. Kent is the only county which is divided into lathes; and Sussex the only one that is divided into rapes. It does not appear that any appropriate officer under the sheriff was appointed to either of these divisions: the trithings, however, were anciently governed by a trithing-reeve. A large division, something similar to trithings, rapes, or lathes, exists in the county of Lincoln: this county is divided into three districts, each of which, like the large divisions of Yorkshire, Kent, and Sussex, contains several hundreds. Perhaps, also, the shires, which are found in some of the northern counties, though now merely nominal, were originally larger divisions of a similar nature; such as Hallamshire, which comprehends the

Statistics.

Wales annexed, 10

Edward I.
Division into hundreds in the time of Alfred.

The next inferior division is that of hundreds. The institution of this division seems rather to have been introduced into England than invented in it; and there is reason to believe, that the Saxons, in the southern part of the island, first introduced it, though this institution, like all the rest, which related to the due administration of justice, has generally been ascribed to Alfred.

It is uncertain, whether the appellation of hundreds was given to these divisions, because they contained a hundred persons; a hundred heads of families; or, as some suppose, a hundred farms; it is, however, most probable, that each hundred contained one hundred heads of families, of freemen. That the hundreds were regulated by population, is evident from the great number of hundreds in those counties that were first peopled by the Saxons, or which, from their local situation, were least exposed to the devastation of war, or from their natural fertility, were most likely to attract, and most capable of supporting a great number of inhabitants; while, on the contrary, those counties, which were gained by the Saxons at a later period, which were held by them on a precarious tenure, and continually liable to invasion, or which were naturally barren and indigent, contained comparatively very few hundreds. Thus, in Kent and Sussex, according to Domesday Book, there were at the period, when that survey took place, respectively 62, and 64 hundreds, the same number which they contain at present; Norfolk, though in size only about the fifth county in the kingdom, contains 660 parishes; a greater number than any other county; and 33 hundreds. Suffolk contains 575 parishes; and Essex 415 parishes; whereas in Lancashire there are only six hundreds; in Cheshire seven; in Cornwall nine; in Northumberland seven divisions, which correspond to hundreds; and in Cumberland five. In some counties there are hundreds that do not exceed a square mile in area, nor contain more than 1000 persons; the hundreds of Lancashire, on the contrary, average 500 square miles; and the population in one of them, Salford hundred, is above 250,000.

In order to remedy the inconvenience resulting from this circumstance, in the reign of Henry VIII., the small hundreds were united, to form divisions, limits, or circuits, while the larger hundreds were partitioned into smaller portions. In the northern parts of England, the counties were not divided into hundreds, but into wards and wapentakes: the former still being the divisions of Cumberland, Westmorland, Northumberland, and Durham; and the latter of Yorkshire. Wards were so called, from the inhabitants of each division being, in ancient times, obliged to keep watch or ward, against the interruptions of the Scots or Picts. The term wapentake is evidently synonymous with weapon-take, and was given to the divisions of Yorkshire from the same circumstance.

The subdivision of hundreds into tithings is undoubtedly owing to Alfred. In ancient times, it was ordained, for the more sure keeping of the peace, that all free-born men should cast themselves into several companies, by ten in each company; and that every one of these ten men should be surety and pledge for the forthcoming of his fellows: for which cause, these companies in some places were called tithings; and as ten times ten make a hundred, so, because it was also appointed that ten of these tithings should, at certain times, meet together for matters of greater weight; therefore that general assembly was called a hundred.

One of the principal inhabitants of the tithing, who was called the tithing-man, or head-borough, and in some counties the borsholder, or boroughs-calder, was annually appointed to preside over the rest, and to take care of their interests. Tithings are seldom mentioned now, except in legal proceedings, or in topographical descriptions.

In Lincolnshire another species of division exists, called Sokes. Sokes, sok, soc, or soka, according to Bracton, signifies the power of administering justice, and the territory or precinct in which the chief lord did exercise his soke, his liberty of keeping court, or holding trials within his own soke or jurisdiction.

Although parishes were originally ecclesiastical divisions, yet now they may be properly considered as coming under the class of civil divisions; and, consequently, claim our attention under that head. It is not easy to determine how ancient the division of England into parishes is: they are mentioned so early as in the laws of King Edgar, about the year 970; but from what occurs relating to them in these laws, it is plain that they were gradually formed. They were originally of the same extent as manors, since it very seldom happens that a manor extends itself over more parishes than one, though there are often many parishes in one manor.

The parochial division of England was nearly the same in Edward First's time, 1288-1292, as it is at present.

Parishes are frequently intermixed with one another. This seems to have arisen from the lord of the manor having had a parcel of land detached from the main part of his estate, but not sufficient to form a parish of itself. It was natural for him to endow the church which he had erected on his principal estate with the tithes of these disjointed lands; especially if it happened, that no church was then built in any lordship adjoinging to these lands.

The setting of the bounds of parishes depends on immemorial custom; though it is probable, that they were not settled with very exact and minute precision till the passing of the poor laws, when, in consequence of the claims of relief from their particular parishes, which these laws gave to the poor, it became a matter of serious consequence to define exactly the limits of each parish. They cannot now be altered, but by legislative enactment.

As it was found, that in the northern counties, where the parishes extended thirty or forty square miles, the poor laws could not be duly administered, a law was passed in the 13th of Charles II. permitting townships and villages, though not entire parishes, to maintain their own poor. Hence townships, in the north of England, may be regarded as divisions subordinate to parishes, and are as distinctly limited as if they were separate parishes.

Towns originally contained but one parish; but many of them now, from the increase of inhabitants, are divided into several parishes. Besides parishes, or townships, there are places which Extra-parochial, or not within the limits of chal places.
any parish. They were formerly the site of religious
houses, or of castles, the owners of which would not
permit any interference with their rights or privileges.
At present, they enjoy a virtual exemption from main-
taining the poor, because there is no overseer on whom
the order of a magistrate may be served—from the
militia laws, because there is no constable to make the
return—and from repairing the highways, because there
is no surveyor. Their tithes are, by inmemorial cus-
tom, payable to the king instead of the bishop. Extra-
parochial wastes and marsh lands, when improved and
drained, are to be assessed to all parochial rates in the
parish next adjoining. In some counties, liberties in-
terrupt the general course of law, as affecting hun-
dreds, in the same manner as extra-parochial places do
with regard to parishes. The number of parishes and
parochial chapellies in England and Wales, is 10,674,
of which about 550 extend into two counties, or into
more than one hundred.

Under the general name of town, are comprehend-
ed the several species of cities, boroughs, and common
towns. A city is a town incorporated, which either is,
or has been, the see of a bishop; for though the bi-
shopric be dissolved, as at Westminster, it still remains
a city. Every town, whether corporate or not, that
sends burgesses to parliament, is a borough. There
are other towns which are neither cities nor boroughs;
some have the privilege of markets, and others not.
To several of these there are attached small appendages,
called hamlets, which originally, according to Sir Hen-
ry Spelman, consisted of less than five freemen. Ham-
lets are sometimes under the same administration as
the town to which they are attached, and sometimes
governed by separate officers.

The number of counties into which England is at
present divided, is forty; and Wales consists of twelve.
Of the former, six may be considered as northern; four
border on Wales; twelve compose the midland district
of England; eight may be classed as eastern; three as
south-eastern; four as southern; and three lie in the
south-west of the kingdom. Wales is divided into two
parts, North Wales and South Wales; in the former
are six counties, and in the latter the same number.

Although, under each of the counties of England and
Wales, a particular description and account of them
will be found, yet it may be proper here, in order to
render this article more complete, to give their bound-
daries, their divisions into hundreds, parishes, &c. and a
list of their principal towns; referring the reader to
each county for further particulars.

The northern division of England consists of North-
umberland, which is bounded by Scotland and Cumber-
land on the west; by Durham and Cumberland on
the south; by the German Ocean on the east, and by
Scotland on the north. It contains one county town,
seven wards, twelve market-towns, and 450 parishes
and townships; the principal towns in it are New-
castle, North Shields, Hexham, Morpeth, and Aln-
wick. Cumberland is bounded by Scotland on the north;
by the Irish Sea on the west; on the east by Northumberland and Durham; and on the south by
Westmoreland and Lancashire. It contains one city,
five wards, 17 market towns, and 99 parishes; the prin-
cipal towns are Carlisle, Whitehaven, Workington, and
Penrith. Durham is bounded on the east, by the Ger-
man Ocean; on the north, by Northumberland; on
the west, by Cumberland; and on the south, by York-
shire. It contains one city, four wards, three detach-
ed hundreds in Northumberland; 14 market towns,
and 118 parishes; its principal towns are Durham,
Sunderland, and Darlington. Yorkshire is bounded
on the north, by Durham and Westmorland; on
the east, by the German Ocean; on the west, by West-
moreland and Lancashire; and on the south, by Cheshire,
Derbyshire, Nottinghamshire, and Lincolnshire. It
contains one city, 30 wapentakes, 60 market towns, and
563 parishes; and is besides, from its great extent, divided
into three ridings, the east, north, and west. In the east
riding, the principal towns are York, Hull, and Beverly;
in the north riding, Whitby, Scarborough, and Rich-
mond; and in the west riding, Leeds, Halifax, Wake-
field, Huddersfield, Sheffield, and Bradford. West-
moreland is bounded, on the north and north-east, by
Cumberland; on the east, by Yorkshire; and on the
south and south-west, by Lancashire. It contains one
county town, six hundreds, 27 market towns, and
61 parishes; its principal towns are Liverpool, Man-
chester, Bolton, Preston, Lancaster, Wigan, Wirral-
ington, Blackburn, Rochdale, and Bury.

The four counties which border on Wales, are Che-
shire, Shropshire, Herefordshire, and Monmouthshire.
The county of Chester is bounded on the north by
Lancashire, and a small point of Yorkshire; on the
east, by Derbyshire and Staffordshire; on the south,
by Shropshire, and a detached part of Flintshire; and
on the west, by Denbighshire and Flintshire. It
contains one city, seven hundreds, 13 market towns, and
68 parishes; the principal towns in Cheshire, are Che-
er, Stockport, Knutsford, Macclesfield, and Nantwich.
Shropshire, or the county of Salop, is bounded by
Cheshire, the detached part of Flintshire, and northern
of Denbighshire, on the north; on the west, by Den-
bighshire, Montgomeryshire, and Radnorshire; on the
south, by Herefordshire and Worcestershire; and on the
east, by Staffordshire. It contains one county town,
14 hundreds, 17 market towns, and 170 parishes;
the principal towns in Shropshire, are Shrewsbury,
Ludlow, Bridgnorth, and Oswestry. Herefordshire is
bounded, on the north, by Shropshire; on the west,
by Radnorshire and Brecknockshire; on the south, by
Monmouthshire and Gloucestershire; and on the east,
by Worcestershire. It contains one city, eleven hun-
dreds, seven market towns, and 176 parishes; its prin-
cipal towns are Hereford, and Ledgister. Mon-
mouthshire is bounded, on the north, by Hereford-
shire and Brecknockshire; on the west, by Glamor-
ganshire and Brecknockshire; on the south, by the
Bristol Channel; and on the east, by Gloucestershire.
It contains one county town, six hundreds, seven mar-
ket towns, and 127 parishes; the principal towns in
Monmouthshire, are Monmouth, Chepstow, and Aber-
gaveny.

The twelve midland counties of England, are Not-
tinghamshire, Derbyshire, Staffordshire, Leicester-
shire, Rutlandshire, Northamptonshire, Warwickshire,
Worcestershire, Gloucestershire, Oxfordshire, Bucking-
hamshire, and Bedfordshire.

Nottinghamshire is bounded, on the north, by
Yorkshire and Lincolnshire; on the east, by Lincoln-
shire; on the west, by Derbyshire; and on the south,
by Leicestershire. It contains one county town, six,
hundreds, nine market towns, and 168 parishes; the principal towns in this county are Nottingham, Newark, and Mansfield. Derbyshire is bounded, on the north, by a small part of Cheshire and Yorkshire; on the east, by Nottinghamshire; on the south, by Leicestershire, a point of Warwickshire, and Staffordshire; and on the west, by Cheshire and Staffordshire. It contains one county town, six hundreds, 11 market towns, and 106 parishes. Its principal towns are Derby, Chesterfield, Buxton, and Matlock. The county of Stafford is bounded on the west by Cheshire and Shropshire; on the east, by Derbyshire and Warwickshire; on the south, by Worcestershire; and on the north, by Cheshire and Derbyshire. It contains one city, one county town, five hundreds, 19 market towns, and 150 parishes. The principal towns in Staffordshire are Lichfield, Stafford, Newcastle under Lyme, and Burton upon Trent. Leicestershire is bounded on the west by Derbyshire and Warwickshire; on the east, by Rutlandshire and Lincolnshire; on the north, by Nottinghamshire and Derbyshire; and on the south, by Northamptonshire. It contains one county town, six hundreds, eleven market towns, and 192 parishes. Its principal towns are Leicester, Longborough, Hinckley, and Lutterworth. Rutlandshire is bounded by Lincolnshire on the north and north-east; by Northamptonshire on the south and south-east; and by Leicestershire on the west. It contains one county town, five hundreds, two market towns, and 55 parishes. The principal towns in this county are Rutland, Oakham, and Uppingham. Northamptonshire is bounded on the north and north-west by Rutlandshire, Lincolnshire, and Leicestershire; on the west, by Warwickshire, Northamptonshire, and Oxfordshire; and on the east, by Bedfordshire and Huntingdonshire; on the south, by Bedfordshire and Huntingdonshire, and a small point of Cambridgeshire. It contains one city, one county town, twenty hundreds, twelve market towns, and 302 parishes. The principal towns in Northamptonshire, are Northampton, Peterborough, Wellingborough, Kettering, and Daventry. Warwickshire is bounded on the south by Oxfordshire and Gloucestershire; on the west, by Worcestershire; on the north-west, by Staffordshire; on the north, by Derbyshire; on the north-east, by Leicestershire; and on the east, by Northamptonshire. It contains one city, one county town, five hundreds, fourteen market towns, and 158 parishes. Its principal towns are Warwick, Coventry, Binningham, and Stratford on Avon. Worcestershire is bounded on the north by Salop and Staffordshire; on the west, by Herefordshire; on the south, by Gloucestershire; and on the east, by Warwickshire. It contains one city, five hundreds, eleven market towns, and 159 parishes. The principal towns in this county are Worcester, Kidderminster, Stourbridge, and Dudley. Gloucestershire is bounded on the south by Wiltshire, and part of Somersetshire; on the north, by Worcestershire; on the west, by Monmouthshire and Herefordshire; and on the east, by Warwickshire and Oxfordshire. It contains two cities, one county town, 23 hundreds, 26 market towns, and 280 parishes. Its principal towns are Gloucester, Bristol (in part), Cirencester, and Tewksbury. Oxfordshire is bounded on the north by Northamptonshire and Warwickshire; on the west, by Gloucestershire; on the south, by Berkshire; and on the east, by Buckinghamshire. It contains one city, 14 hundreds, 12 market towns, and 280 parishes. The principal towns in this county are Oxford, Witney, Woodstock, and Banbury. Buckinghamshire is bounded on the north by Northamptonshire; by Berkshire, and a point of Surrey, on the south; by Middlesex, Hertfordshire, and Bedfordshire, on the east; and by Oxfordshire on the west. It contains one county town, eight hundreds, 16 market towns, and 185 parishes. Its principal towns are Buckingham, Aylesbury, and Eton. Bedfordshire, the last of the midland counties, is bounded on the north by Huntingdonshire and Northamptonshire; on the west, by Buckinghamshire; on the south, by the same county and Hertfordshire; and on the east, by Cambridgeshire and Hertfordshire. It contains one county town, nine hundreds, ten market towns, and 124 parishes. The principal towns in this county are Bedford, Dunstable, and Ampthill. The eight eastern counties the, Linconshire, Huntingdonshire, Cambridge, Bedford, Farnsfolk, Essex, and Hertfordshire, and Middlesex. The county of Lincoln is bounded on the north by Yorkshire; on the east by the German Ocean, and by a part of Norfolk; on the west by Nottinghamshire and Leicestershire; and, on the south, by the counties of Rutland, Northamptonshire, and Cambridgeshire: it contains one city, 31 hundreds, 31 market-towns, and 630 parishes. The principal towns in Lincolnshire are, Lincoln, Boston, Stamford, and Gainsborough. Huntingdonshire is bounded on the south and south-east by Cambridge, on the north-east by the same county; on the north and north-west by Northamptonshire; and on the south-west by Bedfordshire. It contains one county town, six market-towns, four hundreds, and 107 parishes. Its principal towns are, Huntingdon and St Ives. Cambridgeshire is bounded on the west by Bedfordshire, Huntingdonshire, and a point of Northamptonshire; on the south by Suffolk, Essex, and Hertfordshire; on the north-west by Lincolnshire; and on the north-east by Norfolk. It contains one city, one county town, 15 hundreds, eight market-towns, and 163 parishes. The principal towns in Cambridgeshire are, Cambridge, Ely, Wisbeach, and Newmarket. Norfolk is bounded on the north and north-east by the German Ocean; on the south and south-east by Suffolk; and on the west by Lincolnshire and Cambridgeshire. It contains one city, 33 hundreds, 32 market-towns, and 660 parishes. Its principal towns are, Norwich, Yarmouth, and Lyn. Suffolk is bounded on the west by Cambridgeshire; on the east by the German Ocean; on the south by Essex; and on the north by Norfolk. It contains one county town, 22 hundreds, 29 market-towns, and 575 parishes. The principal towns in this county are, Ipswich, Bury St Edmunds, and Lowestoft. The county of Essex is bounded on the north by Suffolk and a part of Cambridgeshire; on the south by the Thames, which divides it from Kent; on the east by the German Ocean; and on the west by Hertfordshire and Middlesex. It contains one county town, 14 hundreds, five half-hundreds, one royal liberty, 27 market-towns, and 415 parishes. The principal towns in Essex are, Chelmsford, Harwich, Colchester, Bocking, and Braintree. Hertfordshire is bounded on the south by Middlesex; on the north by Cambridgeshire and Bedfordshire; on the west by Bedfordshire and Buckinghamshire; and on the east by Essex. It contains one county town, eight hundreds, 19 market-towns, and 120 parishes. Its principal towns are, Hertford, St Albans, Ware, and Barnet. Middlesex is bounded on the east by Essex; on the west by Buckinghamshire; on the north by Hertfordshire; and on the south by Surrey and a corner of Kent. It contains two cities, six mar-
The three south-eastern counties of England are, Surrey, Kent, and Sussex. Surrey is bounded on the north by Middlesex and a point of Buckinghamshire; on the south by Sussex; on the east by Kent; and on the west by Berkshire and Hampshire. It contains one county-town, 13 hundreds, 14 market-towns, and 140 parishes. The principal towns in Surrey are, Southwark, Guildford, Kingston-on-Thames, Fareham, Dorking, and Croydon. The county of Kent is bounded on the north by the Thames; on the east and south-east by the German Ocean and the Straits of Dover; on the south by Sussex; and on the west by Surrey. It contains two cities, one county-town, five lathes, 62 hundreds, 59 market-towns, and 408 parishes. Its principal towns are, Canterbury, Rochester, Maidstone, Chatham, Gravesend, Dover, and Tunbridge. Sussex is bounded on the north by Surrey and Kent; on the west by Hampshire; on the east by Kent, and the British Channel; and on the south by the latter. It contains one city, six rapes, 18 market-towns, 65 hundreds, and 32 parishes. Its principal towns are, Chichester, Lewes, Hastings, and Horsham.

The four southern counties of England are, Berkshire, Wilts, Hampshire, and Dorsetshire. Berkshire is bounded by Oxfordshire and Buckinghamshire, on the north; on the north-west by a point of Gloucestershire; on the south by Hampshire; on the east by Wiltshire; and on the west by Wiltshire. It contains one county-town, 20 hundreds, 12 market-towns, and 147 parishes. Its principal towns are, Reading, Abingdon, Windsor, and Newbury. Wilts is bounded on the north by Gloucestershire; on the east by Berkshire and Hampshire; on the south by Dorsetshire; and on the west by Somersetshire and Gloucestershire. It contains one city, 29 hundreds, 23 market-towns, and 304 parishes. Its principal towns are, Salisbury, Devizes, Wilton, Bradford, Trowbridge, and Chippenham. Hampshire, which includes the isle of Wight, is bounded on the north by Berkshire; on the east by Surrey and Sussex; and on the west by Wiltshire and Dorsetshire; and on the south by the English Channel. It contains one city, two county-towns, 38 hundreds, 20 market-towns, and 253 parishes. The principal towns in this county are, Winchester, Southampton, and Portsmouth; and Newport, Cowes, and Yarmouth, in the isle of Wight. Dorsetshire is bounded on the south by the English Channel; on the north by Wiltshire and Somersetshire; on the west by Devonshire; and on the east by Hampshire. It contains one county-town, 94 hundreds, 24 market-towns, and 248 parishes. The principal towns in this county are, Dorchester, Poole, Weymouth, Bridport, Blandford, and Shaftesbury.

The three counties in the south-western part of England are, Somersetshire, Devonshire, and Cornwall. Somersetshire is bounded on the north-west by the Bristol Channel; on the north-east by Gloucestershire; on the east by Wiltshire; and on the south by Dorsetshire and Devonshire. It contains two cities, and part of a third (Bristol), 43 hundreds, 32 market-towns, and 385 parishes. Its principal towns are, Bath, Wells, Taunton, and Bridgewater. Devonshire is bounded by the Bristol Channel on the north and north-west; by the English Channel on the south and south-east; by Cornwall on the west; and by Dorsetshire and Somersetshire on the east. It contains one city, 33 hundreds, 39 market-towns, and 394 parishes. The principal towns in Devonshire are, Exeter, Plymouth, Barnstaple, and Honiton.

North Wales comprises six counties; Flintshire, Caernarvonshire, Anglesey, Merionethshire, and Montgomeryshire. Flintshire is bounded by the Irish Sea on the north; by the estuary of the Dee and the county of Cheshire on the north-east and the east; and by Denbighshire on the south and west. It contains one county-town, nine hundreds, 27 market-towns, and 198 parishes. Its principal towns are, Bangor, Holyhead, and Caernarvon. Caernarvonshire has the sea on all sides of it, except the east, where it is bounded by Denbighshire; and the south, where it is contiguous to Merionethshire. It contains one county-town, ten hundreds, five market-towns, and 71 parishes. Its principal towns are Bangor and Caernarvon. The county of Anglesey is divided into seven, and comprises one county-town, six hundreds, six market-towns, and 36 parishes. Its principal towns are, Bangor, Caernarvon, and Holyhead.

The six counties in South Wales are, Radnorshire, Cardiganshire, Pembrokeshire, Caermarthenshire, Brecknockshire, and Glamorganshire. Radnorshire is bounded on the north by Montgomeryshire; on the east by Brecknockshire and Monmouthshire; on the south-east by Brecknockshire; and on the north-west by Cardiganshire. It contains one county-town, six hundreds, four market-towns, and 47 parishes. Its principal towns in this county are, Radnor, Presteigne, and New Radnor.

Cardiganshire is bounded from the north-east to the south-west by the Bay of Cardigan; on the north by a point of Merionethshire; on the east by Radnorshire and Brecknockshire; and on the south by Cardiganshire and Pembrokeshire. It contains one county-town, five hundreds, four market-towns, and 77 parishes. Its principal towns are Cardigan and Aberystwyth.
ENGLAND.

Cardiganshire; and on its eastern side, where it joins Caermarthenshire, it contains one city, one countytown, seven hundreds, nine market-towns, and 45 parishes. Its principal towns are, Pembroke, St David's, Tenby, and Haverford West.—Caermarthenshire is bounded on the north by Cardiganshire; on the east by Brecknockshire; on the west by Pembroke and on the south by Glamorgan and the sea. It contains one county-town, eight hundreds, six market-towns, and 87 parishes. The only town of consequence in this county is Caermathen.—Brecknockshire is bounded on the south-east, and partly on the south, by Monmouthshire; on the rest of the south by Glamorgan; on the west by Caermarthenshire and Cardiganshire; on the east by a small part of Herefordshire; and on the north-east by Radnorshire. It contains one county-town, six hundreds, four market-towns, and 59 parishes. Its principal towns are Brecon and Crickhowell.—Glamorgan is bounded on the south and west by the Bristol Channel; on the north by Caermarthenshire and Brecknockshire; and on the east by Monmouthshire. It contains one city, one county-town, 10 hundreds, eight market-towns, and 118 parishes. The principal towns in this county are, Caerphilly, Mold, Swansea, and Myrtwy-Tedwi.

Three of the counties in England are called counties Palatine, viz. Cheshire, Durham, and Lancashire: they are so called a palatia, because formerly the owners of them had the same rights, powers, and privileges, within them respectively, as the King himself possessed in his palace. These privileges appear to have been granted to the counties of Chester and Durham, because they bordered on an enemy's country; and for the same reason, Pembroke and Hexhamshire, (the latter of which is now united to Northumberland,) were formerly counties palatine. Of those which yet remain so, Durham is the only one now in the possession of a subject; the earldom of Chester was united to the crown by Henry III. and has ever since that period given a title to the eldest son of the king; and by various acts of parliament, the inheritance to the whole lands of the Duchy of Lancaster is vested in the crown. The Isle of Ely, though not strictly speaking a county palatine, possesses the same right as a royal franchise; the bishop of Ely, by a grant of Henry I. exercising, within the isle, a jurisdiction over all causes, as well criminal as civil.

Counties corporate, are certain cities and towns, some with more, some with less territory annexed to them; to which has been granted, by the special favour of the kings of England, the privilege to be counties of themselves. They are governed by their own sheriffs, or other magistrates; so that no officers of the county at large have any authority over them. Counties corporate, as well as corporate towns, are not included in any hundred; most of the cities of England, as well as the five towns of Kingston-upon-Hull, Nottingham, Newcastle-upon-Tyne, Poole, and Southampton, are counties corporate.

The town of Berwick-upon-Tweed originally formed part of Scotland; but it was reduced under the possession of the crown of England, by Edward I. by whom a charter, bestowing upon it certain privileges, was granted to it: this charter was confirmed by Edward IV. and James I. It is specially named in all acts of Parliament.

The Isle of Man is a distinct territory from England, and not governed by its laws, nor by any act of Parl-VOL. VIII. PART II.-liament, unless it is particularly named in it. The principal places in this island are Douglas and Castle Town.

The islands of Jersey, Guernsey, Alderney, and Sark, formerly belonged to the Duchy of Normandy; but were united to the crown of England by the first princes of the Norman line. They are bound by their own laws; but an appeal lies from their courts to the king in council. Unless particularly named in acts of Parliament, they do not extend to them. Each of these islands is divided into parishes, which are again subdivided into what are called vintons.

CHAP. II.

Face of the Country.

The most extensive or highly favoured tracts on the face of the globe, can scarcely exhibit a greater variety of features than England displays. In some parts, verdant plains extend as far as the eye can reach, watered by copious streams, and covered by innumerable cattle. In others, the pleasing vicissitudes of gently rising hills and bending vales, fertile in corn, waving with wood, and interspersed with meadows, offer the most delightful landscapes of rural opulence and beauty. Some tracts abound with prospects of the more romantic kind; lofty mountains, craggy rocks, deep narrow dells, and tumbling torrents; nor are there wanting, as a contrast to so many agreeable scenes, the gloomy features of black barren moors, and wide uncultivated heaths." Such is the general description of the face of the country of England, given by a writer who, both from the powers of his pen, and his acquaintance with the country he was describing, was capable of drawing a just and striking picture: but it will be proper and instructive, as well as interesting, to enter into a more detailed description of the physiognomy, as it has been termed, of the country of England. The chief features of any country are its vales, hills, rivers, and lakes; and, of a maritime state, its sea coast. We shall first describe the vales and hills of England, and afterwards attend to its hydrography; under this head comprehending a description of its sea coast, and its rivers and lakes.

In the English language, the words vale, valley, and dale, have very appropriate and distinct meanings:—vale, which corresponds in meaning with the word strath in Scotland, signifies an extent of low country, some miles in width, lying between ranges of higher grounds: the word valley is the diminutive of vale; it is commonly used in the south of England, but in the north of England and in the south of Scotland, the word dale is used in the same acceptation, and in the highlands of Scotland the word glen. In a valley, the lower grounds are narrow, as from half a mile to a mile or two in width, generally with a high steep bank rising on each side. The dell of the south of England corresponds to the groy or gill of the north of England, and the leugh of the south of Scotland is the diminutive of dale or valley, and generally signifies the branch of a valley, or a short or otherwise inferior valley; dingle is the diminutive of dell.

Of these we mean to confine ourselves entirely to a description of the vales of England; the vallies, dells, and dingles, are too numerous; and most of them, though beautiful or striking in their scenery and features, too unimportant to be particularly noticed.
bason formed by eminences on every side, except one narrow outlet for its waters. The rivers which flow through it are the Derwent and Rye. The district of Holderness, though not strictly speaking a vale, has so Holder- decidedly the natural characters of a true vale district, not.

The vale of Pickering, the remaining quarter is filled up with the chalk cliffs of the Wold; its form is an imperfect oval, the larger diameter of which is about 35 miles; its shorter rather more than 10; its area contains nearly 300 square miles. This vale has all the appearance of a lake left dry by nature; it is in fact a

The vale of York may justly be regarded as the first of the Yorkshire dales; it is situated between the Tees and the Wharfe, the marshes of Yorkshire and Lincolnshire constitute its southern boundary; its western limits are the limestone lands of West Yorkshire, and the skirts of the Western moors; the moorlands, limestone heights, and wolds, of the East Riding, constitute its eastern boundary. From north to south its length is about 60 miles; its average breadth is about 10; its area contains more than 1000 square miles. There are nine towns in the area of this vale, the principal of which are York, Helmsley, Thirsk, and Boroughbridge; its western margin is studded with Richmond, Rippon, Knaresborough, Tadcaster, and Doncaster; on its eastern margin there are four towns, none of them however of any size or consequence. The surface of this vale is sufficiently diversified, to give richness and beauty to its appearance; by far the largest portion of its soil is fertile, and its agriculture is generally good. The northern extreme of the vale of York imperceptibly unites with the south-west margin of the vale of Stockton; the rising ground by which they are naturally divided, being so inconsiderable, as to escape the eye in a general view of the country. Thus, there is an uninterrupted continuance of wide spreading vale lands, from the mouth of the Tees to the Humber, a distance of almost a hundred miles.

The limestone lands of east Yorkshire, which stretch westward from near Scarborough, along the feet of the moorlands, to the Hambledon hills, and then bend southward to the extremity of those hills, where the line returns eastward, and along the Howardian hills to Malton, form three-fourths of the outline of the vale of Pickering; the remaining quarter is filled up with the chalk cliffs of the Wold: its form is an imperfect oval, the larger diameter of which is about 35 miles; its shorter rather more than 10; its area contains nearly 300 square miles. This vale has all the appearance of a lake left dry by nature; it is in fact a

There is no vale, or flat tract of land of considerable extent or importance, as we enter England on the west side from Scotland, till we reach Lancashire, if we except the district of Carlisle. This may, with little latitude, be deemed an extensive plain; indeed, for several miles round this city, there is a vale district of the first quality; but the plain, taken in its whole extent, is bounded on the north by the estuary of the River and the moss of the Solway; on the north-east, by the heights of Gillland; on the east, by the moorlands of Cumberland; on the south, it unites with the valley of Appleby; and on the west, by the slate-rock mountains and the inlet of Abbey Holm. Its area is four or five hundred square miles; it is only on its southern margin that in its elevation it rises above the true vale character.

The vale of Woofdale (or Woofdale) is also a vale which enjoys a great degree of fertility, is formed by Warring- the Mersey, and comprises a considerable extent of land, ground, both on the Lancashire and Cheshire side of that river.

Cheshire is in general a flat country; a ridge of high ground crosses it from north to south on its western side; and on its eastern border there are some considerable eminences, which unite with the hills of Derbyshire and Staffordshire: the rest of the county is nearly level.

The vale of Severn, taken in its most comprehensive sense, may be considered as beginning above Chepstow: Severn river receives Worcestershire almost entirely in its outline; it then contracts and closes on the north with the hills of Shropshire and Staffordshire. Its banks on the west, are formed by the forest of Dean, Malvern, and the Malvern hills, and the hills of Herefordshire and Shropshire. Its eastern banks are formed by the lower parts of the river, Warwickshire, closing with the Lye and Clent hills. It is partially divided into three districts, by Brecon hill and some smaller hills, the district of Worcestershire, the vale of Gloucester, and the vale of Evesham; but if we could suppose these hills and some hillocks near Gloucester removed, the whole would form an unbroken vale, which accompanies the Severn from the union of its principal branches till it enters the British Channel. The upper part of this extensive vale is rich, but not picturesque; it is too flat, and the banks in this part are tame. Its more striking and finished
The vale of Gloucester, or that vale which accompanies the Severn through Gloucestershire, and which has already been noticed as part of the vale of the Severn, deserves to be particularly noticed. It may be divided into two districts,—the vale of Gloucester, and the vale of Berkeley. The form of the vale of Gloucester is semicircular, the Severn composing the chord, and the environs of hills the arch: in it lie the city of Gloucester, and the towns of Tewksbury and Cheltenham. Its extent from Matson-hill to Bredon-hill, on the north, is 15 miles; its breadth from the Severn to Dowleshill is seven or eight miles. It contains 100 square miles, or between 50,000 and 60,000 acres.

The vale of Berkeley approaches, in its outlines, nearer to the segment of a circle than to any other regular figure; the river Severn forms an irregular chord; the hills to the south and east, a curve, which is continued to the northern end by the Matson hills; from the foot of these hills to Aynsley, its extent is about 25 miles; its medium width about four miles. It contains about 80 square miles, or 50,000 acres. The waters of the Severn, which here form a lengthened estuary rather than a river, produce infinite grandeur when they mix in the view. The surface, which is somewhat irregular, is clad in perpetual verdure: the bottoms of the hills stretch in many places towards the river, hung with beech of the most luxuriant growth: the soil is uniformly rich, and the scenery, in general, extremely fine. The land is almost entirely appropriated to grass, there being scarcely 1000 acres under the plough in the whole district.

In the south-west of England, the vales of Exeter and Taunton are the most worthy of notice and description. The vale of Exeter accompanies the Exe from the sea to the Tiverton hills, which constitute its northern boundary. This boundary is continued toward the east by Blackdown hill, till it reaches the Honiton hills. The western boundary of the vale is the Halldown hills, and a continuation of some heights that lie to the north of Exeter: here the vale spreads to the west, till it approaches Credington. It contains about 200 square miles, and is watered by the Exe and the Otter.

The vale of Taunton lies in the north-west quarter of Somersetshire. It is bounded on the north by the Quantock hills; on the south, by the Blackdown hills, which separate it from the vale of Exeter; on the west, it is bounded by the skirts of Exmoor; its boundaries on the east are not accurately defined, but in general they are formed by the rising grounds of Curry, and the marsh of South Sedgmore. The vale of Taunton is small, comprising only about 100 square miles; the river Tone runs through it: its productions are corn, particularly wheat, of remarkably fine quality.

The prolific vale of Aylesbury lies in the county of Buckingham. It is formed by the river Thames, and a small stream which falls into that river at the bottom of the vale. It furnishes a rich pasturage to an immense number of cattle, its amazing fertility being principally employed in the support of the dairy and grazing systems.
ENGLAND.

tract of land, in general level, though in some places its surface is varied with gentle eminences. It extends from Ashworth in Kent, to Petworth in Sussex; being bounded, for the most part, by the South Downs on the south, and by the chalk hills of Kent and Surrey on the north. In length it is about sixty or seventy miles, and its breadth is from ten to fifteen. It contains nearly 1000 square miles. The soil of the Weald, for the most part, is a pale clay, interspersed occasionally with tracts of heath, especially in the Sussex division of it. The greater part of it is in a tolerably good state of cultivation; and from the tops of the adjacent hills it affords one of the finest views imaginable. Its original appellation seems to have been the Wild Forest, or Chase; and the Saxon Chronicle informs us, that the Britons called it Andrede, the Marvellous, or Coide Andrede, the Mighty Wood. It was, at that period, a rude uncultivated waste, overgrown with wood, for which it is still famous. In order that it might be reclaimed, the Saxons united parcels of it to the farms in the neighbourhood; and it was applied to the purpose of feeding the hogs of the tenants, being deemed unfit either for arable or pasture. The valleys in which it abounds were first brought into a state of cultivation, and took their respective apppellations from the persons who brought them into this state; as Haldean, (or valley,) Tenterden, Maldean. In process of time, and in the Kentish part of the Weald, in consequence of the custom of gavelkind, these deeds are become, by division and subdivision, very small, in comparison of what they originally were. In the winter season, and in wet weather, the roads in many parts of the Weald are scarcely passable. On the principal roads, which are from fifty to sixty miles broad, there are generally paved causeways, about three feet wide, for the accommodation of the foot passengers.

The other level tracts of England that deserve, on account of their extent, to be particularly noticed, are the fens, Romney marsh, and the marshes of Somersetshire, together with some of the principal heaths that lie on level ground. The fens, as they are emphatically termed, lie in the counties of Northampton, Lincoln, Norfolk, Suffolk, Cambridge, Huntingdonshire, and part of the isle of Ely. These fens are frequently mentioned by our ancient civil and ecclesiastical historians. During the period of the power and splendour of the Catholic religion, they were maintained in tolerably good order, under the direction and patronage of the clergy and monks, who had many rich religious houses scattered through them, such as Peterborough, Ely, Croyland, Ramsey, Thorney, &c. After the dissolution of these religious houses, at the Reformation, the estates belonging to them coming into private hands, the dikes and drains which the clergy had caused originally to be erected, and which they had kept in repair, fell into decay, and, in consequence, the country was overflowed, and reduced gradually into a wretched condition. The legislature at length found it absolutely necessary to interpose; and a statute was passed, 43d Elizabeth, chap. ii. for the purpose of draining them. Great objections, however, were made to this plan by some, on account of its supposed impracticability, or on account of the enormous expense which it would require; and by others, on the ground, that, even in the state in which they were, they would pay better than if they were to be drained and embanked, at the expense which would necessarily be required. In consequence of these objections, this plan was not carried into execution at that time. In the reign of James I., two laws were passed in favour of draining these fens; but these also were not carried into effect. At last, in the 13th year of the reign of Charles I., a charter was granted to a corporation, with Francis, Earl of Bedford, at their head, for draining the great level. The civil wars for a time prevented the commencement of the work; and when, in 1653, it was begun, it was again opposed, on the allegation that the fens produced as much in reeds and sedge, as they could be made to do by expensive draining. In answer to this, an account was taken that year, from which it was proved, that the wheat, barley, oats, hemp, flax, &c. which grew on 28,000 acres, yielded L.113,000. After the Restoration, the corporation was legally and permanently settled, by the 15th Charles II. chap. 17; and on the basis of this statute, this important undertaking has rested ever since. By the Bedford Level, as it is called, upward of 500,000 acres of land have been drained; and since the completion of that work, other large tracts in this fenny country have also been reclaimed.

Romney Marsh, in the county of Kent, is an extensive tract of level rich land, lying on the south coast. What is strictly included under this appellation, comprehends about 23,925 acres; but when it is described, as it generally is, in connection with the Wealden Marsh, which adjoins it on the south-west, and with Denge Marsh, which unites with the latter on the south-east, it includes about 43,326 acres. The level tract of land, however, in this part of England, is still more extensive; for Guildford Marsh, which lies to the west of Wealden Marsh, comprises 3263 acres: most of this latter tract is in the county of Sussex. The soil of those sparsely levels is uncommonly rich, being almost entirely a deposit from the sea; it consists of a soft and unctuous clay, mixed with a greater or less proportion of sea sand. In the summer season, when the surface is clothed with luxuriant verdure, and covered with numerous flocks of sheep and droves of cattle, the appearance of these levels is uncommonly beautiful and interesting. They differ from the fens in this respect, that they were not recovered, but wrested from the sea; but at what period is not accurately known. It is probable, however, that parts of these lands were gained during the early part of the Saxon period of our history. Somner, in his discourse concerning Roman ports and forts in Kent, produces a charter of marsh land by Plegmund, who was archbishop of Canterbury, from A.D. 889 to 913; and this charter seems not to have been among the first. The clergy, indeed, in this part of the kingdom, had a great interest in regaining these lands, as most of the property in the vicinity of them belonged to them; and the practice of innining, as it was called, that is, wresting land from the sea, is commonly supposed to have originated with them. The archbishop of Canterbury, in particular, applied themselves to this object, and gave their names to the land which they respectively gained. Thus we read of Becket's, Baldwin's, Boniface's, Peckham's innings. The whole level is prevented from being overflowed at high water, by an immense embankment, called Dymchurch Wall, from its contiguity to the village of that name. This wall forms the only highway for carriages, along its whole extent, between Hith and Romney. Its perpendicular height from the marshes is, in most parts, from twelve to eighteen or twenty feet. The slopes are steep, and pretty regular. Next the sea, it forms a shelving irregular beach, that is carried out to the distance of more than 100 yards. The width of the top of the wall is

from fifteen to nearly thirty feet. Its length is rather more than three miles. Arched sluices, that pass under the banks; each with two pair of flood-gates, effect the drainage. When the tide is low, the waters are allowed to pass off by means of these gates, while they prevent the sea from entering when the tide is full. By ancient custom, the lords of the twenty-three manors in and adjoining to the marsh, have the management and superintendence of the drainage. They appoint a bailiff, as principal supervisor of the works. Edward III. granted a charter of incorporation for the same purpose. By this charter, the laws respecting Romney marsh are to be administered by a bailiff, twenty-four jurats, and the commonalty; who are empowered to hold a court every three weeks, to decide on all pleas, and to choose four judges from among themselves yearly, besides the bailiff, whose authority is to be similar. The bailiff, chosen by the lords of the manors interested in the marsh, is generally the same person, as the bailiff chosen under the charter of Edward III. The courts are held at Newhall, in Dymchurch; and the scots, or levies, for the preservation of the embankment, are then paid.

We have dwelt thus long and minutely on the fens of Lincolnshire, &c. and the marshes of Kent, &c. because they present very interesting and extensive tracts of level land, and therefore form a prominent feature in the physiognomy of the kingdom, and because their improvement is a matter of great national concern and benefit. But we must pass over the marshes of Somersetshire, and the level heaths of the kingdom, with less particular and extended description. Selgro. 

Selgro is the largest and most remarkable district of marsh and level land in the county of Somerset; besides it, there are the Brent marshes, and the low watery grounds, that stretch themselves to a great extent on that side of the county. If to these we add the Connington fens, and the mirey tracts in their vicinity, we shall comprehend nearly the whole extent of marsh land in Somersetshire.

The most extensive level heaths in the kingdom, are those of Bagshot, and those which lie on the confines of Dorsetshire and Hampshire. Bagshot heath forms the north-western corner of the county of Surrey, and presents a very large tract of uncommonly barren land, for the most part quite level and uninteresting. The heaths of Hampshire and Dorsetshire are much less level, and perhaps not quite so irremovable. They commence about half way between Christchurch, in the former county, and Poole, in the latter.

Such are the principal vales and level tracts of England and Wales; and from this account and description of them, it will be seen, that the most extensive and uninterrupted level tracts are on the eastern side of the kingdom; while, with the exception of the vale of York, the most extensive, as well as the most beautiful, vales are on the western side, between England and Wales.

The next grand and distinguishing feature in the physiognomy of the country, consists of the mountains, hills, and moorlands; under the last denomination, comprehending the principal elevated tracts of heathy or moorish ground.

Through the whole length of England and Wales, there are groups of mountains and hills, which, when viewed on a grand scale, may be considered as forming one chain, extending along the western side of the kingdom, from Cornwall to Cumberland. In this chain, all the highest mountains of England and Wales are situated. The breadth of the kingdom may also be considered as determined by two lower ranges of hills; one of which extends from Dorsetshire into Kent, while the other stretches, in a waving line, from the island of Portland to the Wolds, in the east riding of Yorkshire. The line which is formed by this latter chain of hills, passes on the western side of Wiltshire and Oxfordshire, and through Northamptonshire, Leicestershire, Nottinghamshire, nearly to Scarborough. The Bristol Channel, and the low grounds of Lancashire and Cheshire, break and divide the western chain of mountains into three parts; which have been denominated the Northern, the Cambrian, and the Devonian range.

The northern range enters Cumberland from Scotland, and, passing through that county and Westmoreland, extends its branches into Northumberland and Durham. The branch which enters Northumberland composes the Cheviot Hills. It is not easy to form an estimate of the extent of these hills, as they unite with the morland district of Northumberland to the south, and are continued to the westward by similar green hills in Scotland. On the supposition that their bases occupy a circle of about fifteen miles in diameter, their contents will be from 150 to 200 square miles. In form, many of them are conical, some of them nearly perfect cones, while the shape of others is very irregular; in general, however, they are pointed, their sides are steep and smooth, and their bases are nearly in contact one with another. The soil on these mountains, except at their very tops, where points of rock and loose stones appear, is fertile; from base to summit, they present a refreshing and rich green sward. On the upper parts of that hill, which is emphatically denominated the Cheviot, however, extensive heaths are found.

That chain of northern mountains which may properly be called the Cumberland chain, commences at Geltisdale Forest, fourteen miles south-east of Carlisle, and passes on the west of Durham and Yorkshire. The surface of these mountains, in general, is excessively ragged; and in their disposition there is nothing of regularity, no lengthened ridge or continuous chain. The appearance of the whole is that of a congeries of broken and mostly pointed masses; their bulk immense, and their bases united, or nearly so, except in those places where they are divided by the lakes which are scattered among them. The Cumbrian hills resemble the Cheviot in the green sward with which they are covered; but Skiddaw, like Cheviot, is partially clothed with heath. The extent of this tract of mountains in Cumberland, Westmoreland, and Lancashire, is about 500 or 600 square miles.

The northern range, taking it in its utmost extent, forms, by its mountains and vallies, the fascinating scenery round the lakes of Cumberland and Westmoreland—the gloomy grandeur of Craven, in Yorkshire—and the romantic dales of Derbyshire. The loveliest part of it is seen in all its magnificence on the road from Kirby Lonsdale to Kendal. The general height of these mountains is from 3000 to 3400 feet. According to the barometrical admeasurements of Mr Dalton, the particular heights of the most remarkable are as follows:

England.

Ingleborough is nearly the same height as Whernside. Crossfell, in Cumberland, which borders on the county of Durham, according to Donaldson, is 3590 feet; and according to Mr Bailey, (in his Agricultural Report of Cumberland,) 3400 feet. The height of Saddleback, according to the latter author, is 3048 feet.

The southern division of the northern range, is divided from the northern division, by the valley of the Ribble, Craven, and the valley of the Ayre: its western boundary is formed by the lower, or vale lands of Lancashire and Cheshire; its eastern, by the manufacturing districts of Yorkshire; and its southern, by the upper grounds of Derbyshire and Staffordshire; the extent of these hills is above 60 miles: their width is extremely irregular, being upwards of 20 miles from the feet of the Cheshire hills, to the hills near Sheffield, whereas between Blackstone-edge and Huddersfield, they merely form a ridge. The highest hills in Derbyshire are Kinder Scout, near Hayfield; Edge near Buxton, and Whinbill and Mam Tor near Castleton; but they are much lower than the mountains of Cumberland, the highest part of Derbyshire not being more than 2100 feet above the sea.

As we approach the Alpine districts on the west of England, we meet with some hills, which it may be proper to notice, before we proceed to the consideration of the Cambrian range. The Malvern hills, which are situated partly in Gloucestershire, but principally in Herefordshire and Worcestershire, are from 1100 to 1300 feet high: the highest parts are those distinguished by the names of Herefordshire and Worcestershire beacons; the former rising near 1250, and the latter 1300 feet above the level of the plain; the Malvern hills extend for ten miles, rising on the eastern side, from the flat country, which forms the vale of the Severn; they are connected on the western side with a range of lower hills, which extend several miles into Herefordshire.

The Cotswold and Stroudwater hills, in Gloucestershire, are by some regarded as a continuation of the central chain, proceeding south from Derbyshire, and passing through Gloucestershire into Wiltshire, thence swelling into the Salisbury downs, and afterwards running west towards the Land's End in Cornwall. If viewed in this light, they may be regarded as connecting the northern with the Devonian range. The extent of the Cotswold hills, from Broadway hill to near Tetbury, is 30 miles; their area, about 200,000 acres; their surface is billowy; and their climate, if the natural elevation of the land is considered, unusually mild. The sides of the hills abound with springs, "and almost every dip has its rill, and every valley its brook." The Stroudwater hills partake, in some parts, of the character and features of the Cotswold hills, and in other parts, they partake of the vale character.

The Wrekin.

The Wrekin hill in Shropshire is so much higher than the surrounding hills, that it appears to rise alone from the middle of the plain. It is craggy at the top, its form is that of a long oval, pointing nearly north and south; it has been supposed very exactly to resemble a whale asleep on the surface of the sea. The most precipitous side of this mountain, is the eastern; its height is reckoned about 1200 feet. The Wrekin may be considered as the northern extremity of a ridge, lying in the same line with it, and consisting of the hills of Frodsham, Caradoc, &c; each of these, has the long diameter from north to south. They are craggy at the top, and ascend from the plain of Salop very abruptly, at an angle of about 60°.

The Cambrian range of mountains is considerably more elevated in North than in South Wales, extending through Caernarvonshire and Merionethshire, and declining in height as they pass through Cardiganshire. The direction of this range in Caernarvonshire is north-eastern, from Bardsey Island to a promontory in the bay of Conway. The mountains composing it are the highest of any in Wales, and gradually ascend from each extremity of the range towards the centre, which is formed and occupied by Snowdon, the loftiest of all; the altitude of the highest point of this celebrated mountain is about 3600 feet from the high-water mark on Caernarvon quay. It is composed of various cliffs, rising one above another; and that particular peak, to which the name of Snowdon is given, scarcely exceeds in height several of the summits that surround it on all sides.

From Snowdon, a line of mountains extends by the sea to Plynlimmon, a boundary of North Wales; of these mountains, the most lofty and the most celebrated is Cadar Idris. In height it is the second in Wales. It rises on the seashore about a mile above Torvyn. Its ascent is gradual, first in a northerly direction for about three miles, then for about 10 miles east-north-east. From its summit, a branch spreads out in a south-west direction, nearly three miles long, which is parallel to the main ridge. On all sides it is steep and craggy, but the southern side is almost perpendicular. It is about 3540 feet above the level of the sea, which is 80 yards higher than most of the mountains in Cumberland. On the east of North Wales, the hills do not attain nearly such great elevation, gradually declining to the hills of Shropshire, which have been already noticed. In South Wales, a chain proceeds to near Cardiff; its direction is nearly south, a small branch diverging to the west: this chain is of far inferior elevation. On the east of South Wales, are the hills of Herefordshire.

The Devonian range of mountains passes through Devonian part of Somersetshire, through Devonshire and Cornwall, and terminates at the Land's End. The highest part of this range is formed by the mountains of Dartmoor in Devonshire, the altitudes of the principal eminences being from 1500 to 1800 feet. On approaching this tract from the south and south-east, the eye is bewildered by an extensive vale, exhibiting gigantic tors, large surfaces covered with vast masses of scattered granite, and immense rocks. Dartmoor, and the waste called the Forest of Dartmoor, occupy the greatest portion of the western district, and include between 200,000 and 300,000 acres of uncultivated land; of these Dartmoor alone is supposed to comprise upwards of 60,000. In the highest parts to the north and west are vast tracts of wet swampy ground, which supply the inhabitants with peat for fuel. From Dartmoor the chain extends to the extreme of Cornwall: the only other hills in this range are the Mendip hills; they are situated in Somersetshire, stretching from Whately near Frome, Selwood on the east, to Axbridge on the west, and from Redminster on the north, to Glastonbury on the south.

It has already been mentioned, that the breadth of the island may be supposed to be determined in the southern and eastern parts by two ranges of hills, across the considerably lower than that range, which determines.
its length; according to some, one of these chains extends from Dorsetshire to Kent, while the other is represented as stretching from the isle of Portland to the Wolds. According to others, the three loftiest and most naked ridges of the south-eastern quarter of the island, commence on Salisbury plain, an amazing extent of high and chalky land, stretching 25 miles east to Winchester, and 28 miles west to Weymouth; its breadth, in some places, being from 35 to 40 miles. The first of the ridges which takes its rise from this quarter, after intersecting Hampshire and Sussex, terminates at Beachyhead; that part of it which lies in Sussex, forms the famous South Downs, which are nearly 50 miles long, and about five or six broad. The second ridge extends to the eastern shore of Kent, and forms the Surrey hills or downs, little less celebrated for the goodness of their sheep-pasture than the South Downs. A little to the east of Farnham, in this county, they are merely a narrow ridge, called the Hogsback; but as they penetrate more deeply into it, their breadth becomes considerable; their southern side, in general, is steep; their northern, gently sloping. The third range, which, by some, is supposed to take its rise on the Wiltshire downs, crosses Oxfordshire, &c. into Norfolk. The hills of Gogmagog in Cambridgeshire, belong to this range. The Chiltern hills, another upland tract of considerable elevation, extend from Tring in Hertfordshire to Henley in Oxfordshire.

The most extensive and celebrated moorlands are those of Northumberland; of the five counties, as Mr Marshall denominates them; of Lancashire; the eastern and western moorlands of Yorkshire; and the moorlands of Staffordshire. The moorlands of Northumberland may be divided into the western and the southern; the latter, however, unite with, and therefore properly belong to the moorlands of the five counties, according to Mr Marshall's arrangement. The western moorlands occupy more than one-third of the surface of the county. The north Tyne rises in their north-western quarter, and runs nearly through the middle of them.

The moorlands of the five counties, of Durham, Northumberland, Cumberland, Westmorland, and the northern part of Yorkshire, form one united mass of mountain heights, which is separated, on the north, from the main body of the Northumberland moorlands, by the valley of the Ithling, and on the south by the valley of the Greta, from the western moorlands of Yorkshire. The moorlands of Lancashire are separated into two divisions, by the valley of the Ribble. The northern division is insulated, being separated from the western moorlands of Yorkshire by Craven, and the district which intervenes between Craven and Lonsdale. This district forms their boundary on the north; on the west, they are bounded by the cultivated lands of Lancashire. The southern division of the moorlands unites itself with the southern range of the mountains of the north of England, which has been already described. The eastern moorlands of Yorkshire are bounded, on the west, by the vale of York; on the east, by the sea coast district of the north riding of this county; on the north, by the vale of Stockton; and on the south, by the limestone lands of east Yorkshire. Their extent, if the valleys which lie among them are taken into the calculation, may be about 400 or 500 square miles. The elevation of this minor class of English mountains is much below that of the Cumberland mountains. Their surface is tame, their soil poor, and in natural economy they resemble the moorlands of Northumberland and Durham, rather than those of the west riding of Yorkshire.

The western moorlands of Yorkshire, which form a tract of black, heathy mountains, are bounded on the north by the valley of the Greta; on the south, they are divided from the more southern mountains of the north of England, which have been already mentioned, by the manufacturing district, and by the valley of the Ayre; on the north-west, they extend into Westmoreland and Cumberland; on the west and south-west, their boundary is formed by the district of Craven, which contains the mountains of Ingleborough and Whernside, already described as forming part of the great northern chain on the east; these moorlands shelve down to the cultivated lands that constitute the western bank of the vale of York. The elevation of the western boundaries of these mountains is very considerable; inferior, indeed, to the elevation of the Cumberland mountains, but much greater than the elevation of the eastern moorlands of Yorkshire. Their surface, however, is tame, merely swelling: from this character, indeed, must be excepted their western margin, which is much broken, and strongly featured.

The moorlands of Staffordshire lie on the northern part of that county, to the north of a line drawn from Uttoxeter to Newcastle under Lyme. Their elevation must be considerable, as some of the numerous streams which take their rise in this tract of country run into opposite seas. That part of them which lies between Cheadle and Oak-Moor, consists of an immense number of rude heaps of gravel, thrown together without order or form, into sudden swells and deep gams. To the north of Oak Moor the calcareous part of the moorlands begins, reaching in length from the Weaverhills to Longnor, and in breadth from Dove to Morridge, and including fifty or sixty square miles. This is the best part of the moorlands; the worst part lies north-east of Mole Cop, and west of Leek. The summit of some of the hills in this district terminate in huge tremendous cliffs, particularly those called Leek rocks; here single blocks of immense size are heaped together; and some of prodigious bulk have evidently rolled from the summit, and broken in pieces.

The Wolds of Yorkshire have already been mentioned as being considered by some to be the northern extremity of the chalk hills of England; and, indeed, their natural character is the same as the chalk hills of the southern counties, but their termination differs from that of their western extreme. Here they end abruptly, in tall, steep, cliffs, the mass having the appearance of having been impelled in a southern direction; there the extremity is more shelving, broken, and irregular, fragments being found insulated, and scattered at several miles distance from the body of the hills. The outlines of the wolds are irregular; with respect to their extent, if they are measured from the vale lands of Holderness to those of the vale of York, and from those of the vale of Pickering to the now calcareous lands at their southern extremity, cannot be less than 500 square miles.

In elevation, surface, soil, and substrata, the wolds are very similar to the chalk hills of Kent, Surrey, Sussex, Hampshire, Wiltshire, and Dorsetshire.

In describing the sea coast of England and Wales, we shall begin with the mouth of the Thames, and proceed northward. The mouth of this river is formed by the Naze, a hooked promontory in Essex, to the south of Harwich, and the North Foreland, in the county of Kent, or, perhaps, more accurately and strictly speaking, it may be fixed at the Nore, between Leigh in Essex, and Sheerness in Kent. The coast of Essex from the mouth of this river, thus defined, receding, turns abruptly to face the east, and is indented by the bays that are form-
Of Suffolk.

The coast of Suffolk rises in a wavy line towards the north, a little inclined to the east. The first promontory we come to is Orfordness, a low beach running out into the sea. The town of Orford, formerly a sea-port, is now at some distance from the sea. Dunwich and Aldeburgh, on the contrary, have been almost washed away by the sea, which began its encroachments before the Norman Conquest. From Orfordness to Southwold, the coast lies due north, with a bold shore; a little to the south of the latter place, the sea, breaking in upon the shore, forms a creek, which, spreading out, divides to Dunwich, Southwold, and Walberswick. The bay before Southwold is Solebay, the scene of the great sea fight in 1672, between the Dutch under De Ruyter, and the English commanded by the Duke of York. This bay was formerly bounded by Eastonness, and another cape to the south-east of Dunwich; but the sea has removed these marks, and consequently changed the mouths of the bay. From Southwold northwards, the coast is much embarrassed with shoals, and presents nothing remarkable, till we come to Lowestoffe, which is built on a cliff above the sea, at the most easterly point of Great Britain. The whole extent of the coast of this county is about 60 miles; for the most part, it is composed of leamy cliffs, which, being undermined by the waves, are continually falling down; in some parts, however, there are hillocks of sand, and in other parts, especially near the borders of Essex, it is flat and marshy.

Of Norfolk.

The Norfolk coast, to the north of Yarmouth, runs out in a point into the German Ocean. This point is called Winterton Ness. Beyond it the coast tends west-north-west, and then west, the shore being low and flat, besiegued with dangerous sands, especially between the Ness and Happisburgh. The most remarkable of the banks of sand, which lie off at sea, run parallel to the coast of Yarmouth, and form the celebrated Yarmouth Roads. From this place, however, north-west to Cromer, and thence to Sheringham, there are steep and high cliffs, from 40 to upwards of 80 feet perpendicular. Proceeding westward the shore is low and flat; but about Hunstanton achange takes place. The Wash lies off and cliffs appear again. At Lynn Regis the great bay is formed between Norfolk and Lincolnshire, which indents the country deeply to the south-west. The sea coast of Norfolk is formed either by clayey cliffs, which are continually sapped and overthrown by the waves, or by low sandy shores, covered with loose pebbles. In some places, a kind of natural bank is formed of the sand, held together by the roots of the sea-reed grass. Hunstanton cliff, already mentioned, is the only rocky eminence on this coast. It is composed of chalk and friable stone, resting on a base of iron coloured pudding stone.

Of Lincolnshire.

After crossing the Washes, the main land of Lincolnshire presents its extended coast, in the form of a bow, to the German Ocean. In general, it lies low and flat, or with a small declivity to the east. In some parts, the land has been gained from the sea, though in other parts, the sea has in its turn invaded the land; and the remains of a forest are visible under the waves. Its sea-ports, which were formerly numerous, are now almost entirely choked up with sand, and some of them are quite deserted by the ocean. The coast of Lincolnshire at first stretches a little to the east of the north, and then gradually inclines to the west, to the mouth of the Humber. Its extent is upwards of 100 miles.

The extremity of Holderness, in the East Riding of Yorkshire, contracts into a small neck of land, forming a curve in the sea, towards the south-west. The extremity of the neck of land is the Spurn Head, a sickle-shaped promontory, that guards the mouth of the Humber, nearly opposite the port of Grimsby in Lincolnshire. Amidst the sands of this river, Sunk Island is formed on the Yorkshire side. In this part of the coast of this county, several ports have suffered from the sea. Headon, which was a free burgh in the reign of King John, and which, in subsequent times, was so populous as to have three parish churches, is now dwindled into a small and insignificant place, with scarcely any harbour. The coast continues low and flat, like that of Lincolnshire, till it has passed the little port of Hornsea, and approaches the quay of Bridlington. This sea-port is covered by the point of land called Flamborough Head, from north-east and north-west winds. Flamborough Head is formed by the Wolds, which here advance towards the coast. It is a very remarkable promontory, the white perpendicular cliffs of which protrude themselves far into the German Ocean, and serve as a direction for ships. Many of the rocks which compose it are insulated, of a pyramidal form, and soar to a great height. The bases of most of them are solid; but some are pierced through and arched. On the north side, there are large caverns. Beyond Flamborough Head, a rocky promontory, of a round figure, projects into the sea, by which it is surrounded on all sides, except on the west. On the summit of this rock is built the castle, and on the side of it the town of Scarborough. The shore here is remarkably bold; and the height of the cliffs gives it some resemblance to the coast near Dover. Between this place and Whitby, Robinhood's bay lies: the land is still high, and the sea deep, but the bay is exposed to the east wind. The Eastern Morelands extend over the whole country, to the north of Scarborough, to the coast, one deep hollow of which, formed by a small river, is occupied by the port of Whitby. From this place the shore declines west-north-west, and west by north. The next conspicuous point of land is Hunley cliff; beyond this, still more to the north, appears Redcliff, that makes one side of a bay, as the promontory, on which Hartlepool, in the county of Durham, stands, does the other; the River Tees rushing with a rapid tide into the German Ocean between them. From this description of the coast of Yorkshire, it will be seen, that from the Humber to Flamborough Head it is low and flat, and from Flamborough Head to the Tees uncommonly bold and precipitous. In the first division of it, it is in general composed of clay. Flamborough Head is limestone. Whitby presents a coast composed of aluminous schistus. There are many fishing villages on the northern part of the coast of this county, singularly placed, like nests, upon the ledges of the rocks. No coast in England furnishes a greater variety of fish than this.
land and the Ribble, is more extensive, as well as flatter than the former division; to the south of the Lune, the marshy tract surrounding Poulton, on the Wier, succeeds; afterwards the coast is indented by the great estuary of the Ribble, descending from below Preston.

In the last division between the Ribble and the Mersey, the Lancashire coast makes another swell; in no part is it bold or high, and, as it approaches the southern confines of the county, it becomes quite flat.

The sea coast of Cheshire is neither extensive nor interesting, being formed entirely of that broad neck of shire land, which stretches far into the Irish Sea, between the Mersey and the Dee.

The coast of North Wales, from the mouth of the Dee, is for a long space marshy; but near Holywell, in Flintshire, the mountains advance towards it, though they again recede and give place to marshes, at the termination of the vale of Clwyd. As we enter Caernarvonshire, the first object on the coast that presents itself, is the promontory of Llandudno, a steep precipice hanging over the sea, and stretching out far to the north, at the mouth of the Conway: this promontory forms one of the horns of a great bay, with Trwynder point in Anglesey, at the Menai Straits. Beyond the Conway is the once tremendous precipice of Penmaen-mawr, overhanging the sea, now safely crossed by a good road. The coast here is very rocky. The southern extremity of the coast of this country is formed by the peninsulated hundred of Lyn; here many sharp points of land run out into the sea, with bays between them. Off the most westerly point of this peninsula lies the small isle of Bardsey.

The Menai Straits, which separate Anglesey from Caernarvonshire, abound in peculiar beauties,—sometimes appearing landlocked, like a great lake, and at other times assuming the form of a large navigable river, flowing with several curves, nearly in a direction from north to south. The form of the island of Anglesey is nearly that of a parallelogram; that part of its coast which borders on the Menai Straits, is finely wooded; its northern, eastern, and western points, are sharp and narrow, and the southern angle is more rounded. The peninsula which stretches far to the west stands Holyhead; this peninsula terminates in a high mountain, hollowed by caverns, and frequented by falcons and sea fowl; from Holyhead, the shore inclines to the south-west, and thus completes the figure that the island forms. Off the eastern point, is the steep rocky islet of Priestholme; and off the northern point is another, called the Skerries, or the Isle of Seals.

The north-west horn of the great bay of Cardigan, which is the most considerable indenture made by the sea on the west side of our island, and which is equally distributed between North and South Wales, is formed by the coast suddenly turning round the point of Aberdaron. The sea coast of Merionethshire, which lies in this bay, is wild and mountainous: the only port in this county is Barmouth, on a little arm of the sea, into which several small rivulets discharge themselves. Below Aberystwyth, the coast of Cardiganshire fronts the west for some distance, after which it diverges towards the north; the extent of this county along the shore is nearly 40 miles; it has suffered greatly from the depredations of the sea, having been formerly celebrated for numerous towns, but containing now only a few poor villages. A promontory on the north of St David's, in Pembrokeshire, forms the southern horn of
the bay of Cardigan. The sea coast of Pembrokeshire is in general hilly, with steep or perpendicular cliffs: its north-eastern point is at the mouth of the Tivy. The first remarkable place is Aberkluk Bay, formed by Kennace Head on the north, and Pendower Head on the south; next succeeds Newport Bay; and after that Fishguard Bay: hence the coast tending to the south-west winds round Strumble Head, to that of St David's, off which lies Ramsey island, together with a group of rocks called the Bishop and his Clerks; these are frequented, in the breeding season, by vast numbers of sea fowl, many of which are unknown in every other part of the island. The large bay of St Bride's succeeds; and beyond some islands which lie on its southern side, is the entrance to the celebrated Milford Haven; this is an inlet of the sea, indenting deeply the southern coast of Pembrokeshire, and occupying a large space of that county, with its great basin, and the different creeks into which it branches off. It is fed by some inconsiderable streams from the interior of the country, few of which are dignified with any certain appellation, though most of them from small rivulets become extensive estuaries, when they unite with the main basin. Near Pembroke Castle, Milford Haven expands, inclining chiefly to the west, but near its mouth, turning abruptly southward; and when viewed from within, appearing perfectly land-locked: the ports of Hherbronster, Haiken, and Milford, occupy one of the many bays near the centre of this great sheet of water. The view of Milford Haven would be much more picturesque, if it were not for a deficiency of wood: it also loses much of its effect from the want of grandeur in the surrounding hills.

Beyond Milford Haven, the coast of South Wales continues rocky: it is also full of coves and remarkable apertures, to the entrance of the bay of Caermarthen. The northern horn of this bay is formed by the rock on which Tenby is situated: the opposite horn, by the point of Penrhyn Gwyne,—the extremity of that singular peninsula in Glamorganshire, that is called Gower. On the other side of this peninsula lies the bay of Oxwich, and still lower the bay of Swansea expands itself.

The greatest part of the sea coast of Glamorganshire swells into a semicircular sweep, but the western extremity is formed into a narrow beak, between the open channel, on the one hand, and an arm of the sea, which runs round to the Caermarthenshire coast, on the other. Beyond the bay of Swansea, the shore presents the castles of Dunraven, St Donats, and Fliemuni: the bay of Glamorgan next succeeds; and from its shore the Bristol Channel being here much contracted, the heights of the opposite coasts of Devonshire and Somersetshire, between Ilfracombe and Minehead, appear finely elevated: the sea, which separates England and Wales, contains in this place the two small islands of the Steep and the Flat Holmes, which however are much nearer to the Welsh than the English coast.

The shore of Monmouthshire inclines chiefly to the south, verging at last towards the east: the first part of it is marhsy and low, but as we approach the Wye, it becomes rocky and lofty.

The coast of Somersetshire receives the Bristol Channel into an extensive bay, which forms a kind of semicircle; and, if the indented outline of the shore is taken into the account, it will be found to stretch nearly 60 miles; at first it forms a broad plain, bordered by marshes, and it continues chiefly level, till it reaches the bay of Minehead, where the majestic pile of Dunster Castle appears powerfully elevated. From this the coast of Somersetshire, together with that of Devonshire, which soon joins it, may be called mountainous, abounding in dark cliffs and rocky hollows. The shore of the latter county extends at first to the west, and then turning to the south, the land is very irregularly indented, so as to form Barstaple Bay. It then again westward, and, afterwards advancing north, forms the bay which is called Portridge Mouth, at the extremity of which lies Hartland Point; the extent of the whole is rather more than 36 miles.

Soon after we pass Hartland point, the coast of Cornwall commences, the land declining to the south-west. The first place we meet with on the Cornish shore is Budehaven. A long range of broken coast succeeds to St Ives, its inclination being more and more westward from the south. After passing the semicircular bay of St Ives, the coast begins to turn, and after Cape Cornwall, the Land's End, the most westerly point of the island, makes its appearance. After doubling this point, the Cornish shore advances southward, with some swells to the east, and soon expands into the capacious bay of St Michael. The Lizard is the next remarkable object, a promontory that stretches out farther to the south than any part of the western coast of England, being somewhat below the 50th degree of latitude. The shore next inclines, for a short space, in a north-east direction, and then turning irregularly towards the south-east, becomes indented as far as the southern horn of the Ram's Head, which is opposite to the coast of Devonshire. In this part of the Cornish coast, there are several bays and havens, the most remarkable of which is Falmouth Haven; the estuaries of the Fowey and the Looe follow in succession; that of the Tamarr being the last and most important, where the harbour and Sound of Plymouth are formed between the shores of Cornwall and Devonshire.

Throughout that part of the English Channel, which runs from the entrance of Plymouth Sound to Portmouth harbour, the coast principally fronts the south: it is, however, deeply indented with various bays, that are formed by great projecting headlands. The harbour of Plymouth is double: the outer harbour, principally for merchantmen, lies beneath the Old Town, while the noble road, called the Sound of Plymouth, is formed by the confluence of the Plym and the Tamarr with the sea. Plymouth Sound opens to the south-east, opposite to the rock on which Eddystone lighthouse is built. The Eddystone rocks are a congeries of irregular rocks, situated about 12 miles from the middle of the Sound: they are so much exposed to the heavy swells from the Bay of Biscay and the Atlantic Ocean, that the waves frequently break over them with inconceivable fury. In consequence of the many fatal accidents that happened to ships, from running against these dreadful rocks, a light-house was erected on one of them in the year 1696: this stood many violent storms; but in the dreadful storm that happened on the 27th of November, 1708, it was blown down, and all within it perished. A second light-house was erected in 1708, and burnt in 1755. The present edifice, which was built by Mr Smeaton, and finished in the year 1759, is universally admired, for the mechanism and architecture displayed in its construction, and bids fair to hand his name down to a very late posterity as an engineer of the first rate talents and experience.

In proceeding to the east from Plymouth, the first bay that presents itself is Salcombe Haven: this was formerly a port of some note; at the head of the basin stands the town of Kingsbridge. Between the Hart
Point, one of the most celebrated promontories on the coast of Devonshire, and Froward Point, the bay of Dartmouth is formed; this is a spacious haven, capable of sheltering a large number of ships. The coast from hence winds to the north-east, and shoots out into a promontory called Berry Point, which makes one side of Torbay. The other side is formed by the promontory of Torquay. This bay is in its general form semilunar, inclining a circumference of about 12 miles; on both sides its shores are winding, and are screened with grand ramparts of rock; between these, in the central part, the ground from the inland forms a gentle vale, falling easily and gracefully to the water's edge. All round the bay, even on its rocky sides, wood grows with great luxuriance. This noble bay fronts the south-east: it has frequently afforded shelter to the navy of England. In the rocks which form the promontory of Torquay, there are various fissures of great magnitude, and some of them of singular construction: that of the greatest magnitude is called Kent's Hole; it is a vast cavern about 600 feet in depth.

Beyond Torbay, the small river Teign flows into the English Channel, and soon afterwards, the Exe: from the mouth of this river the Devonshire coast gradually turns to the south, as it unites with that of Dorsetshire near Lyme. The shore from hence turns to the south-west, terminating far to the south in Portland Island. Thus is it immense gulf formed, which includes the greater part of the south of Devonshire, and much of Dorsetshire, together with the several smaller bays of these counties, which lie between the Start Point and the Bill of Portland. To the north of Portland is a safe road for ships; but its southern point, called the Race of Portland, is one of the most dangerous places in the English Channel.

Immediately below this island, the Bay of Weymouth expands itself; on the opposite side of which, that part of Dorsetshire called the isle of Purbeck, stretches out, terminating in the point called St Aldhelm's Head. The eastern extremity of the coast of this county is called Peel Point, between which and another promontory, lying to the north, called Hand Fort Point, is included Swanage Bay. "Turning round the extremity of Purbeck, towards the north, the Bay of Studland is seen, the remotest headland of which extends to the mouth of the harbour of Poole. Opposite to this tongue of land is another promontory, but not quite so long, which shoots out from the main land of Dorsetshire. Immediately within the entrance between these, lies Branksay Island. There are several other small islands, round which the sea forms a vast body of water, constituting Poole harbour.

The Isle of Wight terminates the bay which is formed by the eastern extremity of Dorsetshire, with a vast range of cliffs in full front. The western side of this island is fenced with ridges of rocks, the most remarkable of which are those called, from their sharp extremities, the Needles. The appearance of these, and the advancing point of Hurst Castle on the opposite shore of Hampshire, afford strong grounds to believe, that in former times the island and the mainland were united. The southern coast of the Isle of Wight is edged with very steep cliffs of chalk and freestone, which, in various parts, are hollowed out into caverns. Between the island and the main land are several sand-hanks, especially on the eastern part, where is the safe road of St Helen's. Hurst Castle, which has already been mentioned, is situated near the extremity of an extraordinary natural causeway or point of land, which runs two miles into the sea in a south-east direction, and approaches the Isle of Wight within the distance of a mile. Through the strait which is thus formed, the tide rushes with very great force, and has deepened the channel no less than 28 fathoms. This natural causeway, at high water, scarcely exceeds 200 yards in breadth: it is a sterile beach, covered with loose gravel and pebbles. Towards the Isle of Wight, there is a bold shore, broken into ledges or terraces of pebbles by the violence of the waves; whereas, the other side, from its sheltered situation, is undulating, marshy, and undermined, forming the water, when the tide flows, into a smooth land-locked bay.

The coast of Hampshire, adjoining to Dorsetshire, of Hampshire, fronts the south-west, as the Avon descends by Christchurch. The bay of this name is formed by that river and the Stour, which unite their streams a short distance below the town. The western termination of the bay is Hengistbury-Head, generally called by the seamen Christchurch-Head, from its apparent connection with that place, as viewed from the sea. It is a bold headland, about a mile from the extremity from which the cliff dips for a considerable distance, and the estuary of the Stour and Avon is there only separated from the sea by a narrow neck of land. A little to the east of this is Lymington Bay, from which, till we reach the mouth of Southampton Water, nothing remarkable presents itself.

Southampton Water, or Trissanton Bay, is a large inlet of the sea, commencing at Calshot Castle, and stretching to the north-west upwards of 10 miles: it is navigable to the head for vessels of considerable burden. Its shores are extremely beautiful and picturesque, being lined on one side by the New Forest, and on the other by the ruins of Netley Abbey.

The English Channel, after the junction of Southampton Water, turns round the northern point of the Isle of Wight, gradually making its compass, till the coast of Hampshire fronts the south-west, opposite to that part of the Isle of Wight where the river Medina enters the sea. Between the island and the shore of Hampshire, is the noted road of Spithead: it lies directly opposite to the narrow neck of land on which the town of Gosport stands.

As we proceed to the west from Portsmouth-harbour, the coast is indented with another large basin, interspersed with various islands. From this basin, several branches run up into the country, one of them forming the harbour of Chichester. This basin is filled in by the small river Lavant, which flows by that city in a southward direction. The coast here is extremely level, and continues so towards the south, till it is terminated by the bill or peninsula of Selsey. A little further on, a few low rocks appear in the sea, near Bognor, but the coast becomes again low and marshy near Littlehampton. As we proceed to the east, the South Downs form a nearer back-ground, and at length advancing close to the coast, break into stupendous cliffs, till they are terminated by the bold point of Beachy Head. This promontory lies between Hastings and Shoreham, projecting perpendicularly over the beach, from which it has its name. It is the highest on all the south coast of England. It is noted for shipwrecks in stormy weather, and has several caverns made in it by the sea.

Beyond Beachy Head, the coast turns to the north-east, and becomes a sandy and marshy level near Pevensey: it continues of this description till it reaches...
The coast of Kent, adjoining to Sussex, is flat, abounding in sand and pebbles, and continues so till we pass Sandgate. Here the hills close in; a steep and downsward tract succeeds, descending from the interior of the county in a fine ridge, and terminating in abrupt chalky cliffs. In one of the hollows of this range, Folkestone stands between Dover Castle and that cliff so strikingly described by Shakespeare. A narrow semicircular range of cliffs is formed, that recedes a little from the coast. Beneath this range the town of Dover occupies all the space open to the sea.

The coast of Kent continues formed of high chalk cliffs, occasionally sinking into hollows, till we come to the headland called the South Foreland: from this point the shore fronts the east, receding, so as to surround a large sandy area, which appears to have been left by the sea. This flat tract is terminated in front by the high grounds of the Isle of Thanet.

The Downs.

Between the South and the North Foreland, are the Downs, a greatly frequented road for shipping: they extend about six miles. Off the Downs lie the Goodwin Sands, distant from Deal five miles, extending north-north-east and south-south-west about 12 miles. They are supposed formerly to have made part of the Kentish land, (though this is denied by some), and to have been overflowed about the end of the reign of William Rufus, or the beginning of that of Henry I. These sands are very dangerous for vessels riding in the Downs, which, in high winds, are frequently driven upon them. They are divided into two parts by a very narrow channel: in many parts they are dry at low water, and in some places even before that time. The northern division is of a triangular form, lying north and south towards the sea, and running away south-east to meet the east side, while it tends on the south to the Isle. This part of the sands is about 3½ miles long, and 1½ miles broad: the north end, called the North Land Head, is about six miles from the coast; the west end, which is called Blunt Head, is very dangerous. The largest place that dries on this sand, is called by the seamen Jamaica Island. The south part of the Goodwin Sands is 2½ miles in length, and, at the north end, not above a mile in breadth, from whence it gradually diminishes towards the south-west, till it ends in a narrow point called South Land Head, which is only three miles from the coast. These sands are altered more or less every year, by storms and strong tides.

The South Foreland forms the eastern point of the Kentish shore: two light-houses are erected on it, in order to warn mariners who arrive from the west, of their approach to the Goodwin Sands. The North Foreland forms the north-east point of the Isle of Thanet, and is, by act of parliament, ascertained to be the most southern part of the port of London. This headland projects into the sea nearly in the form of a bastion, and is somewhat higher than the adjoining coast: a light-house is erected on this, as well as on the South Foreland, for the general safety of mariners, but more particularly in order to enable them to avoid striking on the Goodwin Sands. This light-house belongs to Greenwich Hospital; and every British vessel sailing round this point pays 2d. per ton, and every foreign vessel 4d. per ton, towards its support. In this part of the coast of Kent, the sea gains so much upon the land, that above 30 acres have been lost within the memory of some now alive. All vessels passing on the south side of this foreland, are said to enter the Channel; and all the towns and harbours between London and this place, whether on the Kentish or the Essex shore, are called members of the port of London.

No circumstance connected with the progressive geography of England is more interesting than that which relates to the Isle of Thanet. We trust, therefore, we shall be excused for dwelling rather at length on its ancient and present state. At this day, it is scarcely a peninsula, and yet, in the time of the Romans, it was a complete island, nearly of a circular form. At this period, the sea on the south-west side, between the island and the main land of Kent, was at least four miles broad, gradually decreasing as it passed along the south side of the island, till at length its breadth contracted to two miles; and at Sar, which was the narrowest part, it was not more than a mile and a half. Thus far flowed the South Sea: the latter entered at what was, from this circumstance, called Northmutha, or North-Mouth. The direct and accustomed passage to London by sea, lay through the strait between the Isle of Thanet and the main land of Kent, as late as the middle of the 4th century. In the time of Bede, however, the breadth of this passage was considerably diminished; for he tells us, it was then but three furlongs wide, and so shallow, that it was fordable in two places. It continued, however, a passable strait for vessels of some size, till about the time of the Norman Conquest, when the inhabitants perceiving that the tide no longer flowed with any considerable vigour, began to erect dykes to keep it out, and thus brought about the present form and condition of the island. Thus the Isle of Thanet, which was formerly separated from the main land of Kent by the entire channel of what was called the Portus Hicupensis, and was then, in its natural state, all high land, is now a peninsula, or at most a river-valley, only, with the Stour-wantsome on the south, the Medway-stream on the south-west, and the Netherwantsome on the west. The other part of the island fronts the East and North Seas as before; but the figure is altered from a circular to an irregular oval. After the junction of the Isle to Kent, the sea, which no longer flowed with the same freedom, began to throw up immense quantities of beach on the opposite shore, which produced Estanore, that is, the East Stone Shore: this was originally an island, but the monks united it by a causeway to the Isle of Thanet.

Below this island, the coast of Kent, which still fronts the north, becomes marshy as it descends by Whitstable to the narrow arm of the sea called the Swale, which flows along two sides of the isle of Shepey. After this, the coast turns to the east till it reaches the point where the Medway terminates its course, by its junction with the Swale. Beyond this the fort of Sheerness projects, and the mouth of the Thames opens.

Of the rivers of England, the most celebrated and important are the Thames, the Severn, the Mersey, the Dee, the Tyne, the Tees, the Trent, and the Medway. As most of these flow through more than one county,
The sources of the Thames are generally admitted to be four rivulets, that rise in different parts of the Cotswold Hills in Gloucestershire, viz. the Lech, the Colne, the Churne, and the Isis. The last, which is the most important, and which retains its name the longest, after receiving the two other streams, becomes navigable; but for a considerable space the navigation is tedious and difficult, on account of its winding course, and its prevailing shallows. The country through which the Isis flows at first is not pleasant or interesting, as it pursues its way almost unseen, in the middle of an unvaried plain, first towards the east, and afterwards inclining to the north. After being augmented by two small streams, it turns suddenly to the south, and the plain now expands into a spacious amphitheatre, bounded by some striking hills, in the centre of which Oxford appears in sight. At this place the Isis divides into several small channels, leaving this city on the left: the branches, however, soon reunite, and the river turns round the city towards the north-east. Below Oxford it is joined by the Cherwell, which, passing on the eastern side of that city, together with the Isis, nearly insulates it.

The windings of the river through the great level which it flows through, after passing Oxford, are frequent; but the general direction of its course is to the south, with a small inclination to the east, as it passes the Berkshire hills, and the town of Dorchester in Oxfordshire. A short distance below this place it is joined by the Thame. This river takes its rise from several small streams, some of which descend from the central parts of Buckinghamshire, others from the borders of Hertfordshire, and many from the lower parts of Oxfordshire. After the junction of the Isis and the Thame, this river obtains its proper name, being originally called Thame-isis from this circumstance. From Wallingford to Pangbourn the inclination of the stream is almost due south; at the latter place it begins to form a considerable circle by the east to the north, below Reading, till it reaches Henley; after passing this latter place it inclines by the north-east to the south again, to approach Maidenhead; hence it winds in various directions, but generally south-east, till it passes Maidenhead and Staines. There it forms a vast circle by the south to the east, till it reaches Brentford; after which, as it approaches London, its direction, is, for the most part, to the north-east. In the vicinity of the metropolis it turns with a bold swell to the east: this direction it preserves, though occasionally varied by broad reaches, as they are called, till it falls into the sea.

In its passage the Thames receives no fewer than six considerable rivers that are not navigable, and eleven that are. Its course has been computed about 550 miles, of which it is navigable above 150 from its mouth. As far as Deptford it is navigable for vessels of almost any burden; to the pool for vessels of 400 tons; to London Bridge for those of 200. The tides flow up to nearly the distance of 50 miles from its mouth. The fall of water from Oxford to Maidenhead is about 25 feet in every ten miles; from Maidenhead to Chertsey 28 feet in the same distance; from Chertsey bridge to Mortlake 16 feet; from Mortlake to London about one foot per mile. Afterwards the fall diminishes more gradually, till the river unites with the sea.

The Thames is one of those rivers which rather derive their character from the country through which they flow, than impress their own character by their boldness and rapidity on the tract they pursue. It passes through some of the most beautiful, as well as the most fertile districts of the kingdom; but even where the country through which it flows is hilly, it never can be called a rapid stream; it is not, however, sluggish, but is more distinguishable for its majesty, and the purity of its waters, which generally fill its verdant banks, and are seldom discoloured by mud, except after great floods. When these occur, the whole country in the level parts of its tract appears like a sea; but the mischief which is thus occasioned, is much less than that produced by smaller and more rapid streams, when they overflow their banks. The part of its course most distinguished for romantic scenery or picturesque beauty, is that which stretches from Wallingford to Reading, Henley, Marlow, and Maidenhead bridge. About Henley in particular it sweeps through a rich and highly beautiful country, to which it adds a majestic and imposing feature; its valleys in this part of its course are bounded by hills richly clothed with beechwood, and finely embellished by the seats of many of the principal of the English nobility. Vast plains succeed, in which the Thames constitutes the chief feature. As it approaches London, its character changes, and the richness of nature gives place to evidences of the power, the wealth, and the skill of man. Mighty works of art adorn its banks, which abound in populous towns and villages. At London it is a superb tidal river, "full of vessels of every description, which arrest the eye strongly in the bold sweeps it afterwards makes, through increasing marshes to the sea, and to the end it preserves that air of placid dignity and imposing consequence, which distinguish so eminently this monarch of the British rivers."

The Severn, the second commercial river in the kingdom, has its principal source in a small lake on the eastern side of Plinlimmon, not far from the head of the Wye. At first it bears the name of the Hafren river, the name by which, through its whole course, it was known to the Britons. From this source it flows towards the south-east, and afterwards turns to the north-east, as it approaches Newtown, where it takes its proper name of Severn. Hence, through the delightful vale of Montgomery, its course is almost due north, till, entering the great plain of Shropshire beyond Welshpool, it turns abruptly to the south-east. Afterwards pursuing the same direction, it almost encircles the town of Shrewsbury. Flowing through the celebrated Colebroke dale, and passing Bridgnorth, it pursues a southerly course, as it leaves the county of Salop, and enters Worcestershire, at Bewdley. Here it again, a little lower, becomes a commercial river, being joined by those numerous canals which bear all the trade of Birmingham, Kidderminster, and the other manufacturing towns of Warwickshire, Staffordshire, and Worcestershire.
The Severn, now a broad stream, crowded with barges, flows through a pleasant country, between high banks, till it approaches the city of Worcester. It then traverses a part of what is generally called the vale of Evesham, though that name more properly belongs to the vale through which the Avon flows, between the fine ridge of the Malvern hills, and the bold rising ground of Bredon. After this, its banks become high and steep, so that it almost disappears as it flows through the vast plain of Gloucestershire. About a mile above Gloucester, it divides into two streams, which unite a little below that city, forming the tract of land called Alney Island. Soon after this junction, its depth and width are increased by several streams, as well as canals, from the clothing districts of this county. At a bend of the river, where the Strondwater canal joins it, it forms nearly a semicircle of ten miles, and flowing again south-west, grows gradually wider, till it receives the Wye near Chepstow, and the Avon from Somersetshire, thus forming the Bristol Channel. Between Tewksbury and the sea, there is only one passage over this river by bridge; this is at Gloucester; the other passages are by boats.

The Severn, particularly below Gloucester, has frequently overflowed its banks; and by sudden risings of the tide, occasioned much damage to the contiguous country. It is remarkable for its tide, which rolls in with a head three or four feet high, with a great noise. This arises from the circumstance, that it receives the waters of the great Atlantic Ocean with such considerable violence, as to fill the channel of the river all at once; and the opposition which the tides from the ocean meets with from the strong current of the river, occasions that dashing of the waves which is called the hygro or eage.

In describing the Mersey, it will be necessary to notice the origin and course of the Irwell, which contributes so largely to the waters of the former river. The Irwell rises in the moors that divide Lancashire from Yorkshire: it passes through the district of manufacturing towns in the former county, flowing at first westward, and then descending in a southward direction to Bury. Below this town, having been joined by the Roche, it makes a great curve to the westward again, till being joined by a small stream from Bolton, it turns suddenly to the south-east; this course it preserves till it reaches Manchester, where it is united to the Irk and the Medlock. From Manchester, its course is nearly westward, till its junction with the Mersey, which takes place near the village of Flexton. The Mersey derives its source from a conflux of small streams at the junction of Cheshire with Derbyshire; its course is considerably serpentine, but generally with an inclination to the south-west. The principal place it passes by before its junction with the Irwell, is Stockport. After this junction, the latter river loses its name, the united streams taking the appellation of the Mersey. Its course continues westward as it passes the town of Warrington, a little below which it forms a great arm of the sea, which, turning abruptly to the south west, grows a little narrower as it passes the port of Liverpool, near its exit. At that part of the Mersey where it swells into a basin, it is joined by the Weaver. This river rises in the northern part of Shropshire, and flows northward to Nantwich and Northwich, where it is joined by two rivulets, one from the northern confines of Staffordshire, and the other from Middlewich. After this junction, its course inclines to the north-west, till it falls into the Mersey, a little below Frodsham.

The Mersey, and the rivers which join it, have little of the mountainous character, except just about their source, as they soon reach a country abounding in manufactures, though not distinguished for beauty. The Mersey is navigable for very vessels of considerable burden, for about 35 miles from Liverpool to the mouth of the Irwell; and the latter river has been made navigable for boats, barges, &c. as far as Hunt's Bank, Manchester.

The Mersey and Irwell.

The Dee rises in the mountainous part of Merionethshire, from two rapid streams, which unite, and descending from the heights which separate Dolgelly from Bala, form the lake of Penible-meer, one of the largest in Wales. After issuing from this lake, the Dee pursues an easterly course beneath the town of Bala, and passing through the beautiful valley of Llangollen, with various windings, enters the great plain of Cheshire, beneath the park of Wyne Stay. Soon afterwards it changes its course, pursuing a northerly direction, forming a deep valley for itself through that plain; then crossing over to the city of Chester, it half encompasses its walls; and flowing from thence to the sea, it forms a broad sandy estuary, inclining to the north west, which divides Cheshire from Flintshire. By inland navigation, it has communication with the Mersey, Ribble, Ouse, Trent, Derwent, Severn, Avon, Humber, and Thames. It is navigable from near Ellesmere in Shropshire, to Chester; but at this city the navigation is rendered difficult and broken by a ledge of rocks running across the bed of the river, which form a kind of cascade.

The Dee is a most beautiful and romantic river: it is singular, from the circumstance that it increases its rapidity as it recedes from its source, being fed by numerous rapid streams from the surrounding mountains; one of which, called the Ceiro, precipitates itself down the curious falls of Glyndyfia. Perhaps the grandest view of the Dee is where it passes into the great plain of Cheshire, as the mountains recede, and lay it open to the view. It loses its romantic character as it approaches the city of Chester, and becomes a deep and tranquil river. At Chester it is discoloured by the tide; and though its windings are numerous, yet they are not picturesque, as it passes through a broad marsh before it swells into its grand basin.

The Tyne is formed from two branches, called the South and North Tyne. The former takes its rise on the borders of Durham and Cumberland. At first, its direction is northward, a little inclined to the west, by Aldstone; it then turns eastward to meet the North Tyne. This rises in the moorlands of Northumberland, close on the borders of Scotland; and being joined by the Reed, near Bellingham, pursues a south-west course, till it unites with the South Tyne. After their junction, the Tyne takes an eastward direction, and at last turning a little towards the north, falls into the sea beneath Tynemouth Castle.

The course of both the branches of this river is wild and romantic; till they reach Tynedale, when its character changes into a milder and more beautiful east. After passing Hexham, which occupies a central spot, near the junction of the two branches, the Tyne flows through a vale, rich in manufactures, as far as Newcastle. Here ships of moderate burden can come up; but the towns of North and South Shields are the proper ports of this river. Its estuary presents an intere-
The Trent.

The source of the Trent is contiguous to that of the South Tyne, in the vast moors which separate Yorkshire from Durham, Cumberland, and Westmoreland. At first it flows in a south-easterly direction; but beneath the town of Darlington, it turns abruptly to the north-east, and falls into the sea below Stockton, which may be considered its port. This river, flowing for a considerable part of its course through a wild and romantic country, bears the same character. During the latter part of its course, however, its character changes, and its banks are rendered busy and populous by a great variety of works. In many parts, they are fringed with wood of considerable growth and value.

The Trent deserves a fuller notice than we have given to any of the rivers, except perhaps the Thames and the Severn, on account not only of the length of its course, but also of the fertile districts through which it passes; the immense number of canals, by means of which it has an inland communication with almost every part of the kingdom; and the multitude of rivers, some of them of considerable size and note, which it receives in its course to the sea.

The Trent takes its rise in the hills beyond Newcastle-under-Lyme, in that part of Staffordshire that borders on Cheshire. At first, its course is nearly south-east; it then makes a sudden turn by the east to the north near Barton. From this place it divides Leicestershire from Derbyshire for a short time. It then crosses the south part of Derbyshire, and skirting the north-west part of Leicestershire, it enters Nottinghamshire a little below Thirsk. After passing Nottingham and Newark in a north-east direction, it suddenly turns to the north, near the latter town, and flowing past Gainsborough, enters Lincolnshire at East Stockwith; and about five miles below Burton-upon-Strather, falls into the Humber. It is navigable upwards of 100 miles.

The general character of the Trent is that of a full transparent stream. It flows among rich meadows, and through populous districts; but unless increased by floods, it is in no respect, and in no part of its course, resembles the rivers of the north of England. Soon after it passes Newcastle-under-Lyme, it meets with the numerous canals which abound in this manufacturing district; these frequently follow a course parallel with it, through the pleasant valley near Stone. After its junction with the Blythe, Taine, Soar, Dove, Derwent, and Erwark, it becomes a considerable stream, flowing through a range of beautiful and fertile meadows, bounded by finely wooded hills, and chequered with villages. After passing Nottingham, another rich vale receives it, with the hills of the forest of Sherwood on the left. Before it reaches the town of Newark, it divides itself into two streams, one of which washes the walls of that place, and the other passes by Kelham: the two branches again unite a little below, in a broad plain, which gradually declines in beauty as it becomes more level. Here the surrounding flat and sward permits the Trent to be distinguished. With the assistance of the tide, vessels of some burden can navigate it as far as Gainsborough. After passing this town, it flows through a range of fens, without any distinguishing feature, till joining the Yorkshire Ouse, the grand estuary of the Humber is formed, which divides Yorkshire from Lincolnshire.

Of the auxiliary streams which unite with the Trent, the Blythe is the first of any consequence. It rises a few miles to the eastward of that river, and pursues nearly a parallel course, till it joins it near King's Bromley. The Tame rises near Coleshill in Warwickshire, and after a short course, in which there is nothing remarkable, except the castle of Tamworth, it unites with the Trent a few miles above Burton. The Dove rises near the Peak in Derbyshire, and after various windings, generally inclining to the eastward from the south, it falls into the Trent below Burton. This river is very romantic in its character for a considerable part of its course, particularly where it forms the dell of Dove-dale. It afterwards flows through more expanded vales, and joins the Trent near Burton. Near Sawley, on the borders of Leicestershire and Nottinghamshire, the Trent is augmented by the Derwent, which also rises near the Peak of Derbyshire, and pursues a course nearly parallel to that of the Dove to Derby, where it inclines to the east. The features of this river are still more peculiar and extraordinary than those of the Dove. The Soar is a river of an entirely different character, rising westward of Hinckley in Leicestershire, passes through a rich grazing country, and more than half encompasses the ancient town of Leicester; after which, it receives the Wreke from the north-east, and then turns to Mount Soar Hill, where an abrupt rock, (an extraordinary feature in so level a country), overhangs it, watering, in its course, meadows of extraordinary beauty and fertility, till it falls into the Trent, not far from Cavendish Bridge.

Yorkshire also supplies various streams, to increase the size of the Trent. The Don rises in the high moors of this county, near the confines of Derbyshire. It takes a south eastern direction to Sheffield, and then turns north-east by Rotherham to Doncaster. At Thorne it alters its course to the north, and soon after joins the Northern Ouse. The character of this river does not correspond with its mountainous origin, except very near its source. Near Doncaster it forms a most beautiful vale, but after passing this town, it sinks into an extensive flat and tame country, which environs the Ouse. Just before its junction with this river, it is divided into two branches, the lower of which appears to be a navigable cut, and is called the Dutch river. The Calder rises in Yorkshire, near the borders of Lancashire. Its course is very winding, but nearly in an easterly direction, till it reaches Wakefield; it then turns to the north, and joins the Ayre near Ferrybridge. This river is more rapid than the Don, but is more remarkable, from the circumstance of the numerous canals by which it is intersected, and which form a junction between the eastern and western seas, than by any peculiar feature. The origin of the Ayre is mountainous, a little to the north-east of Settle, in Yorkshire. It pursues a course to the south-east, nearly as far as Leeds, where it turns nearly eastward; after its junction with the Calder, it traverses a flat country, and receiving the Don, joins the Ouse near Howden. The district of Craven, through which it flows in the first part of its course, is singularly romantic; while at Leeds its character is entirely changed, its banks being covered with the various manufactories of that place. Between Leeds and Ferrybridge, it divides one of the richest plains in the kingdom; afterwards it possesses little beauty, passing through a level country, to join the Ouse, not far from the Don.
The Ure, and the Swale, which may be regarded as the parents of the Ouse, rise near each other in the romantic borders of Westmoreland. The Ure flows at first eastward, and then inclines to the south to Rippon; from this place it turns again more to the eastward to Boroughbridge; and at Aldborough it unites with the Swale. The character of this river, through most of its course, is that of a mountainous stream; and this character it particularly displays in its passage through Wensley-dale. The direction of the Swale, at first, is to the south-east; it afterwards turns to the north-east to Richmond, and from this place it pursues nearly its original direction till it joins the Ure. The country through which this river flows is uncommonly romantic, till it reaches the great vale of York. Swale-dale, and the view of the river from the castle at Richmond, are particularly celebrated.

These two rivers, after their junction at Aldborough, take the name of the Ouse. From this town, its course is nearly south-east to York, south to Cathwood, where being increased by the junction of the Wharfe, it turns again to the south-east, and pursues that direction, with various windings, till it meets the Trent, and forms the Humber.

The Humber is a name almost exclusively given to the great estuary that divides Yorkshire from Lincolnshire, being formed, as we have seen, principally of the Trent, and the Ouse, and of the streams which fall into these two rivers.

The river Medway rises from four sources; the first at Crowherst in Surrey, the second at Stewards-meal in Sussex, the third at Goldwell, and the fourth at Biggenheath, both in Kent. The first three soon unite their waters, and take a north-east direction to Tunbridge and Maidstone, at which latter place they are joined by the fourth stream. The tide flows up hither, and the river is navigable for barges and other vessels of the burden of fifty tons. After passing Maidstone, the Medway turns with a long compass by the north to the east, to reach Rochester and Chatham. Between this place and Gillingham, which is about a mile and a half to the north-east of it, some of the largest ships in the royal navy are usually laid up. Afterwards it winds with various curves to the eastward, till it joins the arm of the sea called the Swale, (which divides the isle of Shepey from the main land of Kent,) and then turning again northward, it enters the Nore near the mouth of the Thames, under the fort of Sheerness. Its whole course is about 40 miles; and that circumstance considered, it is perhaps one of the deepest rivers in Europe.

During the first part of its course, it is so buried within its banks, that it adds little to the scenery of the country through which it flows; but between Tunbridge and Maidstone, the valley expands, and the character of the river is seen in its true light. This character is still more marked, after it winds round the decayed town of Aylesford, and becoming suddenly a bold and wide stream, flows with considerable rapidity under the arches of the ancient bridge of Rochester. Below the bridge, it takes a broad sweep, and when increased by the tide, exhibits, in connection with the superb buildings and dock of Chatham, and the great ships within it, a grand and striking spectacle. From Chatham to its mouth, the banks of the Medway are marshy and uninteresting, till its approach to the sea is indicated by the immense number of masts which encompass Sheerness.

Besides these rivers which we have described, the following deserve notice. The Blackwater, which takes its rise near Saffron Walden, in Essex, and flowing by Coggeshall and Wetham, falls into the sea at Maldon in the same county. The source of the Chelmer is near that of the Blackwater; it winds through the middle of Essex, and passing Chelmsford, also discharges itself into the sea at Maldon. The Colne rises near Clare, in Suffolk, and after passing Colchester, falls into the sea between Mersey Island and the main-land of Essex. The Stour divides this county from Suffolk; it rises on the southern boundary of the latter county, and falls into the sea at Harwich; near its mouth it is joined by the Orwell, which runs up to Ipswich. Proceeding northward, the next river of consequence which we meet with, is the Waveney, which forms part of the boundary between Norfolk and Suffolk, and unites with the Yare a little above Yarmouth. This river is navigable from Bungay. The Yare, which falls into the German Ocean below Yarmouth, is navigable as high as Norwich. But the most important rivers in this part of England, are the Great and Little Ouse; the former rises on the borders of Northamptonshire and Oxfordshire. Its course, at first, is east, a little inclining to the north through Buckinghamshire; it then bends to the south, with many windings, and reaches Bedford, where it becomes navigable; it afterwards proceeds through Huntingdonshire, Cambridgeshire, and the Isle of Ely, to the county of Norfolk; and inclining more and more to the north, it falls into the Wash, beneath the walls of Lynn Regis. In its course, it receives the Nene from Northampton and Peterborough; the Cam, from Cambridge; the lesser Ouse from Norfolk; and the Macksonhall from Suffolk; all of them navigable rivers. The entire course of this river may be 100 miles. The character of this river through the whole of its course, is very tame and uninteresting. In the latter part of its course, it sinks into those great marshes that abound on this part of the eastern coast: The Welland has its source between Lutterworth and Harborough; and after flowing in a north-east and northerly direction, and separating Northamptonshire from Leicestershire, Rutlandshire, and Lincolnshire, it contributes to form the Wash of Fosdyke. The Witham falls into the sea at the same place, taking its rise north of Stamford, and pursuing a northerly direction by Grantham to Lincoln; it afterwards changes its course, and flowing first to the east and next to the south, its course is terminated near Boston. As the principal rivers which join the Trent have already been noticed, we shall proceed to the Wear. This river rises to the north of the Tees; at Bishops Auckland, it changes the south-easterly course which it had hitherto pursued, turns to the north-east, and after nearly surrounding the city of Durham, it flows northward to Chester-le-Street, and then inclines a little to the east to reach Sunderland.

As the Tweed is rather a Scotch than an English river, we shall proceed to a brief notice of the secondary rivers in the west of England. The Eden, the first English river on the south-west border of Scotland, has its source in the moors of Westmoreland; for a short way its course is to the north-east, after which it inclines to the north-west till it reaches Crosby, when it turns to the south-west to pass Carlisle; for the remainder of its course, its direction is again north-west. At its mouth it meets the Esk, and both rivers fall into the Solway Frith. The Ribble rises in the district of Craven; it flows in a south-easterly direction, till it has passed Settle, when it turns south-west by Clithero,

1
where it enters Lancashire. After passing Ribchester, it enters a vale of considerable beauty, to which it gives name; it next compasses the handsome town of Preston, soon after which it discharges itself by a broad sandy outlet. No rivers occur (except such as have been already described) that need detain us between the Ribble and the Wye. This latter river rises on the south side of Plinlimmon, near the source of the Severn. It flows at first towards the south, with a trifling inclination to the east; and this direction it pursues through the great plain of Herefordshire; but as it approaches Monmouth, its course is south and south-west. It falls into the mouth of the Severn near Chepstow. The grandiose beauties of the Wye, which flows in a deep bed, between lofty rocks, clothed with hanging woods, and here and there crowned with ruined castles, have employed the descriptive powers of the pen and pencil, and frequently engage the curiosity of travelers.

Avon is a name which no fewer than seven rivers in England and Wales bear; but of these, only the Upper and Lower Avon, and the Avon of Wiltshire and Hampshire, call for our notice. Our account of the last we shall defer till we come to the rivers on the south coast of England. The Upper Avon rises on the borders of Leicestershire and Warwickshire, and, bringing a large influx of water past the castle and town of Warwick, it afterwards flows through a fine county to Stratford on Avon. From this place, it traverses the great level of Worcestershire, by Evesham, and, bending to the south, falls into the Severn near Tewkesbury. The Lower Avon has its source near Wotton Bassett, in the hills of North Wilts, bordering on the county of Gloucester. From these hills it flows with a winding course into the vale that leads to Chippenham; hence its windings are still greater and more numerous, the country through which it passes being very hilly. It next enters the clothing district of Wiltshire, and for a short space divides that county from Somersetshire. Its course is next to the south, and afterwards it takes a long compass by the west and the north. The city of Bath is now nearly encircled by its waters. From this place, with frequent meanderings, it descends to Bristol, whence it falls into the Bristol Channel at King's Road. The country through which the Lower Avon flows, is in general rich and picturesque; but its waters are frequently discoloured, after heavy rains, by the chalky soil of Wiltshire, and the ochry soil of Somersetshire.

The Tamar, one of the most considerable rivers in the west of England, rises in a moor near Marvingtow, the most northern part of the county of Cornwall: It pursues nearly a southerly course, by Taverton, to the vicinity of Launceston; at a small distance from which, its current is increased by the small river Ottery. After their junction, it inclines to the east, till it unites with the Lyd and the Tavy. It now resumes its south direction, and, uniting with Lynher-creek, and continually increasing in importance as it winds along, it forms, between Plymouth Dock and Saltash, the spacious basin called Hamoaze, or Plymouth Harbour, which has been already described. Its course, though short, is in many parts very striking; about Launceston, its banks are finely fringed with wood; while lower down it receives the character of grandeur, from the numerous large vessels with which its broad curving branches are crowded.

None of the rivers in the south of England so strongly resemble the bold character of the rivers of the north of England and of Scotland, as the Dart. It rises in the mountainous district of Dartmoor, and first descends southward, and then inclines considerably to the east before it leaves that part of the country. Afterwards its winding course is to the south-east, as it passes Totness, and falls into the sea between Dartmouth and Kingswear. It is particularly distinguished for its rapidity; and this character it retains even after it leaves those mountains which inclose its source. When it descends into the rich plains of the southern part of Devonshire, its character is changed; and a little to the west of Ashburnham, it forms a charming valley, through which it flows in a placid stream. At Totness it is joined by the tide, when its character again changes; now exhibiting, in a striking union, its original boldness and its subsequent beauty, rolling, in a majestic stream, between hills covered with vegetation, woods, and villages, disclosing new beauties at every curve, and presenting a grand object to the adjacent country, varied perpetually both in its form and attendant features. Nearer its mouth, the hills that inclose its channel become more lofty, while the river, winding between their wooded and rocky bases, passes the hamlet of Kingswear on its eastern, and the irregular town of Dartmouth on its western bank.

The Exe calls for our notice, more on account of its The Exe. beauty, than on account of the length of its course, or its importance. It rises in the hills of Exmoor, and at first inclines to the south-east; but afterwards entering a deep valley, it flows southward, with a little bending to the west, to Exeter. From this city, its course is rather to the east of the South, as it forms a gradual transition to Exmouth, where it meets the sea. The most striking circumstance attending the course of this river, is the sudden change of character which it undergoes, from a furious torrent to a placid rivulet, as it descends from its mountainous origin into verdant meadows. This striking change of feature takes place, when it forces itself a passage through the wild hills near Minehead, into a valley, whose sides are richly clothed with wood; but the valley through which it flows does not become expanded till the Exe is joined by the Culm. From their junction, it flows through a district of uncommon richness and beauty.

None of the rivers of Dorsetshire present any circumstance which calls for notice: their course is not long, nor is the country through which they flow distinguished either for much beauty or fertility. We shall, therefore, pass on to the consideration of the Hampshire and Wiltshire Avon. This river springs from three sources; one near Marlborough, and the two others between Marlborough and the Devizes. After these branches unite, the Avon flows to the South, forming a valley between Marlborough Downs and Salisbury plain. It passes by Amesbury, and under Old Sarum, to Salisbury. On one side of this city it is joined by the Willey, and on the other by the Bourne. After this junction, the Avon continues to flow in a southward direction, through a part of the New Forest, by Ringwood, till the Stour meets it at Christ Church, when it falls into the English Channel. By the aid of the tide, large ships go up to Christ Church; and a few miles above this place the navigation by locks commences, which continues to the vicinity of Salisbury. From this description of its course, it will be seen, that the country through which it flows is generally destitute of beauty, and not remarkable for its fertility; but
Ullswater is situated partly in Westmorland and partly in Cumberland. It is about nine miles long, but at its greatest width a little more than one. Its shores are uncommonly bold, and the falls which are in its neighbourhood rise with great sublimity; yet, notwithstanding the vastness of these accommodations, Ullswater retains a character of high and impressive dignity. This character is intermixed with one little less striking, though of a more mild and captivating nature: The rocks of the lake, and of its vicinity, are celebrated for reverberating sounds, so that, by the introduction of a few French horns and clarionets, according to Gilpin, "the whole lake is transformed into a kind of magical scene, in which every promontory seems peopled by aerial beings, answering each other in celestial music!" Thirlmere, or Leatheswater, is a narrow irregular sheet of water, about three miles in length. It skirts the huge base of Helvellyn; it is situated in the interior of a very sequestered district; and its shores being for the most part naked and rocky, it displays a scene of desolation, heightened in no trifling degree by the huge masses of stone which appear to have fallen from Helvellyn. The impression made on the mind and feelings by this scene, is deepened by the noise of the water-falls, which, on every side, are tumbling from immense heights. Derwent-water, or Keswick-lake as it is also named, is about three miles in length, and one and a half in breadth, somewhat approaching to an oval figure. In beauty it is superior to all the other lakes, but in dignity and grandeur it is much inferior to that of Ullswater. Its greatest blen- dish to the eye of taste, arises from its want of proportion, when viewed in connection with the scenery around it. This scenery is on a very grand and sublime scale; whereas the lake is not only too small to be grand, but also in its features and form excludes all idea of grandeur; for, being seen all at once, it leaves nothing for the fancy to feed upon. But, in respect to beauty, it has undoubted and large claims on the man of taste: "The soft undulation of its shores, the mingled wood and pasture that paint them, the brilliant purity of the water, that gives back every landscape on its bank, and frequently with heightened colouring; the fantastic wildness of the rocks, and the magnificence of the amphitheatre they form, are circumstances, the view of which excites emotions of sweet and tranquil pleasure." When visited by moon-light, the deep shades of the frowning mountains—the reflected light of the moon on the unruffled surface of the water—and the silence of the night, only broken by the murmurs of the water-falls, are represented as filling the mind with inconceivable pleasure.

About three miles to the west of Derwent-water, Brood-waite, Bassenthwaite-water, or Brood-water, is situated: it is ten about four miles long, and at one end nearly a mile across; but at the other end, its breadth is not more than a quarter of a mile. There are many points in the surrounding scenery, which give to this lake a striking character: on the east of it is spread the beautiful and extensive vale of Bassenthwaite, beyond which Skiddaw rears its lofty head; on the west, mountains, low in comparison with Skiddaw, fall abruptly to the water's edge, disclosing here and there small patches of cultivation, and partly covered with thick woods. The situation of Overwater is naked, and the country neither sufficiently picturesque or sublime, to engage the attention of such as have already viewed the beauty of Derwent-water, or the grandeur of Ullswater. It is about half a mile in length, and rather more than a quarter of a
England.

Statistics.

691

mile broad. Lowes-water is a beautiful lake, but its beauty is of a somewhat different character from that of Derwent-water; woodland and cultivated fields, finely intermixed, ornament its borders, while its southern shore is bounded by some lofty eminences, descending in some parts precipitately to the water: the northern shore is more humble, and soon softens into an open country. It is about a mile long, and a quarter broad. None of the lakes in this part of England have juster claims to the character of picturesque, than Crummock-water; the barren Mofflock, and other lofty mountains, border the western bank of this lake, while its opposite shores are much indented, and varied with low bays, curious promontories, little coppices, and trees scattered among small farms; the whole terminating in a rich scene of woodland, impending in a beautiful manner from the superior eminences. On each side there is a chain of mountains; some naked, others wooded to their bases; some verdant, some rocky and heathy, and some covered with red shiver, which streams down their furrowed sides, exhibiting a singular appearance. This lake is nearly four miles long; its breadth about half a mile; its waters are very deep and clear.

Buttermere. About a mile south from this lake, Buttermere-water is situated, being separated from it by a fine, level, and luxuriant vale. A range of rugged mountains, rising abruptly from the margin of the water, hem in its western shores; its eastern shores rise more gently, and are partly adorned with wood. This lake, though undoubtedly beautiful, is more deservedly celebrated for the cataracts which are near its southern extremity, and particularly for the water-fall, called Scale-force, about a mile and a half to the west of it. The length or Buttermere is rather more than a mile and a half, and its breadth about half a mile. Ennerdale-water is guarded on every side except the west, by wild and craggy heights, which are almost impassable. The terrific gloom of these objects is relieved and enlivened in some degree, by the small farms, which are scattered along its eastern shores; but, on the whole, the scenery is melancholy. This lake is about two miles and a half long, and its breadth, at the widest part, about a quarter of a mile. Wast-water is situated in the middle of Wasdale, on each side of which, the western mountains rise to a great height, and almost meet at their bases: the form and position of these mountains add greatly to the effect of the scenery of the lake: some lean from the opposite sides of the vale towards each other, so much as to render the distance between their tops, when contrasted with the distance between their bases, very singular and romantic; while others rise perpendicularly, covered with loose stones of different colours, which are continually falling down; and when, during their fall, the sun shines upon them, they are represented as somewhat resembling the Aurora Borealis. The character of the vale is quite different: here every thing is rural, and in the genuine style of pastoral beauty and simplicity. This lake is about three miles long, and about three quarters of a mile broad in the widest part.

The other lakes of Cumberland do not require particular description, as they present little that is grand or interesting. Burnmoor-tarn is seated among the wildest mountains at the head of Mertledale, to which there is scarcely a sheep tract to direct the steps of the curious traveller. The waters of this lake do not cover more than 250 acres. Devock-water is a little larger, occupying about 300 acres. It is situated among the hills, about five miles south-east from Ravenglass. Talkin-tarn includes a space of about 40 acres. This lake, as well as Tindale-tarn, which covers about 50 acres, is situated among the bleak moors, a few miles to the south-east of Brompton. Turn-wattdale spreads its waters on a naked and barren common, about one mile to the westward of the river Eden, at Arnthwaite, above which it rises 600 feet perpendicular. It covers about 100 acres.

Winandermore is a lake, that serves as a boundary between the counties of Westmoreland and Lancaster. It occupies an area of about 15 miles in length. Its average breadth is about one mile. Its greatest depth, near Eccles-cragg, has been ascertained to be 800 feet. In the middle of the stream, a smooth rock forms the bottom of this lake. The stream, in many places, are perpendicular, and in some they continue so for a mile without interruption. This lake is principally formed, or fed, by four rivulets. The Brothay and Rothay join at its west corner; and about four miles lower down, on the east side, Troutbeck river descends from the falls, and falls into the Mere. At Causey-beck, its waters are further augmented by a small rivulet called Estwaite-water. The waters of Winandermore fall generally with great rapidity, at its south end, which terminates at Newly-bridge, through the channel of the Leven water, and in their course form several cascades over the craggy rocks. The character of this lake possesses many striking beauties, with just so much of the romantic, as to vary and enliven those beauties. Its sides are finely skirted with rich and picturesque scenery, and the effect is greatly heightened by several small islands, some of which are ornamented with castellated buildings. Coniston lake is situated about four miles west from Hawkshead in Lancashire, is about six miles in its greatest length, three quarters of a mile in breadth, and in depth about 40 fathoms. It is chiefly characterised by the nature of its shores, which are frequently indented, and open into small bays, in a variety of forms.

Chap. III.

Meteorology of England.

With respect to climate, England, from its situation in the northern part of the temperate zone, cannot enjoy long, or in great vividness, the genial influence of the sun; and from its being an island, it is exposed to great variations of dryness and moisture, as well as of heat and cold, at all seasons; indeed, its atmosphere is inclined to be chilly and damp, and is therefore not so favourable to the ripening as to the growth of the productions of the earth. There is, perhaps, however, no country in Europe, which displays such a rich and beautiful verdure, for such a large portion of the year; since the rigour of its winter is seldom so great or so lasting, as to destroy this verdure by cold, and the rains of its summer, interrupted by cooler weather, and refreshed by frequent showers, do not wither up the grass. On the continent of Europe, the period when the different seasons may be expected to arrive, the mode in which they will respectively commence, and their durations uninterrupted by unseasonable weather, can safely be predicted and relied upon; but in England it is quite the reverse. The winter months, indeed, are generally reckoned to be December, January, and February. The spring months, March, April, and

General description of the climate.
May; the summer months, June, July, and August; and the autumn months, September, October, and November; but it never happens that the seasons respectively confine themselves to these months: not infrequently in the month of January or February, a foreigner, unaccustomed to our climate, would imagine that spring was about to commence; the air is mild and balmy, the buds begin to burst forth; the birds, which the rigour of winter had kept from sight, again make their appearance; and the whole face of nature seems to rejoice. This, perhaps, continues for the space of a week or two; when suddenly a gloomy change takes place, and winter resumes its power. Open and mild weather is also not unfrequently seen even in December, especially towards the beginning of that month; indeed, in all parts of England, little or no frost is expected before Christmas: this is almost the only circumstance respecting an English winter that can be anticipated with tolerable confidence; the nature of the winter, with respect to severity, and the duration of it, those who have had the longest experience of our climate, and paid the greatest and most minute and particular attention to its changes, and to the apparent or probable signs of its changes, are totally unable to predict.

In one respect, however, our winters differ even when they are most severe, from the winters of countries which lie under the same latitude on the continent; for while the sea-ports of Holland and Germany are every winter locked up with ice, those of England are never known to suffer this inconvenience.

We have said that December, January, and February, are generally reckoned the winter months; but as the weather in the two latter is not unfrequently much milder than proper and regular winter weather, so, on the contrary, the weather of what are called the spring months, March, April, and May, is very frequently the reverse of spring weather. March is almost always a wet and boisterous month, except in those few cases in which the rigours of winter extend into it. Its moisture is so great, as to have given rise to the English proverb, "a peck of March dust is worth a king's ranson." The month of April is usually mild and moist, and spring again, after having made a feeble effort to resume its authority in January or February, attempts, but too frequently with as little success, to establish its power; for May, which on the continent is the month of uncommon blandness, and to which, even in England, notwithstanding our almost uniform disappointment, we ascribe the same quality, seldom appears, or at least advances far, before easterly winds set in, which, to the feelings, are as cold as the coldest winds during the frosts of winter, and which most effectually in all cases check, and in many instances totally blast, the fruit vegetation.

Hence it appears, that, in England, the season of spring can scarcely be said to exist; certainly not to go forward, increasing in beauty and interest, till it expands into the season of summer. But though an English spring is thus uncertain, interrupted, and short, it has charms of its own, to which, in a great degree, the same season on the continent is a stranger; for there are almost every year, and nearly over the whole of England, days, and sometimes weeks, during which vegetation proceeds regularly, and without check, and when the air possesses all the balminess and mildness of summer, without its oppressive heat. Indeed, with respect both to the spring and summer of England, it may justly be observed, that, amidst all their uncertainty and interruption, they favour us with weather, such as, (it may be, perhaps, from the relish and contrast which that uncertainty and interruption create,) even at the period of their highest perfection, they do not exhibit on the continent.

The summer of England scarcely ever makes its appearance before the middle or end of June. The first part of this month, though occasionally mild, too often partakes of the cold easterly winds of May; so that, strictly speaking, May and the beginning of June fall under no division of the year. The weather, during the prevalence of the easterly winds, is as cold as that of winter; but it is not winter; and assuredly there are no signs of spring, while these winds continue. Generally, therefore, vegetation makes little advance towards the luxuriance of summer, till the middle or end of June. At this period, in the south of England, the country is uncommonly beautiful; but in the northern counties, the weather is still very often cold and ungenial. July, August, and September, may be said to be real summer months over the whole kingdom; but slight frosts sometimes occur during the nights of September, even in the southern; while, on the other hand, the month of October, in this part of England, is often mild, dry, and settled. In the northern counties, this month may be said to be the beginning of winter; or, more properly speaking, of that raw, unsettled, wet weather, which always precedes winter in this island. November seldom advances far, before it brings the same kind of weather to the southern counties, attended in London and its vicinity, with thick fogs and mists.

Such is the climate of England, generally speaking; but it will be necessary to be more particular, and to describe the difference of climate in the different parts of the kingdom. It is sufficiently obvious, that in the north of England, the spring, summer, and autumn will be more backward, less certain, and of shorter duration, than in the southern parts of the kingdom. The temperature there is not only colder, but it is also moister. The winters are likewise more severe, and of longer duration; so, that, to the north of the Mersey, and the Humber, the seasons of spring and summer may be reckoned to be nearly a fortnight later in their commencement, than they are in the south and southwestern counties, while the autumn is shorter, and more frequently interrupted with frosts during the night. It cannot be doubted, however, whether the winter in the north of England is more severe, when compared with the winter in the south of England, in the same proportion as the spring and summer are longer and warmer; at least, in the southern counties, particularly in those which lie in the vicinity of London, the winters are nearly equal in severity, though perhaps not in length, to the winters of the counties to the north of the Mersey and the Humber.

Besides the difference between the climate of the north and south of England, there is also a difference between the climate of the eastern and western counties. The climate of the latter is much more moist, and at the same time milder than the climate of the eastern counties. This circumstance arises from three causes: the vicinity of the western counties to the great Atlantic Ocean, the extreme prevalence of westerly winds, and the ridge of hills, already described, which runs along the western side of the kingdom. The Atlantic Ocean saturates the westerly winds with immense quantities of vapours, which being intercepted in their passage by the range of hills, fall in rain. The eastern side of the kingdom, not receiving these winds,
first, and, on the other hand, from being more exposed to the cold and piercing north-winds, its temperature is less pleasant, especially during the summer months. It is well known that the temperature of the ocean is more equable than that of the land; and, of course, at least in our latitudes, milder during winter, and not so warm during the summer; hence, the western counties, being exposed to the winds from the Atlantic Ocean, generally experience a winter rather moist than severe. Snow seldom lies in this part of the kingdom for any length of time. This remark applies with peculiar force to the south-western counties of England, particularly Cornwall and Devonshire, which being exposed to the winds both from the Bristol and English Channel, is favoured with uncommonly mild winters.

The science of meteorology is, even in this inquisitive and enlightened age, so little advanced, and so bare of facts, that it would be rash to attempt to give particular details, either respecting temperature, or the quantity of rain, which would be accurately correct, and unquestionably well-founded, except such as relate to some few districts of England and Wales. These, however, it may be proper to give, in order that a clearer insight may be gained into the nature of our climate, and into its difference in different parts, and its variations in the same part.

First, with respect to the quantity of rain which falls in different parts of England. It has been already observed, that in the western counties much more rain falls in the course of the year than in the eastern counties; and it may be added, that a greater proportion of rain falls on the north-western coast, compared with counties that are situated on the south-eastern side of the island. The proportion of rain which fell in the course of a year at Townley, in Lancashire, was measured, upwards of a century ago, and compared with the quantity which fell during the same space of time at Axminster, in Devonshire; on an average of six years, from 1700 to 1705, inclusive, it appeared that there fell at Townley 42.2 inches, while at Axminster there fell only 19.1 inches. The mean quantity of rain that has been observed to fall in the county of Rutland, in the course of the year, is 20.4 inches. At Selbourne, in Hampshire, where the country is rather hilly, the average quantity of rain which fell annually, between 1780 and 1786, was 36.08 inches.

Perhaps no circumstance more evidently and strongly proves the variability of our climate, with respect to rain, than the following facts, detailed by Dr. Hexton, concerning the quantity of rain which fell in certain years in Devonshire. There can be no doubt, that in this county, the climate is not only much moister, but the actual quantity of rain that falls is much greater, than in the south and south-eastern counties: and yet he informs us, that in 1751, the rain which fell measured only 17 inches, and 266.10ths; in 1711, 20 inches and 34.10ths; and in 1748, 20 inches and 903.10ths.

It appears, from a meteorological journal kept by Major Rooke, that the quantity of rain which fell at the four following places in the year 1798, was as follows: London, 23.22 inches; West Bridgford, Nottinghamshire, 27.22; Lancaster, 48.19; Kendal, 60.85. A farther comparison of the quantities of rain which fall at these places may be made by the following tables, given by Mr. Howe in his Agricultural Survey of the County of Nottingham: In 1793, there fell at London, 23.32 inches; at West Bridgford, 26.27; at Lancaster, 50.81; and at Kendal, 69.65. In 1794, at London, 18.15; at West Bridgford, 24.64; at Lancaster, 48.93; and at Kendal, 57.98. In 1795, at London, 17.86; at West Bridgford, 18.16; at Lancaster, 37.4; and at Kendal, 45.24. The fall of rain this year at Hull, was 22.98. In the year 1805, there fell at London 15.12 inches, while at Bremo the quantity was 26.25. The average gauge of rain at Sheffield is 33 inches in a year, which is about a medium between what falls in Lancashire and on the eastern coast. At Langrove, in Shropshire, a register was kept of the dry and wet days for the years 1796, 1797, 1798, 1799, 1800, and 1801; the result of which is, that in 1796, there were 201 dry days, and 164 wet; in 1797, 184 dry, and 181 wet; in 1798, the same; in 1799, 148 dry, and 217 wet; in 1800, 161 dry, and 204 wet; and in 1801, 163 dry, and 202 wet. In Staffordshire, the annual rains generally exceed 36 inches; whereas, in Worcestershire, under the same meridian of longitude, they fall short of 30—a proof of what was remarked, that those northern counties which lie as far to the west as the southern counties, in general have a moister climate.

In 1796, the fall of rain at Chertsey, in Surrey, was 25 inches; at London, 27; at Dinton, in Norfolk, 25; at Chatsworth, in Derbyshire, 30; at Horncastle, in Lincolnshire, 26; at Nottingham, 25; at Hull, 30; at Lancashire, 40; at Dalton, in Lancaster, 49; and at Kendal, 53 inches.

From the observations on the quantity of rain which fell at Liverpool, for a period of 18 years, beginning with the year 1775, made by Mr. Hutchinson, dockmaster at that place, it appears, that the mean annual quantity of rain which falls at that place, is 34.4168 inches; and that the mean falls of rain in each month, and each season of the year, on an average of the same period, were as follows: February, 1.5471; March, 1.5277; April, 2.1041; mean fall in the spring, 5.4730; May, 2.5729; June, 2.8159; July, 3.5628; mean fall in summer, 9.056; August, 3.3106; September, 3.6344; October, 3.7239; mean fall in autumn, 10.0839; November, 3.4408; December, 3.2876; January, 2.1741; mean fall in winter, 8.9025. At Dover, the mean annual fall is 37.82 inches; at Garsdale, which is a narrow valley, 13 miles to the north-east of Kendal, the quantity of rain that fell in the year 1777 was 49.5200 inches, and the number of rainy days 222. In the year 1778, the quantity of rain was 61.3660 inches; and the number of rainy days 249; and in the year 1779, the quantity of rain was 45.5999 inches, and the number of rainy days 197.

The comparative wetness of the climate in the north-west of England, will further appear from the following results of an account of the quantity of rain which fell at Manchester during eight years, from 1786 to 1793, both inclusive. In 1786, the number of days on which rain or snow fell, was 207, and the quantity of rain 40.5; in 1787, there were 290 rainy or snowy days, and the quantity of rain 47.5; in the year 1788, rain or snow fell on 178 days, and the quantity of rain was 27.15; in 1789, there were 206 days on which rain or snow fell, and the quantity of rain was 51 inches; in 1790, there were 210 of such days, and the rain amounted to 42.75 inches; in 1791, rain or snow fell on 223 days, and the quantity of rain was 64 inches; in 1792, there were 245 days of rain or snow, and the quantity of rain was 35.25 inches; and in the year 1793,...
1793, rain or snow fell on 233 days, and the quantity of rain amounted to 36.5 inches.

The midland counties in England receive, as might be expected, nearly the medium quantity of rain that falls on the western and eastern coasts; or rather, perhaps, the quantity that falls in them approaches nearer to the quantity that falls on the eastern than the western coast. Even in Derbyshire, though a mountainous district, much less rain falls than in Lancashire, or even Staffordshire or Shropshire, as will be evident from the following result, from a state of the falls of rain at Chatsworth, in Derbyshire, for the years 1777, 1778, 1779, 1780, 1781, 1792, and 1793. The average for the annual falls of these seven years, is 27,380 inches; the average falls in each month, classed according to the seasons, is as follows: In February, 1.673 inches; in March, 1.826; in April, 2.725—mean fall in spring, 5.667;—in the month of May, 2.285; in June, 1.944; in July, 2.734—mean fall in summer, 6.695;—in August, 2.033; in September, 3.173; in October, 3.288—mean fall in autumn, 8.944;—in November, 2.183; in December, 2.175; in January, 1.833—mean fall in winter, 6.211. From this account, it will be seen, that in this part of Derbyshire, at least, more rain falls in the autumn quarter than in any other quarter of the year, and less in the spring quarter; while the rain that falls in the summer and winter quarters, is nearly equal in quantity. By referring back to the account which has been given of the mean fall of rains at Liverpool for each season, it will be found that the same is the case there. This remark, as far as it applies to Derbyshire, is confirmed by the result of an account of the quantity of rain that fell at Chatsworth during a subsequent period of seven years, commencing with the year 1784;—the average for the whole period of 14 years, during each season of the year, being as follows: Spring, 4.989; summer, 7.547; autumn, 8.181; and winter, 6.686. It has also been remarked, that as we proceed northward, along the western coast, the quantity of rain which falls annually increases. Thus, the mean annual quantity of rain which falls in Liverpool, has been ascertained to be 34.41 inches; whereas, at Lancaster, from an account of the rain that fell there, during the years 1784, 1785, 1786, 1787, 1788, 1789, and 1790, kept by Dr Campbell, it appears that the mean annual fall amounts to 40.3 inches. At this place, also, the greatest quantity of rain falls during the autumn months, or more strictly speaking, during the months of July, August, and September; which circumstance, when we come to the consideration of the most prevalent winds in different parts of the kingdom, will be satisfactorily accounted for.

The counties in the vicinity of the metropolis are subject to comparatively trifling falls of rain. There are not data sufficiently accurate, and the result of observations continued for a sufficient length of time, to prove this so decisively as could be wished; but the following details of the annual quantity of rain at Youngsbury, near Ware, in Hertfordshire, 20 miles from London, which fell during five years, may be admitted as sufficient evidence, at least as respects that county; and the inference is fair, that unless there are local peculiarities in the adjoining counties, the quantity of rain will be ascertained to be nearly similar. In 1787, there fell 23.664 inches; in 1788, 28.567 inches; in 1789, 29.493; in 1790, 22.970; and in 1791, 24.260. From these details, a tolerably accurate idea of this branch of the meteorology of England may be formed. In those parts of the north-western counties, which lie among the mountains, the greatest quantity of rain falls, as about Kendal, where the annual average is upwards of 40 inches; and even where the situation is not mountainous, the north-western counties are exposed to great falls of rain; as we advance on this side of England to the south, the quantity of rain diminishes, though it is probable, that in the mountainous parts of Wales, and in the peninsula of Cornwall, and the west of Devonshire, this observation will by no means hold good. In the north-eastern counties of England more rain falls than in the south-eastern; but much less than in the north-western counties. Perhaps the county in which the least quantity of rain falls is Norfolk. From the account already given of the quantity of rain at Dover, it would appear to be very large; but the account was kept for too short a period to justify any positive and general inference.

With respect to the seasons of the year, when the greatest quantity of rain falls in different parts of the kingdom, it would seem that in the western counties, the autumn months, or rather the months of July, August, September, and October, are most exposed to rain; whereas on the eastern side of the kingdom, the winter months, that is, November, December, and January, are the wettest. From the greater prevalence of east winds, during the spring, on the east coast than on the west coast, it often happens, that at this season the eastern counties have heavier falls of rain than the western counties are liable to.

There are certainly not sufficient data on which to ground any statement of the annual average quantity of rain that falls in England at large. Dr Halley supposes it to be 22 inches; but this is evidently very greatly below the average. Mr Dalton, with much greater probability, fixes it at 31.3 inches. This result is drawn from what Mr Dalton conceives to be the largest collection of accounts of rain fallen in different places in England, that had appeared previously to the publication of his paper on the subject, in the Manchester Transactions for 1798. The average of these accounts is indeed 35.2 inches; but as the details contain no account of rain in Wales, though they contain an account of the rain in a much greater proportion of maritime than inland counties, and as it may be presumed, that the rain in Wales would exceed the mean given, as much as the inland counties, not contained in the list, from which he drew his mean, would fall short of it, he concludes, that in stating the average of England and Wales to be 31.3, he approximates as nearly as possible to the truth.

In order that the relative quantity of rain, which falls in the inland and maritime counties of England, may be more clearly and satisfactorily ascertained and compared, the following tabular view is subjoined, with the number of years annexed to each place, during which the observations were made:

Tabular comparison of rain in maritime and inland counties.

Statistics.
The observations of attentive meteorologists have ascertained, that in this country it generally rains less in March than in November, in proportion, on an average, of 7 to 12; less in April than in October, in the proportion of 1 to 2; and less in May than in September, at least the chances for this are as 4 to 3.

The nature of the climate of England, with regard to moisture, cannot, however, be accurately determined, unless the quantity of dew that falls annually be also ascertained. On this point there are few observations or experiments of sufficient accuracy and duration to be relied upon. Dr Hales thinks, that the quantity of dew that falls on moist earth in this country is 0.28 inches; but Mr Dalton justly remarks, that this quantity is too small, as the dew which is deposited on grass is much more copious than what falls on moist earth. Hence, he is disposed to take the dew at 5 inches annually, and thus to reckon that 30 inches of water is deposited, at a medium, annually on the surface of the earth in England and Wales, reckoning 51 for rain, and 5 for dew, which is equal to 28 cubic miles, or 115 thousand millions of tons in weight nearly.

Evaporation. 

Closely connected with this branch of the meteorology of England and Wales, is that which regards the evaporation, which takes place from the surface of the ground. As it is evident, that all the water which falls in the form of rain or dew, must either be carried into the sea by some river, or be raised in vapour, Mr Dal-
Statistics.

At Liverpool.

It appears, from an account kept by Mr. Hutchinson at Liverpool, for 25 years, from 1708 to 1785, that the mean heat at that place, at 12 o'clock, is 53° of Fahrenheit's thermometer; the greatest degree of heat during that period, 86°; the least, 22°. The greatest range 64°; and the mean annual range 46°. The mean height of the thermometer, during the month of February, for the period, was 41°.3, of March 47°, of April 44°, of the spring season 48°; of the month of May 58°, of June 65°, of July 65°, the mean heat of summer 62°; of August 65°, September 61°, October 54°, the mean heat of autumn 60°; of November 47°, December 49°, and January 41°, and the mean heat of winter 44°.

The mean heat at Dover is 53°. The greatest degree of heat noticed during the years 1790, 1791, 1792, and 1793, 86°; the least 16°; the greatest range 70°; and the mean annual range 51° nearly. As, however, the observations on which these results are founded, were not complete during the whole of the years to which they relate, it is probable that the temperature of Dover is not accurately given, as it would then not be greater than the mean annual heat at Liverpool.

In Cheshire.

From accounts kept at Middlewich in Cheshire, with a thermometer in a room where there were no fires, at 10 o'clock in the morning, during the years 1768, 1769, 1770, 1771, and 1772, it appears that the mean heat at this place is 52°; the greatest heat 78°; the least 21°; the greatest range 57°; and the mean annual range 49°. In the month of February, the mean height was 46°, in March 48°, in April 50°, and in the spring the mean heat was 44°; in the month of May 60°, in June 63°, in July 68°, giving as the average heat of the summer 64°; in August 64°; in September 60°; in October 59°, the mean heat of autumn being thus 60°; in November 45°, December 42°, January 37°, giving as the mean heat of winter 43°.

At Kendal.

At Kendal, in Westmoreland, it was ascertained, from the observations of five years, beginning July 1787, that the mean temperature there, was 46°58. In winter, during wet weather, the mean height of the thermometer was nearly 40°; and in the same kind of weather during the summer, it was about 54°.

Lancaster.

The mean height of the thermometer at Lancaster during seven years, viz. 1784, 1785, 1786, 1787, 1788, 1789, and 1790, was 51°8 at two o'clock in the afternoon; 45°6 at 10 o'clock at night. The mean heat, noon and night, 48°7; the highest degree 82; and the lowest 18°. The mean heat of January 59°1, of February 41°3, of March 41°6, April 50°, May 59°3, June 64°5, July 64°1, August 68°2, September 59°4, October 52°1, November 45°5, and December 39°2, at two o'clock in the afternoon.

London.

At London, by a mean of the observations made at the Royal Society from 1772 to 1786, it appears that the mean annual temperature is 51°9; and the monthly temperature as follows, January 55°9, February 42°3, March 46°4, April 49°5, May 56°6, June 63°22, July 66°8, August 65°8, September 59°83, October 52°81, November 44°44, and December 41°04. The greatest usual cold is 20°, and occurs in January; the greatest usual heat is 81°, and happens generally in July. The limits of the annual variation are 25.5, that is, 1° above and 1°.5 below the mean. The greatest variations of the mean temperature of the same month in different years, are as follows, January 6°, February 5°, March 4°, April 3°, May 2.5°, June 2°, July 2°, August 2°, September 3°, October 4°, November 5°, December 3°. From this statement it will be seen, that the temperature of the summers differs much less than that of the winters. The most common variations of temperature in London, and its vicinity, within the space of 24 hours in every month, are January 6°, February 8°, March 20°, April 18°, May 14°, June 12°, July 10°, August 15°, September 18°, October 14°, November 9°, December 6°.

From observations made at York, which, however, were confined to one year, it appears, that the mean annual temperature in that city is 49°. The medium heat of each month and season, deduced from the same observations, is as follows: February 35°, March 43°, April 50°, giving as the medium heat of the spring 42°3; of May 59°, June 63°, July 68°, giving as the medium temperature of the summer season 63°; of August 65°, September 56°, October 48°, giving as the medium temperature of the autumn months 59°4; of November 40°, December 35°, January 33°, giving as the medium temperature of the winter season 36°.

From the observations made with two thermometers at the same time, one near Cullumpton in Devonshire, and the other at Yoxhelly in Staffordshire, it was ascertained that the heat in the former county above that in the latter, was, on one day, as follows: November 1794, 5°, December 4°, January 1795, 8°47, February 6°3, March 6°3, April 10°, May 8°7, June 8°3. The thermometer in Devonshire was observed at 8°47, at 11 A. M., and there was frequently a variation of one, two, three, and four degrees, and sometimes even five and seven degrees in that space of time, the thermometer generally standing higher at the latter hours, but sometimes lower. From the observations made by Dr. Babington, with a thermometer at Ludlow in Shropshire, it was ascertained, that on an average of 53 days, the heat was not quite one-eighth of a degree greater than at Yoxhelly in Staffordshire.

The comparative temperature of different parts of England will be further illustrated by the following facts: Dr. Thomas Young remarks, that the mean temperature of the six winter months, from October to March, at London, is 43°5; while at Dawlish, on the south coast of Devonshire, it is 43°3; and at Ilfracombe, on the Bristol Channel, it is so high as 59°. From November to March, the mean temperature of London is 42°6; of Penzance, in Cornwall, 48°1. From January to March, at London, 57°9; at Penzance, 48°3; and at Sidmouth, in Devonshire, 41°7. During February and March, at London, 41°5; and at Clifton, 42°5. From October to December, at London, 47°; and at Sidmouth, 45°7. From December to February, the mean temperature at London is 59°7. In the most sheltered parts of Devonshire, during winter, the temperature is 1.5 above that of London. In the coldest months, at Penzance, the temperature is 4.5 higher than at London.

From observations made the same year at Sidmouth and Derby, the following result is given:

The mean at Nottingham, for four years, was 48°. 75. The mean heat of the month of March, at two o'clock in the afternoon, in Pall Mall, according to Dr Heberden, is 50°. At Lancaster, the mean heat of the same month, at the same hour, is only 41°. 4.

It must not, however, be inferred from these details, that the cold in winter, and the heat in summer, is never very extreme in England; for the climate of this country varies nearly as much with respect to temperature, as it does with respect to rain. It occasionally happens, that very great degrees of cold are felt during the winter months, especially towards the end of December and the beginning of January; in some years the thermometer, without being exposed to the action of any circumstances, which would bring down the mercury to an inferior level, has indicated a degree of cold, not often felt even in countries lying much farther to the north, and not enjoying such a near vicinity to the sea as England does. It is said, that in the years 1794, 1798, and 1813-14, the thermometer was observed to be as low as within five degrees of zero; and from observations carefully made at different places, there can be no doubt, that in the last of these years, it was within eight degrees of zero. The heat, on the contrary, is sometimes very excessive, especially in the southern counties of England. In 1808, the thermometer, at many places in the vicinity of the metropolis, was nearly 90°, if it did not quite reach that point. It may also be remarked, that in the southern and south-western districts, in the months of April, May, and June, if there are a few days, or even hours, of bright unclouded sun, the thermometer will rise as high as in the south of France, or even as high as in Italy. These gleams, however, are often succeeded by frosty or very cold nights; and probably the next day or two, it is followed by hail or cold cloudy weather. In the summer months, even when the heat has been for a considerable time very great, the thermometer is observed to stand low an hour or two before sunrise; and much lower, at this time of the morning, in April, May, and June, than in July, August, and September.

The third branch of the meteorology of England, respects the winds. It has already been remarked, in the general observations on the climate of this country, that the west and south-west are much more prevalent, as well as constant, than the winds from any other quarter; and this circumstance may easily and naturally be accounted for, from the situation of the island, exposed to the Atlantic Ocean. The west and south-west winds are also the most violent, not only on the western side of the country, but likewise in the midland and eastern counties; so much so, indeed, that the effects of their constancy and violence may generally be traced, in the evident bending which they have given to the trees in all parts of the country. The winds that blow from the east and north-east are, next to those that blow from the west and south-west, the most regular and constant, and perhaps next to them the most violent; though it may be remarked, that in England the east and north-east winds seldom blow violently for more than one or two days, whereas the west and south-west winds frequently continue to blow violently for a considerably longer time. The wind that most seldom occurs, is that from the south. In some parts of the island, particularly in the western counties, the south-eastern winds are not uncommon. The north-western winds do not blow for any considerable part of the year, but when they do blow, they are generally steady.

In the summer time, it frequently happens that the wind veers round to several different quarters in the course of the day, or even in the course of a few hours; but this is never observed to be the case when it blows with the least violence. Near the sea coast, and even at the distance of several miles from it, during settled and warm weather, in the summer season, the wind at the break of day will blow from the land; about mid-day, or a little before it, it will veer round towards the sea; and in the course of the evening it will again become a land wind. Sometimes we are subject, in England, to a wind that in some respects resembles the sirocco wind of Sicily, though the variation in temperature, with us, is not nearly so considerable. It sometimes happens towards the end of April, but more frequently in May, the medium height of the thermometer being about 45°, with variable winds: The barometer falls, and the wind then becomes stationary at south-west, or south, blowing briskly: The thermometer then rises to 50°, 60°, or even 65°, and the heat of the air has an oppressive feel. When this wind ceases, it is generally followed by a wind from the opposite point of the compass, i.e., north-east, and the temperature soon lowers again to 45°. With respect to the connection of the height of the mercury in the barometer, with the different winds which prevail in England, it may be remarked, (and the remark will apply, in a greater or less degree to all parts of the island,) that the barometer is always higher and more steady when the wind blows from the north, or east, or from any point between these two quarters, than when it blows from the south, or west, or from any point between these two quarters; so that it generally happens, that rain falls when the barometer, with an easterly or north-easterly wind, is at a height, which, with a west-erly or south-westerly wind, would certainly indicate settled fair weather. In the eastern counties of England, when the winds from the east and north-east blow with the most constancy, and for the greatest length of time, they are often accompanied, especially in the months of April and May, with a blue mist and vaporous atmosphere.

From the observations made by order of the Royal Society, it was ascertained, that, at London, the state of the wind was as follows: The south-west winds blew 112 days; the south-east, 32 days; the north-east, 68 days; the east, 26 days; the north-west, 50 days; the south, 18 days; the west, 53 days; and the north, 16 days. From the same register it appears, that, in the vicinity of the metropolis, the south-west wind blows more upon an average in each month of the year than any other, particularly in July and August; that the north-east prevails during the months of January, March, April, May, and June, and is least common in February, July, September, and December; and that north-west winds occur most frequently from November to March, and less so in September and October, than in any other months.

From other observations made in this part of the island, it has been ascertained, that winds blowing from every point of the compass between the west, north-west, and north, are so very dry as not to produce a day's rain in the year. It sometimes, however, happens, that with a north-west wind small rain falls for a few hours. When the wind veers from the north through the west, it generally continues dry till it reaches the south-west, when it certainly brings rain. On the other hand, when it passes southward through...
The eastern points, the weather is perfectly dry till it reaches about the south-east. These observations apply, with different degrees of accuracy, to the climate not only in the immediate vicinity of the metropolis, but also to most of the counties in the south and south-east of England.

At Liverpool, Mr. Hutchinson made very minute and careful observations, not only on the direction, but also on the velocity of the winds prevalent in that part of the island. His mode of ascertaining the relative velocity, though not, perhaps, perfectly satisfactory, is yet sufficiently so for our purpose. The following is the result of his labours, containing the annual mean, deduced from 25 years' observations: The north wind blew 13 days; its mean velocity is expressed by 8: the north-east wind blew 29 days; its mean velocity is also expressed by 8: the easterly wind prevailed 18 days, with a velocity expressed by 9: the south-east wind blew 115 days, with a velocity equal to 8: the south wind blew 9 days, with a velocity expressed by 7: the south-west blew 54 days, with the velocity of 12: the west blew 49 days, with the greatest velocity of all the winds, being expressed by 13: and the north-west wind blew 58 days, with a velocity equal to 10.

If we take the north and east winds in opposition to the south and west, they will stand as follows:

<table>
<thead>
<tr>
<th>Days</th>
<th>Mean Velocity</th>
</tr>
</thead>
<tbody>
<tr>
<td>North</td>
<td>13</td>
</tr>
<tr>
<td>North-east</td>
<td>29</td>
</tr>
<tr>
<td>East</td>
<td>18</td>
</tr>
<tr>
<td>South-east</td>
<td>115</td>
</tr>
</tbody>
</table>

Total of the N. E. winds = 175, Mean velocity of N. E. winds = 8.3

South = 9, South-west = 54, West = 49, North-west = 58

Total of the S. W. winds = 170, Mean velocity of S. W. winds = 10.1

From these results it appears, that at Liverpool the wind blows more frequently from the south-east than from any other point; and this circumstance, at first sight, may be deemed to contradict the general observations which we affirmed on the most prevalent winds in England; but Dr. Darwin, as well as Dr. Garnett, very satisfactorily ascribe this remarkable deviation at Liverpool to some atmospheric eddy, produced by the situation of the place.

At Dover, upon an average of three years, it was ascertained, that the winds at Dover have blown as follows: North, 27 days; north-east, 118; east, 13; south-east, 37; south, 8; south-west, 195; west, 35; north-west, 91. If we take the north and east in opposition to the south and west, they will stand as follows:

<table>
<thead>
<tr>
<th>Days</th>
<th>Days</th>
</tr>
</thead>
<tbody>
<tr>
<td>North</td>
<td>South</td>
</tr>
<tr>
<td>North-east</td>
<td>South-west</td>
</tr>
<tr>
<td>East</td>
<td>West</td>
</tr>
<tr>
<td>South-east</td>
<td>North-west</td>
</tr>
</tbody>
</table>

Total of the north-easterly winds = 200, Total of the south-westerly winds = 329

The results of these observations, made at Dover, will confirm the remark of Drs. Darwin and Garnett, that the great prevalence of south-easterly winds at Liverpool is owing to some local cause. This will be still further confirmed and illustrated by the following result of Dr. Campbell's observations at Lancaster; where, upon an average of seven years, the winds were observed to blow in the following directions: North, 30 days; north-east, 67 days; north-west, 26 days; south, 51 days; south-east, 35, south-west 92, east, 17, west, 47.

Taking the north and east winds in opposition to the south and west, they stand as follows:

At Derby, from 366 observations, it appeared that the north and north-east winds blew 85 times, the east and south-east 56, the south and south-west 119, and the west and north-west 106.

The observations which have been made in the direction and velocity of the winds in this island, are, however, too few—have been continued for too short a time—and not made in a sufficient variety of places, to justify any very particular conclusion on the subject. From these causes, it happens, that the statements and opinions of meteorologists, on this branch of the meteorology of England, differ so much. According to a meteorological register kept by Major Rooke for sixteen years, from 1785 to 1800 inclusive, the most frequent winds in England blow from the south-west and north-west; and, during the last eight years of this period, the south-west winds were observed to be more prevalent, and those from other quarters to be less so; while the average number of days in which the north-east wind prevailed, appears to have been much the same during both periods. This statement, as far as it regards the prevalence of the north-west winds, is certainly at variance with the observations of all other meteorologists; since the wind from this quarter more seldom occurs in all parts of England than that from any other quarter, with the exception of the south and the east in some parts of the island.

The meteorology of any country must be considerably illustrated by the state of the barometer in it at different periods of the year; we shall therefore give the results of observations on this instrument in different parts of England.

At Liverpool, for twenty-five years, it was ascertained, that the mean height of the barometer was 29.74 inches; the greatest height during that period 30.90, the least 28.6; the greatest range 2.89, and the annual average range 1.96. The mean height in each month was as follows:

January 29.71, February 29.58, March 29.80, April 29.78, May 29.80, June 29.82, July 29.82, August 29.82.
ENGLAND.

29.51, September 29.69, October 29.71, November 29.64, December 29.64. From this statement it is evident, that the mean height of the barometer in this part of the island is greater during the months of May, June, July, and August, than in any other four months. The barometer at Dover was observed by Mr Manton, surgeon at that place, during the years 1789, 1790, 1791, 1792, and till September 1793. From his observations, it was found that the mean height of this instrument, on an average of these five years, was 29.90 inches; the greatest height during that period 30.93; the least 28.49; the greatest range 2.47; and the mean annual range 1.50.

Mr Vernon kept a journal of the height of the barometer at Middlewich in Cheshire for five years, from 1768 to 1772, both inclusive, and he found the greatest height to be 31; the least 28; the greatest range 3; and the mean annual range 1.94.

At Kendal, the mean height of the barometer at Kendal, collected from the observations of five years, beginning July 1787, was 29.7345. In 1787, it was found to be 29.810, and in 1794, 29.793. The greatest height of the barometer at Keswick, during the year 1793, was 30.38; the least height 28.33; the mean height 29.55; the greatest range 1.05; the mean monthly range 1.11. According to Mr Dalton, the mean annual height at this place is 29.79.

The mean annual height of the barometer at York, on an average of four years, was found to be 29.70; the greatest height during the year 1774, was 30.75; the least 28.60; the greatest range 2.15, and the mean range 0.31. The mean of the months from October to March inclusive, was 1.42, and in the six summer months, only 1.016.

The mean height of the barometer in London, upon an average of two observations in every day, kept at the house of the Royal Society, for many years, was found to be 29.88. According to Mr Kirwan, the usual variation of the barometer in England is two inches and a half.

At Sidmouth, an attentive observation of the barometer for one year, gave the following results: Highest, December 29th, 30.61; wind north-east. Lowest, October 19, 28.81; wind south-west. Greatest range, March 3, 4, 0.98; annual mean 29.93. The same year at Derby; highest, December 7, 30.48; wind north-east. Lowest, October 19, 28.34; wind south. The greatest range was observed in February, and was 0.65; annual mean, 29.74.

Thunder and lightning are not very common in England, though it seldom happens that the summer passes over without their occurring. They are very rare after the month of September, and scarcely ever occur between December and May; it is in the months of May, June, July, August, and September, particularly the two last, that we usually expect thunder storms of any consequence or duration. It seems to be ascertained, that in this island, the frequency of thunder and lightning is in proportion to the temperature of the air. There are few observations on this subject, but the following extract from Dalton's Meteorology, pages 29 and 46, will bear out this assertion.

It seldom happens that storms of thunder and lightning in England are very fatal; and it has not been observed, that when they are fatal, the mischief which they do, is greater in the southern than in the northern counties.

The aurora borealis is neither very common nor very brilliant in the southern parts of the island; but in the northern counties it is frequent, and its coruscations very bright and beautiful. It seems to be ascertained, that it was very rare in any part of the island, previous to the commencement of the 18th century; and since 1793, it has seldom appeared. The only particular observations on this part of the meteorology of England that we possess, are supplied by Mr Dalton, and they refer to Westmoreland, where they were made; this philosopher found, that in 1786, the number of the aurora borealis was 16: in 1787, 27; in 1788, 53; in 1789, 43; in 1790, 36; in 1791, 37; and in 1792, 28. In the month of January, on an average of three years, the number was 18; in February, 15; in March, 26; in April, 32; in May, 21; in June, 5; in July, 2; in August, 21; in September, 25; in October, 36; in November, 38; and in December, 9. When Mr Dalton removed from Kendal to Manchester, he continued to make his observations on this phenomenon; and the result confirms the remark we have made, that since 1793, it has seldom occurred in this island; for in 1794, he observed only 6, in January, March, and December; in 1795, only 2, both in September; in the year 1796, none were observed; in 1797, 12; in 1798, none; in 1799, 2; in 1800, 4; in 1801, 4; so that, during this period of eight years, only 32 were observed, whereas during the period of seven years, from 1786 to 1792, the number was 237.

CHAP. IV.

Soils.

The soils of England are so various, that it is impossible to give any general account of them; and in marks most parts of the kingdom, they pass so frequently and suddenly from one kind to another, that it would be tedious, and far exceed the limits of this article, even if the minute and extensive knowledge necessary for such an undertaking were possessed, to describe them all, in different districts. We shall, however, endeavour to give the reader such an idea of them as will enable him to comprehend their leading features, and to become acquainted with the most prevalent and extensive soils in the different districts of England. They may be classed under the following heads: clay, loam, sand, chalk, gravel, and peat; of the first description there are two kinds; deep, dark-coloured, rich clay; and clay of a less fertile quality, of a pale colour, and of comparatively small depth. The latter is by far the most prevalent in England. Of loams, there are several varieties: strong loam, which in general has been formed of clay, long under a course of tillage, and consequently much exposed to the action of the sun and air; loam of a less tenacious nature; calcareous loam, and sandy loam; the last, like the first description of loam, is rather an artificial soil, formed of sand, en-
ENGLAND.

The soils of England, in many parts, though cool, is deep, and lies on an absorbent substratum. A small patch of the red soil, which has already been noticed as stretching from Nottinghamshire to the western counties, is met with in Lancashire, between Eccleston and Preston. The sandy lands lie principally between the Ribble and the Mersey, reaching westward to the eastward nearly to Manchester. The most common subsoil is a red sand rock. The eastern part of the county in general consists of a cold retentive soil.

The soil of the North Riding of Yorkshire, along the coast, consists of brownish clay and loam; in many places coldly calcareous, partly from its nature, and partly from the exposed situation of the ground. Cleveland consists generally of a fertile clay, and of a red sandy soil. The vale of York consists of various soils; the upper parts are occupied by cool strong lands: in the eastern quarter, weak sandy heathlands are found; but, in general, the soil of the vale is a rich dry loam: the western part of this Riding is occupied by moorlands: though, in many of the dales, the soil is sharp and fertile. In the West Riding, the arable soils may be considered as comprehending all the varieties which prevail in Britain, but the prevailing description is loam; limestone land is also met with; and near the Ouse, strong tenacious clay: the western division of this Riding contains extensive moorlands. The wolds occupy a large part of the East Riding; the soil on them is calcareous, with a mixture of gravel: the district of Holderness, which occupies the other part of this Riding, consists, for the most part, of a strong loamy soil. The most prevalent soil in Westmoreland is a dry gravelly mould: in the east and north, sand and hazel mould are found; the subsoil in these districts is calcareous: towards the Eden and eastern mountains, clay is found: the tops of the mountains are in general covered with a dry soil, upon a hard blue rock.

In the district of England which borders on Wales, there is less diversity of soil than in the northern district. The county of Chester consists almost entirely of two descriptions of soil; sand, generally of a rich quality, lying on a substratum of red grit rock; and strong loam; the latter in some places is rather moist and retentive, but on the whole may be regarded as a valuable and useful soil; heaths are found intermixed with the loamy soil, but not to any considerable extent. The sandy soil unites with that of the same description in Lancashire, already noticed. In Shropshire there is nearly an equal quantity of strong and light soils; the former, however, is supposed rather to predominate: on the north-east of the Severn, the soil is light and dry; on the south-west of that river, as low as Cressage, and for eight miles down, a very great variety, and rapid succession of soils, occur: from this place, nearly to Ludlow, the soil, in general, is thin, and rather cold: the remainder of the county, especially on the south-west side of it, is mostly thin soil, some upon clay, some upon rock; upon the whole, there is in Shropshire nearly all descriptions of soil, except chalk and flint. There are few counties, in any part of England, which present such a large proportion of valuable and fertile
soil as Herefordshire: in its general character, it is a mixture of marl and clay, in which, at least in some places, the calcareous earth is very evident and predominant. There is no appearance of chalk or flint; but the tenacity of the clay, besides being reduced and anemiculated by the calcareous soil, is farther divided and softened by sand. In some parts of the county, however, particularly towards the west borders, the clay soil is cold and ungenial; the substratum here is lignitic, of a dark jet black kind; towards the east of Herefordshire, the soil also varies from its general character, being loose and shallow, and not of very great fertility or value. In the centre of the county, especially round the city of Hereford, gravelly soil, to a considerable depth, is met with. On the south, there is some sand, naturally of rather a good quality, and much improved by manure and cultivation. The richest tract of the strong clay soil, extends from Hereford towards Ledbury. In the county of Monmouth, there is much variety of soil, but generally of a good quality, and rather dry and light than moist and heavy: from Rumney Bridge to Newport, loam is found resting on rock, rubble, or clay; in the vale part of this tract, the loam is lighter, much intermixed with mud, and very fertile. Along the coast, from the Usk to Portskewit, the soil is also a rich loam, intermixed with mud and sand, and of a brownish or grey colour: the substratum in many parts is limestone: the proper clay district of Monmouthshire lies in the hundred of Usk: this species of soil is also met with in Raglan hundred: in both these hundred, the clay is occasionally of a great depth, but where not so, it lies on a bed of rubble. Round the town of Monmouth, the soil is various, partly clay, partly gravelly sand; the substratum rubble: the red soil, already frequently mentioned as possessing great fertility, and as stretching from Nottinghamshire into the west of England, is met with in a few spots of the hundred of Abergavenny. On the whole, the county of Monmouth possesses a valuable and fertile soil.

The soil of many of the counties which compose the midland district of England, especially that of Nottinghamshire, Leicestershire, Rutlandshire, and Northamptonshire, is more uniform and similar than that of any district in England of an equal size. The prevalent soils in these counties may be characterised as loam of different degrees of depth, strength, and fertility; but generally rather strong, dry, and sound. Although, however, this description applies generally to the soils of this district of England, there are exceptions to it. In the county of Nottingham, sandy soil is found in the forest district; rich light loam, lying on sand or gravel, stretches along the banks of the Trent; and there are two tracts of land, which are denominated the north and south clays, though perhaps they might be more strictly and justly called strong loams. The Vale of Belvoir is one of the best and fairest specimens of the soil of this county, being a loam of great fertility. That description of country called Wouls, prevails in some parts. The soil on them is generally a cold clay. The subsoil in many parts of Nottinghamshire is limestone; in other parts, sand and gravel; and in other parts again, the soil continues of the same nature and quality for a considerable depth. In Leicestershire, no clay or sand, strictly so called, are to be met with; nor is there any moss or peaty soil, the peat bogs, by draining, cultivation, and manure, having been rendered valuable meadow soil. The soil of Leicestershire, therefore, may be divided into three kinds: strong loam, lighter loam, and loam nearly of an equal strength as the first kind, but of a moister nature. The first description in general is found in the valleys. The characteristic of the upland soil is a reddish friable loam, lying on gravel, rock, or marl. The third description of soil occurs near the banks of the rivers, or in those places where the peat bogs have been drained and cultivated. The prevalent soil of Rutlandshire may be conjectured from the etymology of the name of the county, *riddle*, in many parts of England, being the common appellation of that red clay or loam, with which sheepers mark their sheep. This kind of soil, of a strong nature, is found extensively in Rutlandshire, especially in the centre of the county, and towards the northern and western borders. The soil in the east and south-east parts is mostly shallow, upon a limestone rock. The upland parts of Northamptonshire generally consist either of a brown or a red loam, more or less tenacious. The subsoil in these parts, for the most part, is stone in loose fragments, or what is usually called rubble. This stone is evidently calcareous, though in many places it is not pure enough to be burnt into lime. Besides this subsoil, the brown or red loam, in other parts of the county, rests on gravel and clay. In the north-west of Northamptonshire, the soil is thin and light, though the subsoils are still for the most part calcareous. The east of the county consists of fens; and in the vicinity of these fens, as well as in the meadow lands, fertile deep soil is very prevalent. On the whole, the soil of this county may be described as consisting of rich loam, which seldom changes either into clay or sand. Of the other counties, which, in geographical arrangement of England, we placed in the midland district, the same observation respecting soil will not hold good, which we have affirmed respecting the counties just mentioned. Derbyshire, however, at least the southern part of it, may perhaps be excepted. The most common soil in this part of the county, resembles the red soil so frequently noticed; but it is intermixed with tracts of sand and gravel. On the north-west side of the county, limestone soil is found of different qualities and degrees of fertility. On the east side, clay, generally tenacious, cold, and unfertile, abounds. The same description of soil predominates in the north of Derbyshire. Here also peat and moor soil is very prevalent. In Staffordshire, the soils most commonly met with, are peat in the northern parts, and loams of various degrees of strength and fertility in the central and southern parts. In the neighbourhood of Lichfield, there is much excellent soil. The lands which border on the Trent are also uncommonly fertile.

There are few counties in any part of England that display more unequivocal proofs of fertility of soil, even to those who are not accurately acquainted with the method of distinguishing it, than Worcestershire. Though it varies in its kind, its quality is almost uniformly good. To the north of Worcester, it consists chiefly of rich loamy sand. In the eastern quarter of the county, the prevailing soil is, for the most part, a strong clay, but not cold or ungenial. To the south, between Worcester and the Vale of Evesham, red land and strong loamy clay are found. In the vale itself, the soil is remarkably deep and rich, consisting of a dark coloured earth, in some parts so strong as to be fit for making bricks; and in other places of a more friable nature. The subsoil here is either gravel or strong clay; light sandy soils and gravel prevail chiefly near Kidderminster and Steurbridge. It is generally supposed that one half of the county consists of rich clay and loamy soils, with a substratum of limestone. The soil of the Cotswold
hills, in Gloucestershire, consists generally of a calcareous loam, mixed with gravel and small stones, which, in this and some other counties of England, is provisionally denominated stone brash. The soil on the Stroudwater hills is principally a light loam lying on stone brash. The vale districts of Gloucestershire possess in general a very rich soil, varying from clay of rather a strong quality, to friable loam. In the vale of Evesham, the soil for the most part is of the latter description, though occasionally sand and gravel are met with. The vale of Berkeley is more uniform in the nature and quality of its soil. In the Forest of Dean, which is separated from the rest of the county by the river Severn, the soil is rather strong, and by no means unfertile. On the whole, Gloucestershire possesses a large proportion of rich and valuable soil, and may be reckoned, in this respect, among the most favoured in England. The soil of Warwickshire is not nearly so uniformly good as that of the county just described. In the northern part of this county, there is much barren and waste land, intermixed, however, with large tracts of strong soil. The central and smaller portion of the county, which is called the Fielden, possesses a great fertility. Oxfordshire contains three distinctions of soil; the red land of the northern district, which extends from the borders of Warwickshire and Northamptonshire, to the south of Doddington. This soil, like all the rest of the same description, is very fertile. The substratum is either grit-stone or limestone. The next division of soil is the stone-brash, which lies to the south of the red land, and stretches the whole breadth of the county, from the borders of Gloucestershire to those of Buckinghamshire. It is, however, very narrow on the borders of the latter county. The predominant feature in this extensive tract is that of a loose, dry, friable loam, mixed with limestone, and in general resting upon it. The third division consists of the Chiltern district, lying in the south-east of the county, and bordering on Buckinghamshire. The basis of this part of Oxfordshire is chalk, on which there is a surface of loam, of various depths, and of different degrees of fertility. The most distinguishing mark of the surface loam, is a very considerable quantity of flints. Nearly, however, one half of this county, occupying the centre and part of the southern division of it, includes all sorts of soils from loose sand to heavy clay. The soil of the county of Buckingham is composed chiefly of rich loam, strong clay, chalk, and loam incumbent on gravel, and mixed with it. In the southern parts of this county are the Chiltern hills, which are principally composed of chalk intermixed with flints, similar to the chalk and flints of the adjoining part of Oxfordshire. The soil on these hills is very shallow; the substratum is uniformly chalk. In the northern part of Buckinghamshire, the soil is of a very different quality, being composed of strong rich loam, occasionally mixed with loam of a more friable nature. The vale of Aylesbury occupies the centre of the county, and in richness of loamy soil, is not surpassed by any vale district in the kingdom. The south of Bedfordshire consists of calcareous hills; below which there is a cold, barren, clayey soil. In a line from the middle of the county to the south-east corner, the soil is generally rich, composed of strong loam. The west side is mostly flat and sandy. The sands about Woburn are almost proverbial for their depth. They are not, however, by any means unfertile. The vale of Bedford consists of a rich loam. On the north side of the vale a strong clay occurs. Towards the north and north-eastern parts of the county, the richest soil is met with, consisting of loam of uncommon depth. The substrata most common in this county are limestone, ferruginous sand, and clay.

Of the counties which, in our geographical arrangement of England, were classed under the eastern district, the soil is not very various: this remark more particularly and strictly applies to Lincolnshire, Huntingdonshire, Cambridgeshire, Norfolk, Suffolk, and Essex. In Hertfordshire and Middlesex, there is greater variety of soil. Lincolnshire consists of calcareous, sandy, and loamy soils; the first description is principally found on the heaths to the north and south of the county, and on the wolds; a large tract of sandy soil occurs between Gainsborough and Newark; the same kind of soil is found from Binbrook to Barton; at the latter place, the rich loam commences, which occupies an extensive tract. A loam of an equal, if not superior quality, is found in the island of Axholme. The marsh lands of Lincolnshire are in general composed of loam, though there are some spots of cold tenacious clay. The soils in the upland parts of Huntingdonshire are various, but they consist principally of strong deep clay loam or less in friable chalk loam mixed with loam, or of a deep gravelly soil, with loam. The marshes resemble those of Lincolnshire: the same may be said of the marshes of Norfolk and Cambridgeshire. The soil of the uplands in this last county, also resembles that of Huntingdonshire, only it presents a smaller proportion of strong loam; and calcareous loam, which does not occur in Huntingdonshire, is met with in Cambridgeshire: the substratum is chalk, gravel, or clay. It has already been remarked, that the soil of Norfolk is the most uniform of any in the kingdom; it is, in fact, sandy loam throughout the whole county, though in some parts there is a small proportion of clay; in no part of this county, however, can there justly be said to be clayey soil. It may also be regarded as the most artificial soil in the kingdom. The richest soil lies to the north and north-east of Norwich; this tract consists of a true sandy loam, equal and similar to the best parts of the Netherlands. To the west and north-west of Norwich, the soil is much lighter; and to the south-west of this city, the soil is so very light, that the sand is very often drifted in high winds from one parish to another. Suffolk may be considered as consisting principally of light sand, and of very strong loam, which is sometimes, though improperly, called clay. The border prevails chiefly on the sea-coast, and in the north-west part of the county; the latter occupies the centre of the county; the strongest loam is in that part called High Suffolk. In Essex, there is very little sandy soil, and none which can properly be called clay, but loams of all descriptions prevail: the richest are in the north and north-eastern parts of the county. About Saffron Walden, the loams are rich, dry, and very fertile. Near the banks of the Thames, and along the sea-coast, marshy land prevails. The soils in Hertfordshire consist of loam, clay, chalk, and gravel: the loams may be divided into flinty and sandy; in some places they are of a red colour. The flinty loam lies to the east of the county: the richest sandy loam is near Cheshunt. Chalk occupies the north-west corner, and a small spot in the south, on the borders of Middlesex. In the north-east, from Royston to King’s Walden, is a chalky soil; the gravel is a very poor soil, and prevails near North Mins. Chalk forms the basis of nearly the whole county. In Middlesex, the summits of most of the highest hills consist of sand and gravel. Sandy loam is found on all
that part of the county which lies between the road leading from Hounslow to Colnbrook, on the north, and the Thames on the south; the subsoil here consists of flints and gravel: loam, with a smaller proportion of sand, occurs to the west of Hounslow, and in the parishes of Chelsea, Kensington, &c. Near Harrow, Pinner, and South Mims, on the borders of Hertfordshire, the soil is a strong loam: this soil also prevails in the northern vicinity of the metropolis. Clay occurs in very few places: near Howden, the soil is of this description. From Rickmansworth to Staines, peaty earth, on flinty gravel, prevails; the Isle of Dogs, and most of the ground on the borders of the sea and Coln, consist of a rich mud.

Of the south-eastern district.

The counties which compose the south-eastern district, are similar in the general features of their soil. In Kent, the Isle of Thanet is calcareous: the Isle of Sheppey a strong clay. In East Kent, chalk, loam, and stiff clay, are found: rich sandy loam occurs on the south-coast near Sandwich and Deal. Romney Marsh consists of loam of great fertility. The Weald of Kent, Surrey, and Sussex, has already been mentioned, as containing the greatest extent of clay soil in the kingdom. The richest loam in this county is near Maidstone: the substratum, through nearly the whole of it, is calcareous. The South Downs in Sussex are calcareous; the centre and north are occupied by the Weald: the eastern side of the sea-coast consists of a strong soil, inclining to be wet. The western side, especially near Chichester, contains loam of uncommon depth, and which may justly be reckoned among the most fertile soils in the kingdom. Besides the Weald of Surrey, this county consists of very rich sandy loam, near Guil- ford; of deep calcareous loam between Croydon and Epsom; of chalk on the Downs; and of rich sandy loam about Battersea, Mortlake, Moulsey, &c. Heaths occupy the south-west part of Surrey.

The southern district of England is composed of Berkshire, Wiltshire, Hampshire, and Dorsetshire; in all of which counties, calcareous soils are very predominant. In Berkshire, the most remarkable division is the vale of the White Horse, which is bounded on one side by the Thames, and on the other by the White Horse hills; it extends from Buscot to Streatham: the soil of this vale is a strong grey calcareous loam, evidently formed by vegetable earth and chalk. In the vale of the Kennet, the prevailing soil is gravel: in the forest division, there is gravel, clay, and loam; the last in the centre, and the two former in the southern parts. Through the middle of the lower part of the county, the chalky hills extend: the substratum of the whole of Berkshire is calcareous. Wiltshire, in respect to soil, as well as in respect to the face of the country, is naturally divided into two districts; the south and east parts are composed of chalk hills, which enter the county from Berkshire, Hampshire, and Dorsetshire; among these hills, however, there are valleys of loamy soil. The west and north parts of the county consist, for the most part, of very fertile loam, which stretches south-east and south-west, under the foot of the hills: this tract varies a little in its soil, as the ground rises in the north-west corner, where it joins the high land of Gloucestershire. Below the middle of the county, Salisbury Plain, which has been already noticed, begins: the soil is a light loam, naturally fertile. In Hampshire, the woodlands and wastes of Bagshot consist of clay, sand, gravel, and peat. The second division of soil stretches from Basingstoke to Winchester, and in breadth extends entirely across the county: in this tract, strong flinty loams and hazel-coloured mould or chalk, occasionally mixed with gravel, prevail: in most of the valleys, peat is found. From Bishops Waltham to Christchurch, light sand and gravelly loams generally compose the soil; clay and strong loams, or brick earth, are however occasionally met with: the substratum is argillaceous and calcareous marl: on the heath and low grounds, peat and turf prevail. For some miles round Portsmouth, the soil is a strong flinty loam, lying very near the chalk. The Isle of Wight contains principally three kinds of soil: on the north side it consists of rough strong clay, lying on chalk; in the middle downs, and on the south side, soils of different qualities and degrees of strength, but almost universally very fertile: some of these loams approach to the lightness of sand, but still retaining their fertility.

The south-western district of England comprises the counties of Somersetshire, Devonshire, and Cornwall. In Somersetshire, there is great variety of soils, as well as very different degrees of fertility: the north-east quarter is in general stony: towards the centre, there are fens and marshy moors of great extent: on the west are downs and open heaths. The low grounds of Somersetshire in general consist of loam; on the borders of Dorsetshire, a stone brash soil, of considerable fertility, prevails: perhaps the most fertile parts of this county, are the vale of Taunton, and the district round Bridgwater. The district of Dartmoor, in Devonshire, consists principally of peat; where it is not found, the soil is a thin black mould, lying on pale clay, intermixed with gravel: the vale of Exeter consists principally of red land, of great fertility: the same kind of soil, of an equal if not superior degree of fertility, is found in the district of South Hams: the subsoil here is a strong clay. In West Devonshire, the prevailing soil is cold clay, on a substratum of rubble. North Devon, in general, is not more distinguished for the romantic character of the prospects it affords, than for the goodness of its soil, except on the summit of the hills, where it is thin. In Cornwall three descriptions of soil predominate: the black granite or gravelly; the shelly or slaty; and the loams. The first, which prevails in the western parts of the county, consists of a light black earth, resembling moss in its appearance and qualities, intermixed with small particles of granite. The slaty soil, which is the most extensive, is formed of schistose matter, mixed with loam: and, when properly managed, is by no means unfertile: but of loams, strictly so called, there is but a very inconsiderable quantity in this county: these lie, for the most part, on the low grounds, declivities, and banks of the rivers. The hills, which run through the middle of Cornwall its whole length, consist of very poor soil in general.

With respect to Wales, both North and South, the soils in general afford so little variety, that it will not be necessary to describe them minutely and particularly. In the vales and low grounds, they consist, for the most part, of loams of different degrees of fertility and strength. Some of the vales, especially in North Wales, may vie, in natural richness, with the most favoured districts of England. The sea-coast of some parts of South Wales consists of a sandy loam, which, from the moistness of the climate, is often very productive: the soil of the mountains is frequently thin and cold; but in some places dry and sound.
From this description of the soil of England, though necessarily brief and general, it will be sufficiently apparent that it is suited to almost every variety of produce; though, at the same time, much of it is naturally of such a quality and description, that without skill, labour, and capital, it would but ill repay the agriculturist, and but scantily supply the wants of the inhabitants. The soil of a country, however, ought always to be considered in reference to its climate: we have seen that the climate of England differs very considerably in different parts of the country; in some parts, it is so moist, as to point out the advantage, or the necessity, if the soil were of a proper description, of pasture; in other parts, it is comparatively so dry, as to be well suited to arable husbandry. The soil, also, varies in the same manner; in some districts, though midsted with soils of a different quality, it is evidently better fitted for grass than for the plough; while, in other parts of England, both the soil and the climate point out the advantage of arable husbandry. When we come to treat of the agriculture of this kingdom, we shall observe in what manner, and to what extent, these circumstances have been attended to and improved.

CHAP. V.

Natural History.

Our account of England would be imperfect, if it passed over its natural history; and yet our limits will not admit of a regular and complete treatise on that subject; we must therefore adopt a middle course, so as to give a clear idea of the natural history of this country, without pretending or endeavouring to give a full and regular account of it. The natural history of a country comprehends its Zoology, Ornithology, Amphibiology, Ichthyology, Entomology, and Helminthology, or what, in the more strict and limited sense of the term, is called Natural History. The species in the two last of these divisions are so numerous, that we shall content ourselves with noting the number contained under each genus that are found in England, and with particularizing only the most remarkable: For the CONCHOLOGY of England, we may refer to that article. In Botany, also, which forms the next division of Natural History, taken in its most comprehensive sense, we shall confine ourselves to a general description of the most remarkable vegetables found in England; referring such of our readers as wish to learn particularly what plants under each genus flourish here, to the article BOTANY.

The last division of our account of the Natural History of England, will embrace its Mineralogy, which will naturally lead to the consideration of its Geology.

Sect. I. Zoology.

Primates.

In the class Mammalia, and order Primates, the only genus that is found in England is Vespretilia, the bat. Of this we have four species: V. auritus, eared bat. V. murinus, common bat. V. noctula, great bat; and V. ferrum equinum, the tailed bat. The first is the most common of the English species; the third is the largest; the fourth is very rarely found here. Of the genus Phoca, belonging to the next order Ferae, we have two species: P. vitulina, sea-calf, or common seal; and P. barbata, great seal. The last, however, is very seldom seen on the English coasts, confining itself generally to the northern coasts of Scotland. Of the genus Canis, and species C. familiaris, there are several varieties in England; the most noted are the mastiff, bull-dog, and the different breeds adapted to the chase. C. vulpus; there are three varieties of the fox in England: the greyhound fox is the largest, tallest, and boldest; he will sometimes attack a fully grown sheep: the mastiff fox is not quite so high, but he is stronger built, and more heavy in his appearance: the least and most common of our species is the cur fox. Of the genus Felis, we have F. catus; the variety of this, which is wild, is still found in some of our woods, particularly in the county of Northampton, and is one of our most destructive beasts of prey. Of the genus Mustela, the M. lutra, or common otter, is very frequently met with in all parts of England: of the martin, we have two species, or perhaps only varieties, Mustela foenis, and Mustela martes, the common, and the pine martin; the former is more frequent found in this island, and is, of all the English beasts of prey, the most beautiful and courageous. Of this genus there are also found here M. putorius, the foumart; and M. vulgaris, the common weasel. Of the genus Ursus, the U. arctos, or common bear, is supposed to have been formerly native here: but if this opinion is correct, it must have been at a very remote period. U. meles, the badger, is too often the sport of the thoughtless or the savage part of the community. Genus Talpa, T. europea, common mole. Genus Sorex, S. fodien, the water shrew: this species is by no means common with us. S. araneus, common shrew. Genus Erinaceus, E. europaeus, hedgehog.

Of the order Glires, the first genus that is found in England is My<sub>r</sub>us: of this we have M. rattus, black rat; M. decumanus, brown rat; M. musculus, common mouse; M. sylvaticus, field mouse; M. amphibius, water rat. Of the genus <em>Sciurus</em>, S. vulgaris, common squirrel. Of the genus <em>Myapus</em>, M. muscardinus, common dormouse; in many parts of England, this little animal is called the sleeper. Of the genus <em>Lepus</em>, L. timidus, common hare; L. cuniculus, rabbit; this last will be noticed under the head Agriculture of England.

Of the order Pecora, the first genus we possess is <em>Pecora</em>. Cervus: C. elaphus, the stag, in its natural state, is very rare in England, but there are still a few remaining on the borders of the county of Cornwall. The usual colour of the English stag is a dusky red; but Buffon says the most common colour of the stag is yellow. C. dama, the fallow deer. There are two kinds of fallow deer in this country, said to be of foreign original; the beautiful dappled, originally imported from India; and the fine dark brown, introduced by James I. from Norway. Of the genus <em>Capa</em>, C. agrarius, the common goat. Mr Pennant remarks that the goats of Wales are commonly white, and far superior in strength, size, and fineness of hair, to those of other mountainous regions; their horns are likewise much longer and thicker at the base. The haunches of these animals are frequently salted and dried, and used as a substitute for bacon. The genera <em>Ovis</em> and <em>Bos</em> will be treated of under the division Agriculture in this article. With respect to the latter, we shall merely remark in this place, that the indigenous horned cattle of this island are now only known to exist in Needwood Forest in Staffordshire, and at Chillingham Castle in Northumberland. They are long-legged,
705

**Ornithology.**

Order Cetæ. Genus Balana: B. mysticetus, the common whale, is sometimes found as far south as the coasts of England. Genus Delphinus: D. phocaena, the porpus; and D. orca, the grampus.

C. coroni, the carrion crow. C. frugilegus, the rook: this bird remains in England during the whole year, whereas in France they migrate. C. monedula, the jack daw: in Hampshire, where there are few towers or steeple, (in which these birds delight to build), they have been known to occupy rabbit-holes. C. glandarius, the jay: this is one of the most beautiful of the English birds. C. pica, the magpie. C. craculus, the Cornish chough: besides Cornwall, in which it is very common, and from which it takes its name, this bird is found in North Wales, inhabiting the cliffs and ruinous castles: a few are found on Dover Cliff, where a pair, sent from Cornwall, escaped, and have since stocked the spot, but do not appear much attached to it. The Corvus corax occasionally visits England. Genus Corvus: C. carrulus, the rook: this bird has been shot in England, but is only an occasional visitor. Genus Oriola: O. galbula, golden oriole, sometimes accidentally appears in this country. Genus Cuculus: C. canorus, the cuckoo: it is not ascertained whether this bird migrates from England or not. Genus Vulpes: Y. torquilla, the wryneck: it derives its English name from its often turning about its head. Genus Picus: P. viridis, green woodpecker. P. medius, middle spotted woodpecker. P. minvors, lesser spotted woodpecker: this species is not nearly so frequently met with in England as the others. Genus Sitta: S. europaea, European nuthatch. Genus Alcedo: A. isipida, the common kingfisher: this bird migrates from England. Genus Uropygs: U. epops, hoopoe: this species does not breed here, nor does it visit us at stated times. Genus Certhia: C. familiaris, the creeper: this is the least of our birds, except the crested wren.

Order Anseres. Genus Anas. A. cygnus, the wild swan. A. olor, the tame swan: this bird is the principal ornament of the artificial waters: it is of the nobility and gentry; and they are seen in great plenty on the Thames, where they are royal property: it is felony to steal their eggs. In the reign of Edward IV, whoever did not possess a freehold of the clear annual value of five marks, was prohibited from keeping a swan. Formerly, there was a noble swannery at Abbotbury in Dorsetshire, but the collection is now much diminished. A. tadorna, the sheldrake. A. nigra, the scoter: in very severe weather; during winter, this bird is sometimes seen on the English coast. A. albinon, white-fronted goose: this species visits the fens and other parts of England, during winter, in small flocks: none are seen after the middle of March. A. anser, the wild goose. The domestic goose will be considered when we come to treat of the agriculture of England. A. segetum, the bean goose: this bird migrates to England in autumn, from the Hebrides, where it breeds. A. moschata, Muscovy duck: this bird, a native of the Brazils, (and not of Muscovy, as has been supposed), would seem to indicate, if domesticated in this country. A. clypeata, the shoveller, remains with us all the year. A. rubens, the red-breast shoveller, is an uncommon bird even in Lincolnshire, where all the species of this genus abound. A. strepera, the gadwall, or gray. A. clangula, the golden eye. A. glandarius, the morillon. This species is seldom seen except on the sea coast. A. glacianus, bimaculated duck. This bird is not common

and wild, like deer; of a pure white colour, with black muzzles, ears, and tails, and a stripe of the same hue along the back.

Of the order Bellæae, the genus Egnus will be afterwards treated of; and also the genus Sus. The wild boar was formerly a native of our country, as appears from the laws of Hoel Dha, the Welsh legislator, who permitted his grand huntsman to chase that animal from the middle of November to the beginning of December. William the Conqueror subjected to the loss of their eyes those who were convicted of killing a wild boar in his forests. It is not exactly known at what period this animal became extinct in England.

Order Cetæ. Genus Balana: B. mysticetus, the common whale, is sometimes found as far south as the coasts of England. Genus Delphinus: D. phocaena, the porpus; and D. orca, the grampus.
in England. A. penelope, the pigeon, migrates from England to the north for the purpose of breeding, and returns in November; it is sometimes domesticated. A. acuta, the pin-tailed. A. ferroginea, ferrugineous duck; this is a rare bird in England. A. glacialis, the long-tailed duck, is only a transient visitor here. A. ferina, the pochard; this bird is very common in the poultry shops in London, where they are called dun-birds. A. querquedula: The garrancy continues in England only during the summer months, after which it migrates southward. A. crecca, the teal; birds of this species are common in the London markets. A. domesticus, the same duck, will be properly considered under the agriculture of England. A. boschas, wild duck, is taken in great numbers in the fens of Lincolnshire. A. fuligula, tufted duck.

Genus Mergus. M. merganser, the goosander. M. minutus, the rough diver; this bird is seen only in the north of England, and there only during the winter.

Genus Alya. A. arctica, the puffin; this bird is seen on the shores of the north of England, about the middle of April, for the purpose of breeding. A. torda, the razorbill, breeds in some parts of this country, but more commonly prefers the western isles of Scotland.

Genus Procelaria. P. pelagica, the stormy petrel; and P. puffinus, the shearwater, are occasionally seen off the coasts of England.

Genus Pelicanus. P. carbo, the cormorant; this bird is not uncommon round the high rocks of the Isle of Wight, where the sailors give the name of the Isle of Wight Parsons; it was formerly domesticated in this country, and trained to fish for the service of its master. Even so late as the reign of Charles I. it appears that there was an officer of the royal household, entitled master of the cormorants. P. bassanus, the gannett, or solan goose; this bird, in following its prey, is sometimes seen as far south on our coasts as Cornwall.

Genus Colymba. C. grylle; the spotted guillemot; this bird, common off the coast of Scotland, is sometimes seen off the shores of England. C. septentrionalis, the red-throated diver, is never seen, except in the hardest winters. C. stellatus, speckled diver; while the stints are in the Thames, this bird accompanies them, from which circumstance they are called spat-loons. C. cristatus, the crested grebe, breeds in the fenny districts of Lincolnshire, &c. C. auritus, the curred grebe, or dochick, also breeds in this country, though its regular abode is in the lakes of the north of Europe. C. obscurus: dusky grebe, like most others of this genus, is met with in great numbers in the fens, where it breeds. C. urinatix, greater dochick, or loon, is not a common bird in England.

Genus Larus. L. tridactylus, the tarrock; L. hybrimus, the winter gull; L. canus, the common gull; L. cinerarius, the legged gull; L. erythropus, the brown-headed gull, breeds not only in the fens of Lincolnshire, but also near the mouths of rivers, in other parts of England. L. fuscus, the herring gull; L. ridibundus, the black-headed gull; this species breeds in great numbers in the pools and fens of this country.

Genus Sterna. S. hirundo, the sea-swallow; S. minuta, the lesser sea-swallow; S. stellata, the black tern, abounds in the fens and in fresh water lakes.

Order GALE. Genus Ardea. A. grus, the common heron; the black crane, often visits England, and is sometimes seen in vast flocks in the fens of Lincolnshire and Cambridgeshire. A. cicinina, the common stork; A. major, the common heron. Heronries are yet met with in some parts of this country, though they are not nearly so numerous, or so carefully attended to, as they formerly were. A. stellarius, the bittern, about the time of Henry VIII. this bird was esteemed a delicious dish at the tables of the great. A. alba, the white heron, is not common in this country. A. minutus, the little bittern; this also is a rare bird.

Genus Scolopax. S. arctica, the common curlew, is very frequent on our sea coasts, and on the fens during the winter season. S. phaeopus, the whimbrel, is not nearly so common here as the former species. S. rusticola, the woodcock; these birds begin to appear in England early in October, but the great body do not arrive till November or December, when they disperse themselves over the country; towards the middle of March, they may be observed to be preparing themselves for their departure to their breeding places, coming down to the sea coasts; as soon as the wind is favourable, they leave this country, but a few sometimes remain behind and breed here; from the progress of cultivation, they are observed to be becoming gradually more scarce in England. S. major, the great snipe, is a rare bird in England. S. gallinago, the snipe; S. galinula, the jack-snipe, is much less frequent here than the former. S. pusilla, the dunlin, is common on the coasts of Yorkshire, but seldom met with elsewhere. S. glottis, the greenshank, appears in the winter time, in small flocks. S. calidris, the red-shank, is common in the fens of Lincolnshire. S. totanus, the spotted snipe, is a rare bird; as are also S. limosus, the stoneplover; and S. lapponica, the red godwit. S. neogoepepha, the common godwit, appears in the month of September on the coasts of Lincolnshire, in small flocks; they are taken in the fens and fattened, when they sell for five shillings a piece. S. canescens, the cinerous godwit, is also common in Lincolnshire. S. cantabricensis, the Cambridgeshire godwit, is generally met with in the vicinity of the town from which it takes its name.

Genus Tringa. T. pugnax, the ruff; these birds appear every spring in the fens of Lincolnshire, and other places of the north of England, where they make a considerable article of commerce. Above six dozen have been caught in a morning in one net; and a fowler has been known to obtain, for his own share, 40 or 50 dozen in a season. They leave this country about Michaelmas. T. vanellus, the lapwing; T. gambetta, the gambit, is a very rare bird, but it has been occasionally shot on the coast of Lincolnshire. T. maculata, the spotted sand-piper, is a bird of passage, and very seldom seen here. T. cinerea, the ash-coloured sand-piper: these birds appear on the coasts of this kingdom, in winter, in large flocks. T. lobata, the grey phalarope, and T. hyperborea, the red phalarope, are seldom seen on the coasts; the same is the case with respect to T. ochropus, the green sand-piper. T. hypoleucus, the common sand-piper. T. canutus, the knot; these birds are said to derive their name from King Canute, who was fond of them at table; they are taken in great numbers on the coast, and fattened in the same manner as the ruffs, to which they are preferred by many people. T. cinclus, the purtie; this species comes in very large flocks on the sea coasts during winter, and leaves this country in spring. T. pusilla, the little sand-piper. T. squatarola, the grey sand-piper, is not very common. T. islandica,
the red sand-piper; these birds sometimes appear in vast numbers off the coast of Essex.

Genus Charadrius. C. hiaticula, the ringed plover, frequents our shores in the summer. C. morinellus, the dotterel. C. pluvialis, the golden plover, is met with but in small flocks, on our moors and heaths, in the winter. C. calidris, the sanderling, is most common on the coast of Cornwall. C. oedicnemus, the stone curlew. C. himantopus, the long-legged plover, is a very rare bird in England.

Genus Recurvirostra. R. avocetta, the avocet, breeds on the shores of France, and during winter make their appearance in this county.

Genus Hematopus. The only species of this genus, H. ostralegus, is frequent on most of the shores of England.

Genus Pudica. F. chloropus, common water hen. F. atra, common coot. F. aterrima, greater coot.

Genus Rallus. R. crex, the rail, is a migratory bird; it begins to be heard about the middle of March, and continues its cry during the breeding season. R. aquaticus, the water rail. R. porzana, the spotted rail.

Order Gallinae. Genus Otis. O. tarda, the bustard, is not nearly so common in England as it was formerly; it is sometimes seen in the open country, near Dorchester; on Salisbury plain; near Newmarket; and on the wolds of Yorkshire. O. tetras, the little bustard.

Genus Pavo. P. cristatus, the peacock; and Genus Melanopsis: M. galloppavo, the turkey, are domesticated in England.

Genus Phasianus. P. Gallus, the cock, will be noticed, when we treat of the agriculture of this country. P. colchicus, the pheasant. F. pictus, the golden pheasant; birds of this species are common in most parts of England, particularly in the county of Norfolk; the female will sometimes hatch her eggs in the woods of this county, if undisturbed by the male; but the pheasant can scarcely be said to have been found in a state of nature in England, most of the birds being brought up in confinement, the eggs hatched under domestic fowls, and the young at a proper age set at liberty. If it were not for this method of rearing and preserving them, it is probable the breed would soon become extinct.

Genus Tetrao. T. tetrix, the black cock, is found in particular parts of the New Forest, in Hampshire, where it is preserved as royal game, and in Wales. T. lagopus, the ptarmigan, is sometimes, but very rarely met with, on the lofty hills of Wales and Cumberland. T. attaggen, the red grouse, is not uncommon in the heathy and mountainous parts of England; in Wales it is more plentiful. T. perdix, the partridge: it is observed that this bird follows cultivation, so that it is found on the inclosed common lands, where it was not wont to make its appearance. T. coturnix, the quail, though this bird is more extensively diffused than the partridge, it is not nearly so common in this country: it is a bird of passage, making its appearance here early in spring.

Order Passerinae. Genus Columba. C. oenas, the common pigeon: this is the parent stock from which C. domestica, the domestic pigeon, is derived; C. palumbus, the ringdove, this is the largest of the species in this country. C. turtur, the turtle dove, this is a bird of passage, arriving in England late in the spring, and departing about the latter end of August; in no county are they so common and numerous as in Kent, where they are sometimes seen in flocks of 20 or more; they frequent the pea fields, in which they commit great depredations.

Genus Alauda. A. arvensis, the sky-lark: about Christmas, immense numbers of this bird are taken and brought to the London markets; as many as 4000 dozen have been caught in the vicinity of Dunstable alone, between September and February. A. pratensis, the tit-lark. A. minor, the lesser field lark. A. arbores, the woodlark, is not common here. A. rubra, the red lark, is common in the neighbourhood of London, but seems to be rare in other places. A. trivialis, the grasshopper lark. A. nemorosa, the lesser-crested lark, is common in Yorkshire.

Genus Sturnus. S. vulgaris, the starling: in the fens of Lincolnshire, myriads of these birds collect, and break down the reeds with their weight. S. cinclus, the water ouzel.

Genus Turdus. T. viscivorus, the missel thrush: this bird, which in Hampshire has received the appellation of the storm cock, from its perching on lofty trees, and beginning its note a little before the new year, is the largest of our songsters. T. pilaris, the fieldfare, does not breed in England: it comes about the end of September, and leaves us about the middle of March. In Hampshire, a singular habit of this bird has been observed; it appears there generally about the 30th of September, and departs after a fortnight's stay. On its return it comes to the same place about the middle of April, and stays a week. T. ilinus, the red-wing, appears in this country a few days before the fieldfare. T. muscius, the thrush, is one of the finest of our song birds, and continues longest in song. T. rosnes, the rose ouzel; this bird is rarely met with in England; there are, however, a few instances of its being found. T. merula, the blackbird. T. torquatus, the ring ouzel, migrates in England, but in Wales continues the whole year.

Genus Ampelis. A. Garrulus, the Bohemian chaffinch, is seldom seen farther to the south in this country, than Northumberland and Durham: in the year 1791, several were taken in these counties, as early as the month of November.

Genus Loxia. L. curvirostris, the cross-bill. L. cothraustus, the cross-beak. L. enucleator, the pine cross-beak. L. pyrrhula, the bullfinch. L. chloris, the greenfinch: the two last species are tamed and domesticated.

Genus Emberiza. E. nivalis, the snow-bunting. E. montana, the mountain bunting, is found in Yorkshire and Northamptonshire, but is not common. E. citrinella, the yellow hammer. E. schenicius, the red sparrow. E. chloroccephala, the green-headed bunting, is a very uncommon bird, having been only once or twice taken in the vicinity of the metropolis.

Genus Fringilla. F. celebene, the chiffinch. F. carduelis, the goldfinch. F. canaria, the canary bird, was brought to England from the Canary Islands, about the beginning of the 16th century. F. spinus, the siskin. F. cannabina, the greater red pole. F. linota, the linnet. F. linaria, the lesser red pole. F. domestica, the sparrow. F. montana, the mountain sparrow.

Genus Muscicapa. M. tristripilla, the pied fly-catcher, is sometimes, but very rarely seen here. M. grisa, the spotted fly-catcher, breeds in England, but migrates in August.

Genus Motacilla. M. lucina, the nightingale, visits England in the beginning of April, and leaves it in August. It is not found to the north of the middle of
Yorkshire, nor in the south-western counties. M. modularis, the hedge sparrow; M. hippoclae, the petty-chap; M. salicaria, the red sparrow; M. sylvia, the white-throat; M. provincialis, the Dartford warbler, as its name imports, is almost confined to the neighbourhood of Dartford in Kent. M. alba, the white wagtail; M. flavus, the yellow wagtail. In the north of England it migrates, but remains in Hampshire during the whole year. M. oenanthe, the wheat ear, is taken in great numbers, in July and August, on the South Downs, the isle of Portland, and on the hills of Surry and Hampshire. M. rubetra, the wheatear, remains the whole year in the southern counties of England. M. ruricola, the stonechat; M. atracapaillla, the black cap; M. phanerius, the red start; M. arundinacae, the red wren, has been seen in few places except the vicinity of Uxbridge. M. rubecula, the redbreast; M. troglodytes, the wren; M. regulus, the golden crested wren, is the least of our birds. M. trochilus, the yellow wren; M. barula, the grey wagtail.

Genus Parus. P. major, the great titmouse, or oxeeye; P. ceruleus, the blue titmouse; P. ater, the cole mouse; P. palustris, the marsh titmouse; P. caudatus, the long-tailed titmouse; P. biarmicus, the beard-titmouse.

Genus Hirundo. H. rustica, the chimney swallow, appears in March or April, and retires in September or the beginning of October. H. urbica, the martin, the "temple haunting martlet" of Shakespeare, comes and stays later than the preceding species. H. riparia, the sand martin; H. apus, the swift, is the largest of our swallows; it comes in May and departs before the middle of August.

Genus Caprimulgus. C. europaeus, the goat-sucker; this is the only bird of this genus that inhabits England.

Amphibiology.

Order REPTILIA. Genus Rana. R. bufo, the common toad; R. rubeta, the natter jack; R. temporaria, the common frog.

Genus Lacerta. L. palustris, the warty lizard; L. aquatica, the water lizard; L. agilis, the nimble lizard; L. vulgaris, the common lizard; L. aurata, the gilded lizard, is found only in Jersey.

Order SERPENTES. Genus Coluber. C. borus, the viper, is the only poisonous animal in this country; C. prester, the black viper; C. natrix, the ringed snake, is the largest of the species found here.

Genus Anguis. A. cryx, the blue-bellied snake; A. fragilis, the blind worm.

Order NAYNTS. Genus Tetrodon. T. mola, the short sunfish, is taken on the western coasts of England; Borlase speaks of one caught near Plymouth, that weighed nearly 500 pounds.

Genus Synagathus. S. typhle, the shorter pipe-fish; S. acus, the longer pipe-fish; S. opilio, the little pipe-fish.

Genus Cyclopterus. C. cornuicenisi, the Jura sucker, inhabits the seas off Cornwall; C. bimaculatus, bimaculated sucker, is found off Weymouth.

Genus Lophius. L. piscatorius, the toad-fish.

Genus Aeppenaeus. A. sturio, the sturgeon, is sometimes found in our larger rivers. It is accounted a royal fish.

Genus Squatius. S. anguila, the greater dog-fish; S. catulus, the lesser dog-fish; S. galeus, the tope; S. mustelus, the smooth hound; S. vulpes, the sea fox, is found on the coast of Cornwall. S. galeus, the blue shark; S. cornutus, the Porbeagle shark; S. maximus, the basking shark; S. carcharias, the white shark. These sharks, especially the last species, are not often seen in our seas. S. acanthias, the piked dog fish; S. spinax, the lesser piked dog fish; S. aequana, the angel fish, on our coast, is frequently caught of the weight of 100 pounds.

Genus Raia. R. torpedo; the torpedo has been occasionally taken in Torbay. R. batis, the skate; R. oxyrinchus, the sharp-nosed ray; R. fullonica, the white horse; R. pastinaca, the sting ray; R. clavata, the thornback.

Genus Petromyzon. P. marinus, the lamprey; P. fluviatilis, the lesser lamprey; P. branchialis, the pride.

Ichthyoology.

Order APODES. Genus Murana. M. ophius, the sea serpent; M. anguilla, the eel; M. conger, the conger eel.

Genus Anarchichas. A. lupus, the sea wolf, is eaten sometimes by the English fishermen.

Genus Ammodites. A. tobias, the sand eel.

Genus Ophidium. O. imberbe, the beardless opilio, is taken near Weymouth.

Genus Xiphius. X. gladius, the sword fish, sometimes appears on our coasts.

Genus Leptocephalus. L. mori, the morris launce, has seldom been seen, except in the sea near Holyhead.

Order JUGULARES. Genus Callionymus. C. lyra, the Jegulares; gommmeous dragonet; C. dranumus, the sordid dragonet.

Genus Gadus. G. anguiss, the haddock; G. morius, the cod; G. luscus, the bib; G. barbatu, the whiting-pout; G. minutus, the poor; G. merlangus, the whiting; G. carbonarius, the coal-fish. G. pollichius, the pollack; G. merluccius, the hake; G. molva, the ling; G. lota, the burbot; G. mustela, the five-bearded cod.

Genus Blemius. B. gallerita, the crested blenny; B. pholis, the hake, is found on the coast of Cornwall; B. pholis, the smooth blenny; B. gunellus, the spotted blenny; B. viviparous, viviparous blenny.

Order THORACICII. Genus Gobius. G. niger, the Thoracici; miller's thumb.

Genus Cotius. C. cataphractus, the pogge; C. scorpius, the father lasher; C. gobio, the bullhead.

Genus Zeus. Z. faber, the doree, is met with principally off the coasts of Devonshire and Cornwall. From its hideous appearance, it is said, that it was not introduced to English tables, till Quin, the epicure and coo-median, introduced it. Since his time, it has been esteemed one of the greatest delicacies. Z. luna, the ophid, has been sometimes thrown on the coast of England. One was taken near Newcastle in 1767; and another, weighing 140 lbs. was caught at Brexham, near Torbay.

Genus Pleuronectes: P. hippoglossus, the holibut; P. platessa, the plaice; P. flesus, the flounder; P. lindara, the dab; P. solea, the sole; P. rhomboides, the-kit, or smear dab, is found on the coast of Cornwall; P. rhombus, the pearl; P. maximus, the turbot.

Genus Sparus: S. auratus, the gilthead; S. pagrus, the red gilthead; S. dentatus, the toothed gilthead, is seldom met with; one was left by the tide, and taken in the mouth of the Terees.

Genus Labrus: L. tinca, the wrasse; L. bimaculatus, bimaculated wrasse: this species is found off the coast of Cornwall; L. trimaculate, the trimaculated wrasse, is found off Anglesey; as are also the next
species, L. variegatus, the stripped wrasse, and L. gibbus, the gibbus wrasse: the three next species are most commonly met with off the Cornish coast, L. cornubius, the goldfinny; L. comber, the comber; and L. coquus, the cook.

**Genus Percus**: P. fluviatilis, the perch; P. puncta, the basse; P. marina, the sea perch; P. cernua, the ruffe; P. nigra, the black fish, is found in the rivers in Cornwall.

**Genus Gasterosteus**: G. aculeatus, the bar stickle, is found in such abundance in the fens and rivers in Lincolnshire, that, according to Pennant, a man earned four shillings a day, by taking and selling them to the farmers for manure, at a halfpenny a bushel; they make their appearance off this coast only once in seven or eight years; G. doctor, the pilot fish, very rarely comes near our coasts, but is sometimes seen in our seas, at a considerable distance from land; G. pungitius, the lesser stickleback; G. spinicauda, the larger stickleback.

**Genus Scophus**: S. scomber, the mackerel. An economical account of this, and other fish caught in the rivers and off the coasts, will be given, when we come to treat of the English fisheries; at present, we shall merely mention a fact connected with its natural history: Pennant mentions an instance of one taken on the English coast, that weighed five pounds. S. thymus, the albicore; S. trachurus, the scad.

**Genus Mullus**: M. barbatulus, the red mullet; M. surmuletus, the striped mullet.

**Genus Triola**: T. lyra, the pipe; T. gurnardus, the grey gurnard. This fish seems to grow to a larger size in the English seas than elsewhere, as here it has been caught from two to three feet long, whereas in the Baltic it is seldom more than a foot and a half. T. cuculus, the red gurnard; T. hilarudo, the tub-fish; T. iliceta, the streaked gurnard, is met with off the coast of Cornwall.

**Order Abdominales**: Genus Cobitis: C. barbatula, the loche; C. taenia, the armed loche.

**Genus Salmo**: S. salax, the salmon, has been taken in England of the weight of 74 pounds; S. eriotha, the grey; S. trutta, the sea trout; S. Fario, the common trout; S. carpio, the gill char; S. alpinus, the char, is found in the lakes of Cumberland; S. eperlanus, the smolt, or spraling; S. lavaretus, the gudgin, is found in the lakes of Cumberland and Wales; S. albula, the juvansis, is said to have been carried from England into Scotland by Robert Bruce; S. thymus, the albicore, the scad.

**Genus Esox**: E. osseus, the great gar-fish, is taken off the coast of Sussex; E. lucius, the pike; E. belone, the sea pike; E. saurus, the saury. In Cornwall, where this fish abounds, it is called the skipper.

**Genus Argentina**: A. sphyraena, the argentine, has been found in our seas, but is very rare.

**Genus Clupea**: C. harengus, the herring. According to Pennant, there is sometimes taken near Yarmouth, a herring, distinguished by a black spot above the nose, which has been seen of the great length of 214 inches. C. sprattus, the sprat; C. alosa, the shad.

**Genus Cyprinus**: C. barbus, the barbel; C. carpio, the carp. According to Fuller, this fish was introduced into England, in 1514, by Leonard Mascali. C. gobio, the gudgeon; C. tinca, the tench; C. auratus, the gold fish; this fish was introduced into England about the year 1691, but was not generally known till 1728, when a great number were brought from China, and presented to Sir Matthew Decker, by whom they were distributed in the vicinity of the metropolis. C. poecilius, the minnow; C. leuciscus, the dace; C. rutilus, the roach; C. brama, the bream.

**Entomology**

**Order Coleoptera**: Genus Searabes: Of the 433 Coleoptera, species of which this genus consists, upwards of 30 are natives of England. The Searabes auratus, golden beetle, is considered one of our most beautiful insects. Searabes fasciatus is rare in England.

**Genus Lucanus**: L. cervus, the stag beetle, is the largest of the order Coleoptera found in this country. It is very common in Kent and Sussex.

**Genus Dermestes**: Of this we have six species.

**Genus Bostrichus**: B. piniperda often commits great devastation on the bark of elms in England. There are four species of this genus; and the same number of the genus *Pius*, and of the genus *Hister*. Genus *Cyrtinus*, G. Natator. Genus *Byrrhus*, B. pilula, and B. varius. Genus *Annulatus*, A. scrophulari, and Verbacis. Of the genus *Silpha* there are twelve species, of the *Nithidia* five, and the same number of the genus *Cassida*. Of the 150 known species of the *Coccinella*, 17 are very common. Of the genus *Chrysomela*, C. Banksii is a rare insect here, but is found in the month of May on a thistle: Besides this, we possess upwards of 30 other species. Nearly 20 species of the genus *Cryptoleon*, which was formerly arranged as Chrysomela, are met with. We have only one species of the *Bruchus*, B. sebroosus. Of the genus *Carcelia* there are upwards of 60 species, four of the *Atelabus*, two of the *Notocerus*. Of the *Cerambyx*, very few are natives; C. coriarius is the largest species. C. violaceus is very rare, and is supposed to have been introduced from Germany. Of the *Leptura* there are six species, of the *Neudalas* three. Of the *Lampyris*, only two species are caught here, and they are by no means common even in the south of England. We have one species of the *Horia*, 11 of the *Cantaria*, 13 of the *Elatia*, four of the *Cicindela*. The C. aquatica is the least of our species. Very few of the numerous genus *Buprestis* are natives of England, only eight having been found. There are four of the *Hydrophilus*, 12 of the *Dytiscus*. Amongst the species of the *Carabus*, or ground beetle, are found some of our largest insects: We possess 26 species of it; two of the *Tenebrio*, five of the *Pimela*; only one of the *Lyta*, L. nuditula; two of the *Meligus*; M. tecta is found in Epping Forest, in July; five of *Mordella*; 15 of *Staphylinus*; two of *Farctica*; F. minor, however, is not common.

**Order Hemiptera**: In this, and the remaining orders, we must content ourselves with specifying the genera found in England, with occasional notices of the more remarkable species: *Blatta*, *Gryllus*, *Fulgora*, *F. Europea*, very rare; *Cicada*, C. sanguinolenta, found on the chalky and sandy soils near Dartford, the most beautiful of our Cident; *Notoceles*, *Nepa*, *Cimex*, *C. rectangula*, the common bug, was not known before the beginning of the 17th century; *C. festivus* is not common; *Aphis*, *Chermes*, *Coccus*, *Thrips*.

**Order Lepidoptera**: Genus *Papilio*: Of the 877 Lepidoptera, species, we possess nearly 70. P. machon, the swallow tail, is found in great numbers in the meadows near Bristol. P. hero is very abundant in the marshy parts of Lancashire, near Manchester. P. populi and P. antiope are not common. The rarest of our species are P. si-billa and P. camilla; the largest, P. paphia. Genus
ENGLAND.

Species. Of this we have 20 species; S. aurota, the Jasmine hawk moth, is the largest; S. celerio, S. fueiformis, S. zonata, and S. chrysothoia are very rare,—the last is found in Kensington Gardens in June; S. apiformis is found in Sussex. Genus Phalaena, of the 13 species which this genus contains, upwards of 300 are natives of England.

Order Neoptera. Genus Libellula: Of this we have 12 species; L. grandis is the largest, and is inferior in bulk to no insect which this country produces. Genus Ephemerina, nine species; E. vulgata is the largest. Genus Phryganecia, 16 species; P. hirta is rare, but has been found at Oxford. Genus Hemerobius, 7 species. Genus Panorpa; of this only one species, P. communis is known here. Genus Raphidia, two species.

Order Hymenoptera. Genus Cynips, nine species. Genus Tenthredo, 19 species. Genus Syrphus, three species. Genus Ichneumon, 44 species. Genus Sphex, six species; S. spirifex has been found near Peterborough. Genus Tiphus, two species. Genus Chalcis, one species. Genus Chrysia, four species. Genus Vespa, 11 species. Genus Aphis; on the English species of this genus, Mr Kirby has written with minute, accurate, and extensive knowledge, and ascertained them to be even more numerous than they were previously supposed to be. Genus Formica, four species. Genus Mustula, one species.

Order Diptera. Genus Oestrus, five species. Genus Tipula, 52 species; T. Ponomae is very rare; T. zoanata has been found at Oxford. Genus Musca, 86 species; M. semi-argentata has been found in Epping Forest. Genus Tabanus, six species. Genus Culex, five species. Genus Empis, four species. Genus Stomoxys, three species. Genus Conope, four species. Genus Asilus, 11 species; A. Crabiformis is the largest, and A. forcipatus is the commonest species in England. Genus Bombylius, three species. Genus Hippobosca, four species.

Order Apidae. Genus Lepisara, two species; L. saccharinum has been brought hither from America. Genus Podura, eight species. Genus Nemes, two species. Genus Pediculus, 32 species. Genus Pulex, one species. Genus Acras, 24 species; A. autumnalis is not common, except in the chalky districts of Hampshire, Surrey, Kent, Sussex, &c. where it is called the harvest bug. Genus Hydracena, eight species. Genus Physaligum, seven species; P. grossipes and P. hisutum have been chiefly found at Milford haven. Genus Aranea, 18 species; A. aquatica is among the largest. Genus Cancer, 36 species; C. salinus is found in the salt pans at Lynmouth. Genus Monoculus, 10 species. Genus Oniscus, 10 species; O. bidentatus has been found near Milford haven. Genus Scolopendra, four species. Genus Julus, four species.

Order Mollusca. Genus Limax, six species; L. larnecolaris (if it may be considered as a Limax) is found in the sea, off the coast of Cornwall. Genus Aplysia; A. deplana is found in the sea about Anglesey. Genus Doris, four species. Genus Aphydritis, six species; A. plana has been taken off Brighton. Genus Amphitrite, one species. Genus Nereis, three species. Genus Neis, three species. Genus Acestus, four species; A. mammillaris is principally found off the coast of Cornwall. Genus Actinia, six species; A. carphophyllum is principally met with at Teignmouth; A. sulcata on the rocks off the Cornish and Welsh seas, and A. Dianthus on the rocks near Hastings. Genus Pediocellaria, one species. Genus Holothuria, one species. Genus Lernaea, four species. Genus Sepia, four species; S. sepia is taken off the coast of Flintshire. Genus Mollusca, five species; M. octopus and simplex are principally taken off the coast of Cornwall. Genus Asterias, eight species; A. membranacea is found at Weymouth.

Order Zoophyta. Genus Taphibora, one species. Genus Madrepora, one species. Genus Millepora, nine species; a variety of M. fassialis is found on the coast of Cornwall; M. alga is found on the same coast. Genus Celleporea, one species. Genus Gorgonia, three species; G. placoanus and G. verrucosa are found off the coast of Cornwall. Genus Aleyronium, six species; A. schlosseri is found on the coast of Cornwall and Wales, and A. ascidiodes off the former coast. Genus Spongia, nine species. Genus Pista, eight species. Genus Tubularia, seven species; T. indivisa is the largest; T. flabeliformis is found at Milford haven. Genus Corella, seven species; C. squamata, C. elongata, and C. corniculata are principally met with off the coast of Cornwall. Genus Scutaria, 48 species; S. pustulosa is found off the isle of Wight. Genus Pennatula, one species. Genus Hydra, eight species; H. Cereus, H. Bellis, and H. Gymnasea are found on the coast of Cornwall. It is unnecessary to specify the genera and species of the order Infusoria, as they are met with in water, or in infusions made with vegetable and animal matter, and consequently not properly natives of any country.

Sect. II. Botany.

It would far exceed our limits, as well as be going beyond the object and nature of this article, to particularize the plants which are natives of England: Referring our readers, therefore, to the article Botany, where the habitats of English plants are given, or at least such as are natives of England are specified, we shall content ourselves here with a general description of English botany, and on this description we shall borrow from Mr Aiken, as being at once concise, accurate, and elegantly written.

"Among the numerous species of vegetable which are natives of England, scarcely any are adequate to the sustenance and clothing of man. Our frequent rains, our blasting winds, and the scanty portion to which we are stinted of the light and heat of the sun, deprives us entirely of those vegetable treasures which, in the tropical climates, offer themselves, in overflowing exuberance, to satisfy the wants and luxurious desires of their human inhabitants. The never-failing verdure of our plains and hills, covered with a rich carpet of grasses and philanthaceous plants, shows how admirably our country is
qualified for the support of graminivorous quadrupeds; and we find, accordingly, that our ancient forests abounded in stags and roe-deer, as our cleared and cultivated lands do now with sheep and cattle.

The flora of England, though it cannot boast the most splendid and exquisite of vegetable productions, yet contains as great a variety of genera and species as any other country of equal extent. The investigation of indigenous plants is continually carrying on here with increasing ardour, and every year brings new accessions to our crowded ranks of native vegetables.

The first for importance and variety is the family of grasses. Almost every part of the country that is not under tillage, is principally covered with grass. Under almost all the differences of soil and situation, we find the chief covering of the richest, as well as of the most barren tracts, made up, for the most part, of these plants. To these we are indebted for the luxuriant verdure of our pastures—for the close velvet carpeting of our downs and sheep-walks—and the more scanty clothing of our mountainous districts. Twenty-seven genera, and 110 species of grass, are natives of our island, most of them of common occurrence in situations where they are found at all. None of them have been proved to be poisonous, either to man or beast; on the contrary, whether fresh or dried, they furnish a grateful food to all our domestic cattle. The most important grasses in meadows and pastures, are the meadow fowl grass; two or three species of hair-grass and meadow grass; the cocks-foot fescue, and oat grass. Other species are natives of marshes and wet places: These are generally the largest and most luxuriant; and if in quality they be somewhat inferior to the preceding, yet the defect is probably more than compensated by the quantity of herbage which they supply. Light sandy soils, especially the flat parts of the southern and eastern coasts, abound in grasses that are hardly to be met with in the interior of the island: the herbage of these affords a coarse and scanty pasture; and they are eminently distinguished from their kindred species by the length and strength of their creeping roots. Upon the sides and summits of our mountains are found a few grasses that do not appear elsewhere, mixed with some others of more general occurrence. As, however, in these bleak and elevated situations, covered with snow for some months in the year, and shrouded with clouds for the principal part of the remainder, it would be scarcely possible for these plants to bring their seeds to maturity, we observe in them a wise and striking deviation from the common course of nature: like the rest of their tribe, they throw up flowering stems, and bear blossoms; but these are succeeded, not by seeds, but by bulbs, which in a short time vegetate, and are already furnished with a leaf and roots before they fall to the ground. All the viviparous grasses, except one, (Festuca vivipara,) if transplanted to a lower and warmer situation, accommodate themselves to their new climate, and produce seeds. Besides these, there are others of a more hardy constitution, which appear to be the true natives of the mountains, and multiply their species by seed in the usual way. Nearly allied to the grasses; in general habit, are a number of species, natives of moors, bogs, and pools. These serve to give consistency to the deep mud, or peat, in which they are rooted, and, when young, afford a coarse pasture to sheep and cattle. Several of them are used for matting, thatching, and for chair-bottoms. The stately Typha (Bull-rush) is one of the principal ornaments of our fens and neglected pools; and the several species of cotton grass enliven many a dreary mile of bog, by their gracefully pendent tufts of snowy white.

The leguminous, or papilionaceous plants, so called from their winged blossoms, form a very important division in English botany. The herbage of all when fresh, and of many when dry, is a most grateful food to horses, cattle, and sheep; and several of them, as the clovers and vetches, are largely cultivated for this purpose. Many of this class are climbers, and adorn our thickets and hedges with elegant festoons of blossoms and foliage. Almost all the English papilionaceous plants flourish best in light calcareous soils, either rocky or sandy; and some of them, as the lady's finger and saffron, may be reckoned certain indications of chalk or limestone.

The umbelliferous plants form another large class in the natural arrangement of English vegetables, consisting of about 60 species. The roots and seeds of those kinds which grow on dry light soils, are frequently aromatic; those that are natives of marshes and moist meadows, are, for the most part, in a greater or less degree, poisonous. The whole class, indeed, is a suspicious one, and, excepting the fennel and celery, not a single native species is cultivated for the food of man or beast.

Perhaps the most splendid of all the herbaceous plants are the bulbous rooted, which, from their general resemblance to the lily, have obtained the name of lilaceous; most of these, however, are natives of warmer climates. The sandy deserts about the Cape of Good Hope, and the shores of the Indian Ocean, produce the most beautiful species. Of those which are found wild in England, there are only 28 species; and the greater number of these are of rare occurrence in a truly native state. The spring and autumnal crocus, the snow-drop, the snow-flake, the three kinds of narcissus, including the daffodil, the fritillary, tulip, and lily of the valley, are more familiar to us as garden plants, than as natives of our woods and pastures. The common ones of this class are ramos, a species of garlic, meadow saffron, and the beautiful and fragrant harebell, or wild hyacinth, one of the principal ornaments of our groves and thickets, even at such a time when they are profuse of beauties.

Our native fruits belong to the class of rosaceous plants; such as the wood strawberry, the bullace and black thorn, the hawthorn, crab and mountain ash, the common bramble or blackberry, the raspberry, stone-bramble and snowberry. The cherry, the medlar, the service, and pear tree, whose fruit, when wild, is of so little account, and of such value when improved by cultivation, belong also to this class.

One of the largest of the natural classes of English vegetables, is that of the radiated or compound flowering plants, (including about 120 species). It is rather remarkable, that out of so large a number of plants, many of which are very abundant, and of great size, only a single one, the Fragoponon porifolius, (Parsley,) should be applied to the sustenance of man, and not even a single one should be cultivated for the use of cattle; more especially as the Lactua virosa, (strong-scented lettuce,) is the only species possessed of deleterious properties. Most of this class have an ungrateful bitter taste, and the succulent ones contain a white milky juice, of an acrid flavour. Of all our native vegetables, they are the commonest, thriving by neglect, and multiplying by persecution. The farmer and gardener are unceasingly employed in their destruction, for they contribute...
little or nothing to the support of man and the larger
quadrupeds; nor is the beauty of their appearance such
as to obtain for them a place in the flower garden. The
annual kinds, however, producing vast multitudes of seeds,
and the perennial ones being furnished with long and
deeply striking roots, there is no fear of their expan-
sion. They occupy road sides, ditch banks, and all
waste places that are incapable of cultivation, and seem
peculiarly devoted to the sustenance of the granivorous
birds by their seeds, and of numerous tribes of insects by
their foliage. The sow thistle, hawk weed, burn-dock,
thistle, cud-reed, coltsfoot, groundsel, dandelion, daisy,
and yarrow, are the most commonly occurring genera.

Such of our trees and shrubs as have not been already
mentioned, may be considered as forming a peculiar class,
and one of great importance; it is naturally subdivided
into the evergreen and deciduous. The most valuable
of our native evergreens are, the box, the pine, the yew,
and the bolly. Those of secondary consequence are the
juniper and ivy. The spurge laurel, the cranberry, and
those extremely ornamental plants, the Vaccinium vitis-idaea
(red whortle berries), and Arbutus unc us u rs i, (bear
berry).

The deciduous timber trees, that are either aboriginal,
or at least have been long naturalized to our soil, are the
oak, the chestnut, and beech, all of which are moist bear-
ing trees, or produce farinaceous oil nuts, the favourite
food of hogs, and of many granivorous quadrupeds;
the birch, the alder, the horn-beam, the oaks, the pop-
ular, and the aspen, bearing catkins; the sycamore,
the maple, and the ash; the lime, the elm, and the wych-
hazel. A middle station between the timber trees and
shrubs, is occupied by the hazel and the numerous species
of willow. The pulpy fruit-bearing shrubs are, the
currant and gooseberry, the elder, the barberry, the bil-
berry, the cornel or dogwood, the buckthorn, the guelder-rose,
and the mazereon. The four first are wholesome, and
grateful to the palate; the rest are either insipid or noxi-
ous.

The ferns comprise a number of elegant plants, that
grow in moist, shady, and uncultivated places, the uses
of which have been but little inquired into. About 44
species are natives of this country. The roots of most
abound in a mild sweetish mucilage, which in times of
scarcity has been resorted to for nutriment. The larger
and commonest kinds, such as common ferns and brakes,
are collected and burnt for the potash, which is yielded
from their ashes. The Equisetum hyemale, (shave grass),
is much used by turners and cabinet-makers, as a fine
file to smooth their work with.

The last class of English vegetables that we shall men-
tion, is that of the marine algae, or sea weeds. Between
200 and 300 species are found upon our own shores.
The more tender and gelatinous kinds are eaten, either
raw or boiled; and the rest, on those rocky parts of the
coasts where they can be collected in great quantities,
are burnt into kelp for the use of the soap boilers and glass
makers.

SECTION III. Mineral Geography, and Geology.

The last branch of the natural history of England re-
lates to and comprises an account of its mineralogical
and geological. The minerals, in an economical point of view,
will be considered afterwards: At present we shall con-
fine our observations respecting them to those particular
which regard and illustrate their natural position and
history. For the geology of England, the materials are
yet very unsatisfactory and incomplete. In fact, it is a
science still in its infancy: but as geologists, at length,
seem to be convinced of the advantage and necessity of
accumulating and comparing facts, resting on minute
and accurate investigation, before they venture to pro-
cede to form theories, or even to lay down general prin-
ciples, we may hope that geology will soon be advanced
to the dignity and precision of a science. The Geologi-
cal Society has done much; and, from the nature and ob-
ject of its investigations and inquiries, as well as from
the character of its leading members for philosophical
views and general information, much more regarding the
geology of England may fairly and confidently be expected
from them. In what we are about to advance respecting
the mineralogy and geology of England, we shall be
much indebted to their labours; nor shall we pass over
the work of Mr. Bakewell, entitled, “An Introduction to
Geology, comprising an outline of the Geology and Min-
eral Geography of England;” for though in this work
there is a lamentable and discouraging want of arrange-
ment and method, and on many points erroneous or incomplete
information; yet on the whole it must be regarded as a
respectable and useful performance on this subject, at
least till a more scientific and complete one makes its
appearance.

If a line be drawn from the western side of the isle of
Portland, passing through Dorsetshire, about half way
between Dorchester and Bridport, and going a few miles
to the west of Oxford and Northampton; and a very
short distance to the east of Leicester and Nottingham;
and afterwards inclining rather to the west, so as to include
Doncaster and York between it and the German Ocean;
and at length sweeping round the last town in a direction
near to north-east, so as to reach the vicinity of Scar-
borough, it will include between it and the German Ocean
the whole of the low district of England, which is com-
posed of chalk, calcareous sandstone, and other secondary
strata or alluvial ground, and in which no beds of work-
able coal or metallic veins occur. To the west of this
imaginary line, the country is composed of secondary
strata, of a different description, in many parts of which
beds of ironstone and coal are found. This Mr. Bake-
well denominates the middle district. On the north,
this district is bounded by mountains of metaliferous
limestone, which entering England from Scotland, pro-
cede nearly through the centre of the former county,
and terminate in Derbyshire; the same species of coun-
try makes its appearance in the south-western counties
of England and in Wales. The primary and transition
mountains, in which metallic ores occur, are met with along
the western side of the island. These constitute the alpine
district of England, extending from Cornwall and Devon-
shire through Wales, into the north-west parts of York-
shire and Lancashire, and through Westmoreland and
Cumberland. It may be remarked, however, that the
calcareous strata of the low district appear on some parts
of the eastern side of Durham and Northumberland be-
yond Whithy. The principal coal-fields lie in that part
of the middle district, which stretches from Derbyshire
to Northumberland, and in that part of Wales which
borders on the Bristol Channel. On the western side
of Cumberland, the coal strata border on a small part of
the alpine district, and dip under the sea. In the centre
and east of England, the strata generally decline to the
south east; on the western side they are more broken
and irregular. In a direction south-east from Nantwich
in Cheshire to Worcester, all the rock salts, and most of the brine springs, are situated.

- Having given this general description of the geology of England, we shall now proceed to a more particular account of it, as well as of its mineral geography.

What has been denominated the low district of England is distinguished, as has been already remarked, by the absence of any regular beds of coal or metallic veins. Chalk, oolite, calcareaeous sandstone, and earthy limestone, principally compose it. Earthy limestone and calcareaeous sandstone, extend from Dorchester to Northamptonshire, and on the eastern side of Leicestershire, Nottinghamshire, and Yorkshire, into part of Durham and Northumberland. The earthy limestone in this district is far from being pure: it is generally of a yellow colour, and some of it contains 20 per cent. of magnesia.

In the magnesian limestone, there are few organic remains. The strata lie very nearly horizontal, and are, in almost every situation, very distinctly seen. Magnesian lime, however, occurs in this district, composed of beds that are singularly contorted and much elevated. Between the chalk and the limestone, different kinds of calcareaeous sandstone occur; the most singular and important, is the oolite or roe-stone, of which the Portland stone, and the Ketton stone of Northamptonshire are varieties. The roe-stone is separated from the chalk by beds of sand and sandstone mixed with clay: these extend with a considerable degree of regularity over the whole of the south-east of England, but vary much in their thickness. It has, however, been remarked, that in the midland and northern counties, less regularity can be distinguished, and that many of the strata, which are distinctly seen in the south, are there entirely missing. Above the chalk, in the low district, lie, in general, thick beds of clay and gravel. In the upper part of this clay, the bones of the elk, the hippopotamus, and the elephant, have been found. In the southern counties, from Dorsetshire to Kent, and in the midland and eastern counties of Wiltshire, Berkshire, Hertfordshire, Buckinghamshire, Essex, Cambridge, Norfolk, Lincoln, and the east riding of Yorkshire, chalk makes its appearance, in different situations, from under the clay. As the general rise of the strata is to the north, as we approach the coal districts, the strata, which lie under the chalk, rise to the surface. The depth and succession of the strata between the chalk and the coal, have not been ascertained with any degree of minuteness and accuracy, except in one or two places. Mr. Townshend, in a work, entitled, "The character of Moses vindicated as an Historian," has given the following as the thickness and succession of the strata from the chalk on the south coast to the coal districts of Somersetshire.

- Soil and alluvial ground, various thickness; chalk more than 400 feet; three beds of green, grey, and red sand, with sandstone, 300 feet; clay 200 feet; superior oolite, or roe-stone, 40 feet; calcareaeous grit, 30 feet; coral rag, 30 feet; forest marble, 40 feet; great oolite, or Bathstone, 140 feet; clay, 140 feet; inferior oolite and sand, 80 feet; blue clay, 70 feet; lyes, 60 feet; and red marl, 180 feet. Hence it is probable, that, allowing for the depth of the stratum of clay over chalk, the depth of the strata in that part of the low district of England, which comprehends the vale of the Thames, to the strata containing coals, will amount to about 700 yards; but if we estimate the depth of the argaliceous strata, containing coal, where the chalk terminates, and the subjacent sand rises from under it, as at Woburn in Bedfordshire, it probably will not amount to more than 350 yards.

It has been already remarked, that the mineral products of this district are few and trifling: iron pyrites is met with crystallized in some parts of the chalk rocks, and crystals of sulphate of barytes, have lately been discovered in the pits of fuller's earth near Reigate in Surrey. Fuller's earth, also, is peculiar to the strata under chalk. The iron-stone, which is found in part of this district, is not so rich as to bear the expense of bringing fuel from a distance to smelt it. The bones of quadrupeds, already mentioned, are never found in the strata below the chalk, but always in the clay over the chalk.

The middle district of England, in a mineralogical and geological point of view, which is bounded on the east by the calcareaeous range that extends from Dorsetshire to Yorkshire; and on the west from Northumberland to Derbyshire, by the metamorphic limestone mountains of the northern alpine district, or by mountains of millstone grit, resting upon limestone, consists of argaliceous and silicious sandstone. The secondary strata of this district extend west, till they touch the Irish sea, on the coast of Lancashire; or, farther south, are bounded by the alpine districts of Wales and Devonshire. The strata here are very irregular, hills of transition and basaltic rocks rising through them, and branches from the mountains of Wales, shooting, as it were, into this district, especially in Shropshire, and in a line extending from that county to the hills of Charnwood forest in Leicestershire. Basalt, or whinstone, also appears in this district, in the eastern moorlands of Yorkshire, which forms the highest part of it: the sides of the hills composing these moorlands, are covered with a bed of aluminous schistus, upwards of 100 yards in thickness; this schistus forms cliffs, extending in a waving line along the coast near Whithby: above it lie vegetable soils of various thickness: loose stone or rubble of uncertain thickness: coal from four to eight inches thick: compact iron stone, 24 inches thick, and broken iron stone five inches thick.

The principal coal fields, in the northern part of this district, lie in Northumberland and Durham, the west riding of Yorkshire, and Derbyshire: the strata of coal terminate a few miles to the north-east of the town of Derby, but make their appearance again to the south of the Trent in Leicestershire, near Ashby de la Zouch: on the south-east, they terminate at the Charnwood hills; while, on the south-west, a thick bed of coarse breccia and gravel, separate them from the coal fields in the county of Warwick. A considerable part of the western side of the middle district, from the southern division of Lancashire to Somersetshire, is occupied by a red sand rock: which extends through part of the counties of Lancashire, Cheshire, Staffordshire, Shropshire, and Worcestershire: the southern extremity of this rock, in Shropshire, rests on a highly elevated strata of grey wacke; and it is probable that it rests, through its whole extent, on transition rocks. No coal is found under the sand rock, and it seems to cut off the coal fields, which lie near, or upon it: it occurs at a very low comparative elevation. The principal salt springs, and the rock salt of Cheshire, are near, or on the red sand rock, in the vicinity of a range of lofty hills, which extend from the high peak in Derbyshire to Brown's Grove Lickey in Worcestershire. Near Northwich, in Cheshire,
the upper bed of rock salt lies 42 yards below the surface, and is 26 yards thick: it is separated from the lower bed by a stratum of argillaceous stone 10 yards thick; the lower bed has been penetrated to the depth of 40 yards; its breadth is 1400 yards, and, in one direction, it has been ascertained to extend 1½ mile. Three other beds of rock-salt have been found in another part of the county: the uppermost four feet; the second 12 feet thick; the third has been sunk to 25 yards. Brine springs are likewise met with at Droitwich in Worcestershire, in the midst of a similar red sand-stone. The strata here are as follows: from the surface mould, five feet; marl, 35 feet; gypsum, 40 feet; then a river of brine 22 inches; afterwards gypsum again; and below this, a rock of salt, into which the workmen have bored five feet.

Although, as we have already remarked, the red sandstone rock cuts off the coal fields in general, yet in some parts of Lancashire and the western counties, detached coal fields are surrounded by it. The greatest quantities of coal, however, in this district, are in Staffordshire, and that part of South Wales that borders on the Bristol Channel: all the strata of coal and iron stone in South Wales, are deposited in a limestone basin, the form of which is an irregular oval; in length 100 miles, and its breadth from 15 to 20; its greatest breadth is in the counties of Monmouth, Glamorgan, Caermarthen, and Brecon: in Pembroke-shire it is not more than five miles broad. The deepest line in this basin is between Neath in Glamorganshire, and Llanelli in Caermarthenshire: the uppermost stratum of coal is found here; the utmost depth of this stratum does not exceed 50 or 60 fathoms. The succeeding strata of coal lie deeper, and are accompanied with parallel strata of iron ore: the lowest strata at the centre range are from 600 to 700 fathoms deep. In this basin there are 12 strata of coal, from three to nine feet thick, and eleven others from 18 inches to three feet, making in all 95 feet. The limestone that forms the substratum of this mineral deposition, appears to the surface all along the boundary of the basin, and is supposed to have an underground connection from point to point.

As we approach the south-western counties, the middle district becomes very narrow, the calcareous strata of the low district approaching near the primary and transition rocks.

The alpine district of England and Wales is formed by an assemblage of lofty mountains, which pass along the western side of the island; the eastern side of the northern range of these mountains, from Cumberland to Derbyshire, is composed of subcrystalline metamorphic limestone, which in many parts is covered with the millstone grit, and shale grit, that have been already described. In the south-west part of Yorkshire, the limestone, for more than 20 miles, is covered by the incumbent grits; the mountains of Craven again exhibit it; and it rests on slate in Swaledale, at the base of Ingleborough and in other parts adjoining Westmoreland. The mountains of this county and Cumberland are composed principally of grey wacke, flinty slate, roof stone, and porphyry; a low range of granite rock rises near Shap in Westmoreland, and marble is found in different parts of this county. In this part of the northern range, ores of lead, copper, and zinc, are found: in some parts of Craven, carbonate of lead and galena are raised. The north-west of Lancashire, which comprises that district called Furness, consists for the most part of coarse slate and grey wacke; red hematite, a very rich and valuable iron ore, is procured in great abundance in this part of the country, particularly between Ulverstone and Furness Abbey. The southern part of this range consists of the rocks of Derbyshire: these consist of limestone and basaltic amygdaloid: it is supposed that the former rests on slate; there are here three beds of limestone, the depth of which and the basaltic amygdaloid, is upwards of 250 yards; in some parts a fourth bed of limestone is found, thicker than any of the others. The total depth of all the known Derbyshire strata, including the small portion of Nottinghamshire, which contain the magnesian limestone, is 1310 yards. In this range there are 50 beds of coal, varying in thickness from six inches to 11 feet: the total thickness of coal is 26 yards. Hence it appears, that as the thickness of the strata of the low district, (as has been already observed,) is about 700 yards, we must sink 1300 yards deeper, to arrive at the limestone incumbent on slate rocks, the depth of which, below the stratum of clay, in the valley of the Thames, must consequently be about a mile and a quarter.

As we approach the alpine district on the west side of England, rocks of a similar class to those in Wales are met with, but surrounded by the secondary strata of the middle district: the most considerable of these are the Malvern hills, and the Caradoc hills in Shropshire. According to Mr Horner, the central parts of the former are principally composed of granitic rock, mixed with hornblende: the lower deccivities are covered with limestone and sandstone. The Caradoc and Wrekin hills are composed of a variety of green stone; some of them contain actynolite: on the sides of these hills are singular beds of claystone, containing cells, flattened as if by pressure since their formation.

The mountains, on the eastern side of North Wales, are composed of limestone, containing lead and zinc. The limestone is similar to that of the northern range; detached coal fields are met with on their lower deccivities, in Flintshire and Denbighshire. The limestone rests on slate, which, as we proceed to the west, is seen rising from under it: in the same direction, mountains, principally composed of grey wacke, flinty slate, and roof slate, are found: veins of quartz, containing copper ore, also occur. Organic remains have been discovered in the slate of North Wales; it has not been ascertained that any true granite has been found here: in Anglesey there is serpentine, however, which, from its hardness, beauty, and tendency to a crystalline arrangement, may perhaps be regarded as a primary rock. Diaglage, intermixed with stannite, is found in two mountains, on the eastern side of Radnorshire. Rocks composed of cellular claystone, resembling lava, are met with on the west of these mountains, at Llandegley. The north side of Cader Idris, is covered with scattered basaltic columns; composed of porphyritic greenstone: this mountain contains silicious porphyry in mass, intersected by veins of quartz; silicious schistose porphyry, also intersected by veins of quartz; argillaceous porphyry in mass; and granite composed of quartz and schiorl in mass.

It has already been mentioned, that limestone is the foundation rock of the great coal formation in South Wales. The principal mineral treasures of the alpine districts of Wales, are copper, lead, and slate; and of the less elevated districts, coals and iron stone.

We shall now pass to the Devonian range of the al-
pine district. The strata of the middle district rise at an elevated angle, as they approach the granite rocks of this range. The western boundary of the coal district in Somersetshire is formed of metamorphic limestone and grey wacke, which pass from that county into Devonshire and Cornwall. Mountains of granite extend from Dartmoor to the Land's End. Slate, grey wacke, and sometimes metamorphic limestone, occur on their declivities and summits. At the Lizard, the granite rocks are covered with serpentine, near which diallage in rocks is found. In the serpentine also, soft slate is imbedded. The most extensive and valuable mineral treasures of this part of the alpine district are copper and tin; besides these, ores of silver, cobalt, bismuth, manganese, antimony, zinc, and iron are found. Indeed, it has been remarked, that all the 27 known metals are met with in Cornwall, except platinum, mercury, molybdenum, tellurium, tantalum, columbium, and cerium. In some of the granite rocks of Cornwall, school is found intermixed; and in some particular places, it constitutes the principal part of the rock.

Having given this general sketch of the mineral geography and geology of England and Wales, arranged into districts, we shall now proceed, in order more fully to illustrate this important subject, to offer some miscellaneous remarks, though at the risk of repeating some of the statements which have been already made.

To begin with the primary rocks. Granite and granitic rocks occur in Cornwall, Devonshire, North Wales, Anglesea, the Malvern Hills in Worcestershire, Charnwood Forest in Leicestershire, and in Cumberland and Westmorland. The granite of these two counties is, however, porphyritic; and that of Charnwood nearly allied to sienite. Blocks of granite are found detached in some parts of Lancashire and Cheshire. Gneiss is found nowhere in England, except at the Malvern Hills; and here it is imperfectly formed. Mica slate occurs only in Cornwall, where, along with it, lying over granite, serpentine, another primary rock, is also found, exclusively, with the exception of the Isle of Anglesea.

Of the intermediate or transition rocks, slate is found in Westmoreland, Yorkshire, Leicestershire, North Wales, Cornwall, and Devonshire. In the Yorkshire slate are cubic crystals of pyrites. In the slate rock at Charnwood Forest, in Leicestershire, the slaty laminae make an angle of 60 degrees with the principal seam, by which the rock is divided. Graywacke is met with in Cornwall, where it is called kilias. In the northern part of Radnorshire is a lofty range of mountains, composed of graywacke, which, on the eastern side, resembles sandstone, and on the western, roof-slate.

The compact limestone of England and Wales belongs properly to the transition rocks. In Yorkshire and the northern counties it rests on slate, and contains a greater quantity of organic remains than the Devonshire limestone. Trap, or greenstone, is met with in Cornwall in transition rocks; but it possesses no characters by which it can be distinguished from that found in primary rocks.

Transitions from granite to sienite and greenstone occur in the same block at Charnwood Forest. The two latter are also met with in Cornwall, Wales, and Cumberland. Amygdaloid, provincially called toadstone, is found in great abundance in Derbyshire. Porphyry occurs in the western side of England and Wales. It has already been mentioned, that porphyritic greenstone is scattered over the northern side of Cadre Idris. Basalt is found in Durham, Shropshire, &c.

The lowest of the secondary rocks in England is frequently a siliceous sandstone, coloured by red oxide of iron, and called red sandstone: this has been already described. The secondary rocks also include argillaceous sandstone, earthy limestone, calcareous sandstone, and chalk; and contain, besides the rock-salt, gypsum, iron-stone, coal, and basalt. On the eastern side of England, the coal strata generally decline to the south-east; on the western side, they are more frequently thrown into different directions, by faults and dikes. The deepest coal mines in England are those of Northumberland and Durham, some of which are wrought more than 800 yards below the surface. The thickest bed of English coal is in Staffordshire, which is 30 feet deep. In general, the beds of coal in other parts of England and Wales do not exceed from 6 to 9 feet in thickness. From the account which we have already given of the low district of England, it will be apparent, that there is more than one third of this country, in which all search for valuable coal is useless.

With respect to the upper secondary rocks, and the strata containing organic remains in England, there are magnesian limestone, chalk, flint, gypsum, the marl, and sand, over which, in many parts, contain a large quantity of red oxide of iron. Gypsum is principally found in Cheshire, Shropshire, Worcestershire, Derbyshire, and Nottinghamshire. In the gypsum of the two latter counties, no organic remains have been discovered. The organic remains found in the clay and gravel which covers the chalk in the southern counties, have already been noticed. The gravel over the clay is composed principally of flint, containing distinct impressions of unknown aquatic animals. Between the clay and the gravel there is sometimes a thin layer of fresh-water shells, which are also met with under the clay. In the strata over chalk, in the Isle of Wight, fresh-water shells have lately been detected.

If we were to cross England, from Hull into Lancashire, we should first meet with a flat country, formed of alluvial ground. A few miles to the west of this town, the land becomes more elevated, and we pass over a range of chalk hills, which consist of the southern extremity of the Yorkshire Wolds. After descending from these hills, near the Humber, we again enter on alluvial ground, covered with clay and gravel, which extends nearly to Ferrybridge. Here the magnesian limestone makes its appearance, which, with the earthy limestone, form hills of a low elevation, distinctly stratified. The strata are nearly horizontal, and divided by seams of clay. The extreme breadth of this range of hills is not more than three miles. Yellow silicious sandstone comes next, which is the boundary of the low calcareous district. Proceeding towards Wakefield, the argillaceous coal strata of the middle district, extending westward more than 20 miles, is met with. Wakefield and Leeds stand near the east side of the coal district, and Halifax and Huddersfield near the western. A few miles to the west of these towns, and also of Sheffield, hills, composed of millstone grit and shale grit, rise from under the coal strata. These are more than 300 yards thick; and no workable coal is ever found in them. The bases of these hills are metalliciferous. If we proceed still farther to the west toward Manchester, we descend the steep western declivities to the plains of Lancashire; and, lea-
statute.

The surface here in many parts is covered by beds of gravel; and in clay pits, under the surface, are found detached blocks of granite, basalt, scetnite, and slate, similar to the rocks in North Wales and Westmoreland. From the vicinity of Prescot to Liverpool, the immediate substratum is formed by the red rocks, which may be seen dipping under the waves of the Irish Sea.

If we had crossed the island, about 25 miles to the south of the direction we have just described, near the latitude of Sheffield and Chester, we should travel over nearly a similar series of rocks, except that beyond the vale of Derwent, 12 miles to the west of Sheffield, we should meet with the mettalliferous limestone of Derbyshire. The same mettalliferous limestone would also be met with, if, after crossing the red sandstone of Cheshire, we continued our line into Wales. Here it occurs in Flintshire, forming the boundary of the alpine district.

If we cross the island in the latitude of Lancaster, the mettalliferous limestone mountains of Craven, in Yorkshire, would be observed, rising from under the grit-stone, and resting upon slate. In this latitude, the grit-stone mountains of Wharfsdale approach near the earthy limestone on the eastern side, and nearly shut out the coal district.

In travelling from Kent to Cornwall, nearly 150 miles of chalk and calcareous sandstone, as far as the western district of Dorsetshire, are passed over. After we leave the chalk, a few miles of the lower secondary strata occur, before we arrive at the transition and primary rocks.

A brief notice of the principal mineral waters of England seems properly to belong to this part of our subject. They are thus classed by Dr Saunders: The simpler thermal, viz. Bristol, the temperature of which is 74°; Matlock, the temperature of which is 66°; and Buxton, with a temperature of 82°. The simple saline, of which Epsom is the principal: the simple carbonated chalybeate, of which Tunbridge is the principal: the hot carbonated chalybeate, or Bath waters, the temperature of which is 116°: the saline carbonated chalybeate, as the Cheltenham and Scarborough: the vitriolated chalybeate, as the Hartfell waters: and the cold sulphureous, as the Harrowgate. The waters of Malvern and Holywell seem to owe their medicinal virtues entirely to their purity.

CHAP. VI.

Agriculture.

Having thus fully considered, and, we trust, faithfully and accurately described England, as it came from the hands of nature, with respect to its climate, soil, and natural history, we shall now proceed to the second grand division of our subject; and consider and describe it, as it has been operated upon, by the exertion of the labour, and by the application of the science, the knowledge, the skill, and the capital of its inhabitants. From the sketch which we have given of its natural state, it will be seen, that while it presents no great obstacles, in any respect, to the successful exertion of human industry; on the other hand, it does not hold out what is requisite or desirable for the subsistence, comfort, or luxury of man, to be acquired by ease and indolence. To the man of enterprise and science, it is a valuable country, or may be made so; to the man of indolent habits and confined knowledge, existence in it could not be desirable.

This division of our subject naturally comprises several important branches. In the first place, the agriculture of the country; the leading principles on which it is practised; the more prominent particulars of the agricultural practice itself; and a comparative view of agricultural knowledge at present, and at former periods, claim our attention. In the second place, the mines and quarries, especially the former, as exhibiting evidences of the industry, ingenuity, and success of the people of this country, and as contributing to their defence, subsistence, power, and wealth, will be considered in an economical point of view, having been already treated of as branches of the natural history of England. In the third place, our manufactures, in which, more than in any other branch of human industry, England stands proudly pre-eminent over the rest of the world, will be considered at considerable length. It will easily be seen, that, under this head, we have no concern with the processes themselves of the different manufactures, except so far as a general description of some of them may contribute to point out and explain the great improvements which have from time to time made in manufactures. In treating on this subject, also, we shall intermix or premise historical notices, concerning the state of our principal manufactures at former periods. Neither our information, our limits, nor the nature and object of this article, will permit us to render these historical notices numerous, regular, or connected. What we have in view in giving them, is only to enable our readers to form some idea of the comparative state of our manufactures now and at former periods; and probably, in some instances, such historical notices may be important and interesting, as pointing out those changes in national manners and habits, which are sometimes indicated by the changes that take place in the manufactures for home use. In the fourth place, we shall consider the fisheries of England under their two natural and grand divisions; of the fisheries on our own coasts, or in our own rivers, and the fisheries which are carried on abroad, at Greenland and Davis’ Straits, in the South Seas, and off the coasts of Newfoundland. Lastly, the trade and commerce of England will claim our notice. The former divided into the inland and coasting trade; the latter embracing our mercantile connections with foreign nations. We are well aware of the extent and magnitude of this plan; of the importance, interest, and advantage, which would result from the complete and accurate execution of it; and of the extreme difficulty, and numerous obstacles, which lie in the way of such execution. Even if it were attempted by numerous individuals, each most judiciously and impartially selected for his information and knowledge in one particular branch, omissions and errors must appear; it must, therefore, be a matter of wonder or of certainty, if, in the present article, those who are conversant in any particular branch of the various and dissimilar subjects which are treated of, should detect omissions or errors.

SECT. 1. State and Management of Landed Property, Size and Rent of Farms, &c.

The natural and proper introduction to an account of the agriculture of England seems to be a description of

716
of the state of landed property there; with this, therefore, we shall begin this division of our subject.

In England, landed property is tolerably well defined, and protected by the laws of the land. Through the various changes, however, that have taken place in our laws and constitution, in consequence of the conquests and revolutions to which the kingdom has been exposed, its landed property at present is of various descriptions; and the laws and regulations respecting it are almost without number.

The lands of property connected with the lands of England may be divided under two heads, namely, into possessory property, or the actual possession of the lands and their appurtenances; and into abstract rights arising out of them. Those who are inclined to trace the origin and decline of the ancient structure of English tenures, and to search for the fragments of them that are still in force, may consult Blackstone's Commentaries on the Laws and Constitution of England.

The first division of the species of property relating to the lands of England, or possessing property, comprises the soil or land itself; the minerals and fossils it covers; the waters annexed to it; the wood and herbage it produces; and the buildings, fences, &c. thereon erected. The other division of the species of property relating to the lands of England, or abstract rights, comprises seigniorial rights, as chief rents, &c.; manorial rights, as quit-rents, fines, &c.; prescriptive, or common rights; predial rights, or tithes; and parochial rights, or taxes. To these, advowson and parliamentary rights may be added, as they are not unfrequently attached to landed property.

It will be evident, from the consideration of these abstract rights, that possessory property in this country is further liable to analysis, and to more particular distinctions. In case lands are held unconditionally, and in full possession, without any other superior than the laws and constitution of the country, they are termed freehold. This term again admits of still further distinctions.

If the lands are liable to regular and fixed annual payments, which payments are beneath their annual value, and without being liable to fine, heriot, or forfeiture, they are freehold, or are comprised under the denomination of other inferior holding. When they are held of a superior, as part of a royalty, honour, or manor, and are liable to fines, on account of deaths, transfers, or other circumstances, they are copyhold.

Copyhold property is subject to the customs of the royalty, manor, or honour, of which it is a part.

Leasehold property is also of various descriptions and value in England; long leasehold, as for a thousand years; life leasehold, with a fine certain or under certain limitations on a renewal; life leasehold, with an uncertain fine, which is payable to the proprietor or other superior; in this case, he reserves merely a conventional rent; the tenant having paid down a sum of money to obtain the lease, and the right of alienation: this practice is common in the west of England. The conventional rents are reserved and exacted in these cases, in order that the proprietor of the lands may have the right of conveying the tenants to his court or audit, as well as to know which of his tenants are alive, in order that no fraud or overholding may take place. There is also another kind of life leasehold with an uncertain fine: this fine is payable to the proprietor, who receives the full rent of the land at the time of granting the lease; the lessee having a power of alienation; this is a common practice in Wales and in some parts of England. The last distinction of leasehold property, which exists in England, is leasehold for an ordinary term, with the power of alienation. These various rights of possession are styled tenures. Where a lease is granted, without the power of alienation or transfer, it is a species of holding, which merely gives the right of occupancy.

Legal possession of landed property is gained, by grant, as from the crown; by prescription, or long usage; by descent, as from an ancestor; by deed of gift or settlement; by the testament of the deceased owner; by forfeiture, as to a mortgage; and by purchase, either entered on a court roll, or ratified by a deed of conveyance.

In most parts of England, the tenures are nearly of the same kind; and landed property descends in the same manner; but nearly in the whole of Kent, and in some small portions of other counties, gavel-kind, or the equal distribution of landed property among all the sons of a family, prevails. In some parts also, another species of tenure prevails, which is that of borough English, by which the younger son succeeds to the land on the death of his father, to the exclusion of his eldest and other brothers.

Landed property varies in size and value very much. Size of estates.

In different parts of England, perhaps the largest income derived from land may amount to nearly L.100,000 per annum; but the general annual income arising from this kind of property is probably not more than one or two thousand a year. In some counties, particularly in the west of England, landed property is much divided: this is also the case in other parts of the kingdom; while in some counties, nearly the whole of the landed property is in the hands of a very few individuals. In Cheshire, the estates are perhaps more nearly of a size than in most other counties, running from L.5000 to L.15,000 a year. In the manufacturing districts, the small landed proprietors of L.200 or L.300 a year, have been driven away by the introduction of manufactures, and the high price of the necessaries of life, or have been induced to dispose of their property, by the great rise in the value of land in these parts.

The management of landed property in England is generally in the hands of stewards; in some cases, these are men practically conversant with the management and improvement of estates, but too often they are bred to the law, who are better acquainted with the legal language and formalities of a lease, than with the value of land, or the mode in which, for the advantage of the tenant, the landlord, and the community, it ought to be cultivated.

The size of farms varies very much, not only in different parts of the kingdom, but even in the same country. Farms of the extent of 500 to 1500 acres are deemed large farms. Those that are under 100 acres are considered small ones. The largest farms in England are to be met with in the northern parts of Northumberland, in Norfolk, Suffolk, Essex, Kent, and Dorsetshire; a few also occur in other counties; and in general it may be remarked, that farms are larger in the north, eastern, and south-eastern counties, than in the south-western, western, or north-western counties of England. In Wales, farms are for the most part very small.

The practice of letting land on lease is by no means common in England; and it is certainly on the decline. Where leases are granted, they are generally for 7 or 14 years; seldom for 21 years, or a longer period. Leases are most usual in those counties where farms
England.

are the largest. It has already been remarked, that life-leasehold is very common in the west of England, and also in Lancashire, Cheshire, &c. Where no leases are granted, the tenant either holds at will, the only tie between the owner and occupier being the custom of the estate or of the county in which it lies, and the common law of the land; or he holds from year to year, under a written agreement with specified covenants: this is a modern usage, but it is becoming more and more prevalent.

Where leases are granted in England, they are in general much clogged with restrictive clauses; so that the tenant is either under the necessity of carefully avoiding all attempts to improve his farm, by introducing new practices and courses of crops, or he exposes himself by deviations from the covenants of his lease, to the payment of those heavy fines which are specified in it.

When the advantages that the English agriculturist possesses, in respect to climate, are considered, it will probably be found that the rent, which he pays for land, is comparatively low. It is impossible to fix with accuracy the average rent, either of arable or of pasture land, throughout the kingdom; but we shall not be very wide of the truth, if we estimate the average of the two, together, at 20s. per acre. Perhaps, indeed, in the opinion of many, this may be reckoned too high, since the average of the county of Norfolk, which, though of inferior soil, is much better farmed, than most of the arable counties of England, is not above 16s. per acre; but, on the other hand, it should be considered, that most of the arable farms in the north of England, particularly in Northumberland, Durham, and Yorkshire, as well as in many of the arable counties in the south-east of England, as Essex, Kent, Hampshire, &c. are let much above 20s. per acre, and a very small proportion of the grass land is let at so low a rent as this. From communications made to the Board of Agriculture, it was ascertained, that the rise of rents in England between the year 1790 and 1804, was 39 per cent. and since that period a still farther rise has taken place, probably to the amount of 50 per cent. All the other expenses of cultivation have also increased, some of them in as great a proportion. The highest rents for arable land (subject to the payment of tithes, poor rates, &c.) in England, do not, perhaps, exceed 50s. unless where some peculiar and local advantages exist: much land, even of a moderately good quality, is let from 10s. to 12s. per acre. Pasture land varies from 20s. to L.3; and where it is of smaller extent, and occupied for local purposes, especially in some of the manufacturing counties, it is let as high as L.5, or L.6 per acre, or even higher.

The English farmer, besides the payment of his rent to his landlord, is subject to the payment, in most cases, of tithes and poor rates. The latter vary very much in different parishes, and even sometimes in the same parish, at different periods. The former are more steady and regular in their amount. Perhaps, together, they may amount to one half, or 3/5ths of the rent.

The ordinary term of entry to a farm in England is Lady-day; but Candlemas, Whit-sunday, and Michaelmas, are also common terms in some parts of the kingdom. Michaelmas and Lady day are the customary terms of payment; the first payment commences six months after entry to the possession of the farm. Letting lands for a term of years for a former rent, but making the farmer pay a considerable sum by way of fine, was formerly a very common custom, but it is now chiefly confined to the crown and church lands.

Sect. II. Agricultural Departments.

Having premised these general remarks, we shall now proceed to an account of the agriculture of England. This kingdom, not including Wales, in an agricultural point of view, may very properly be divided into six departments or districts: by an agricultural district, meaning that tract, which is distinguished from other parts of the kingdom, by a uniformity or similarity of practice, whether it be characterised by grazing, sheep-farming, arable management, or mixed cultivation; or by the production of some particular article, as dairy produce, fruit-liquor, &c. The six agricultural departments distinguished from one another in this point of view, are the northern, the western, the midland, the eastern, the southern, and the south-western.

The northern agricultural district includes the principal parts of Northumberland and Durham, the whole of Cumberland, Westmorland, Lancashire, and York- shire, (excluding the Pennines and marshy land bordering on Lincolnshire,) with parts of Cheshire, Staffordshire, and Derbyshire. This department is distinguished by a coolness of climate, and a backwardness of seasons, as compared with the more southern parts of the island; but its most striking natural feature is derived from its mountains. As a field of rural economy, it is also strongly distinguished from the other agricultural districts. On its western side, manufactures indeed, have prevailed over agriculture; but on its eastern side, all the branches of the latter flourish. It would not, indeed, be easy to point out any portion of the kingdom, in which a greater degree of agricultural skill and industry is displayed, than in the northern parts of Northumberland, and on the banks of the Tyne.

The western department extends from the Mersey to the banks of the Somersetshire Avon; being bounded on the west, by the Welsh mountains; on the east, by the lower hills of Staffordshire, and the uplands of Warwickshire and Oxfordshire, and on the south, by the chalk hills of Wiltshire, and the Sedgemoors of Somersetshire. Nearly the whole of this agricultural department, comprises an uninterrupted succession of vale districts, formed by the passage of the Severn, the Avon, the Dee, and the Mersey, to the sea. It is no less distinctly marked by agricultural produce, as the whole of it, with the exception of the high lands of Shropshire and Herefordshire, the Cotswold hills in Gloucestershire, and the Mendip hills in Somersetshire, may be almost said to be applied to the produce of the dairy. It is also distinguished as an agricultural district, by its fruit-liquor.

The midland department is bounded by the mountains of the northern, and the chalk hills of the southern departments, in its length; and by the rising grounds, which separate it from the western department, and the banks of the marshes, where the eastern department commences, in its breadth. Compared with the great variety of soil and surface, exhibited by the other departments, this may be regarded as one widely extended plain of fertile lands, without a single eminence, except the Charnwood hills. In its agricultural character, it is distinguished by its mixed cultivation, to which the nature of its soil and surface is almost uniformly suitable. As a wide field of agriculture, (to use the words of Mr. Marshall,) in which every
branch of the profession is highly cultivated, it has been long popularly known. Here not only the spirit of improvement, but of enterprize, may be said to inhabit. The art, science, and mystery of breeding has here been carried to a height, which in any other country probably it has never attained;—the same enterprising spirit, which led to this pre-eminence, still continuing, with little or any abatement.

The eastern department is not more strongly marked in its natural, than in its agricultural character; in the former, its fens and marshes, as well as the light sandy quality of its uplands, features that are united in no other district of the kingdom, mark it out; in the latter, the turnip husbandry is the most distinguishing feature. The agricultural pursuits of the eastern department, are directed, in a principal manner, to grazing, not only in the marshes and lower grounds, but on the uplands. Sheep, as well as cattle, are grazed here; and it may also be remarked, that in a very considerable portion of this agricultural district, arable husbandry is very extensively and intimately connected with the fattening of sheep and cattle. Its boundaries are distinctly marked, including the fen lands of Lincolnshire, Northamptonshire, Cambridgeshire, Huntingdonshire, and Norfolk, as well as the rest of Norfolk, and the counties of Suffolk in Essex, with those parts of the adjoining counties which lie close to them.

The southern department, which includes the chalk hills in the vicinity of the metropolis, as well as those in the more remote counties, is, by the circumstance of these hills, distinctly marked out, in its natural character, from the rest of the kingdom. That part of it which lies in the more immediate vicinity of the metropolis, is, of course, directed, in the nature and objects of its husbandry, by the demands created by the metropolis; and thus an artificial character is, as it were, given to its agricultural pursuits. The other part of this district is distinguished by its flocks of sheep, which are fed on its chalk hills; the breeds, and mode of management, of which are very different from those in the midland and eastern departments.

The natural situation of the last, or south-western agricultural department, is very remarkable; it stretches away from the main body of the island, in a peninsular form, into the western sea. This peninsula is nearly 200 miles long, and is bounded by that sea, except where it touches the southern and western departments. The natural characters of its area, as well as of its situation, are also singular. Slate rock hills, which are comparatively unknown in the rest of the kingdom, except in a small portion of the northern department, here abound. The surface, indeed, almost throughout the department, (its north-eastern angle excepted,) is of a singular character, consisting of bare steepled sides, separated by narrow valleys: the hills, in general, are productive to their very summits. In its agricultural character and pursuits, it is not less remarkable; the husbandry that is carried on there being more nearly allied to the ancient husbandry of the Romans, than any pursued in this island. Arable, as well as pasture and dairy husbandry, are indeed pursued, but the mode of uniting them, the practices which prevail in each, and the grand features of the whole, are remarkable, and strongly distinguished.

Notwithstanding this general division of the kingdom into agricultural departments, it may be proper to specify the counties which are principally occupied in the three great branches of agricultural industry, followed in England, namely, arable husbandry; dairy husbandry; and that husbandry which is directed to the breeding and fattening of cattle and sheep.

The following are the principal counties in which arable husbandry is pursued to a greater extent than in the other parts of the kingdom: Kent, Essex, Suffolks, Norfolk, Hampshire, Berkshire, Bedfordshire, Surrey, Sussex, Hertfordshire, part of Yorkshire, Durham, and Northumberland. The dairy counties, either for butter or cheese, or both, are Cheshire, Shropshire, Gloucestershire, Wiltshire, Buckinghamshire, Essex, Suffolk, Yorkshire, Derbyshire, Cambridgeshire, Dorsetshire, and Devonshire. The counties most distinguished for breeding and fattening cattle and sheep are Lincolnshire, Somersetshire, Leicestershire, Northamptonshire, Teeswater in Durham, and Cleveland and Holderness in Yorkshire.

It will be evident, however, that in this arrangement, many counties must be specified, in which more than one of the three great agricultural pursuits are carried on; and it may be remarked, that the arable husbandry, in some counties, is closely connected with the fattening of sheep, but seldom with the dairy husbandry; while the latter is often connected with the breeding and fattening of cattle and sheep.

Sect. III. Arable Husbandry.

In giving a general sketch of the arable husbandry of England, it will be proper to consider it under two heads, namely, the instruments employed in carrying it on, and the crops cultivated. On the first head, our remarks must be brief, since it would lead us far beyond our limits to particularise or describe nearly all the agricultural implements used in England.

The ploughs employed are of various and numerous sorts, but they may be divided into three principal classes: the swing-plough, the wheel-plough, and the turn-wrest plough: the first seems to be the oldest plough in England, at least in its original construction: it is for the most part a heavy ill made implement. In its original form, it is not however now often met with; but in its improved construction, it is general in the northern, north-western, and some of the midland counties: in Suffolk, a peculiar kind of swing-plough is used. Ploughs with one or two wheels are common in the southern, and south-western counties of England, as well as in some of the midland counties: a peculiar plough of this construction is almost exclusively seen in Norfolk. Turn-wrest ploughs are general over Kent, and on the chalk hills of Sussex and Hertfordshire: they are not common in other parts of the kingdom. Besides these three kinds, double moulded ploughs are used; but their use is by no means general, nor is it likely to continue. On the whole, it may be remarked, that the ploughs, as well as most of the other agricultural implements in England, are by no means constructed on those scientific principles, and with that skill which enables them to do their work well with the least expence of labour and time.

Perhaps the imperfect construction of the ploughs may be one cause why in England a greater number of horses than necessary are employed in them. If we except the counties of Norfolk, Suffolk, and Essex, in the south of England, and those of Northumberland, Durham, Cumberland, and Westmoreland, in the north, there is perhaps no other county in which more than two horses will not be seen in a plough. In some counties, the practice of ploughing with two horses is never followed, even on the lightest soils; and it may in general be remarked of the south, south-eastern and

---

**Number of horses in a plough.**
Few of the other implements of agriculture used in
England require particular notice; they are very num-
erous; almost constant changes are making in them;
but simplicity of principle and construction are too
little attended to. With the exception of the northern
counties, waggons are almost universally used in hus-
bandry, as well as carts. In the northern counties, on
the contrary, waggons are seldom seen in the occupa-
tion of a farmer. The thrashing machine is now pret-
ty common, in most parts of the kingdom, but it is only
within these very few years that it has been introduced
into the midland and southern counties: though the
minutiae of its construction vary considerably, yet in
almost every case it operates by beating, not rubbing
out the grain.

Before agricultural improvements began in England,
there appears to have been little or no fallow land: one
of the first, or at least one of the most striking and im-
portant improvements in its agriculture, was the intro-
duction of fallows: they are very common on most of
the strong and wet lands in the arable districts, though
attempts have been made, especially in the southern
counties, which are favoured with a long and dry sum-
mer, to do without them. On the light dry soils, in
every almost part of the kingdom, they have been en-
tirely superseded by the introduction of turnips and
other green crops.

The courses of crops commonly cultivated vary very
much, not only according to the nature of the soil and
climate, but even with the same soil and climate. In
the best farmed counties, which may justly be con-
dered to be Norfolk, Suffolk, Kent, and Northumber-
land, a general principle is laid down, not to sow two
white crops in succession: this principle is gradually
extending itself, and is acted upon by the best farmers
in all parts of the kingdom. It is, however, still ne-
eglected by too many; and oats or barley after wheat,
after oats, and two or three crops of oats in suc-
cession, are by no means uncommon. On light soils,
the most judicious rotation, and that which is pursued
by the most intelligent and successful agriculturists, is
borrowed from the county of Norfolk, and thence cal-
ded the Norfolk system: it consists of turnips, barley,
clover, and wheat. On heavy soils, no one rotation
is nearly so common as this is on light soils. Those
most pursued are fallow, wheat, beans, oats: fallow,
wheat, oats: fallow, wheat, clover, beans, oats. Bar-
ley is not often introduced into the rotations on strong
lands; and tares or cabbages are sometimes substituted
for fallow. In the Isle of Sheppey, in Kent, and in a few
other spots of uncommon fertility, wheat and beans are
grown, without the intervention either of a fallow or
any other crop.

Besides these rotations, in the course of which the
ground is constantly under the plough, there are other
rotations founded on the principles of what is called
the convertible husbandry. According to the prin-
ciples of this husbandry, the ground, after being laid
down for three, five, or more years, to grass, is bro-
ken up, and sown with different species of corn for
some years, after which it is again laid down to grass.
This mode of husbandry is making its way into the
best farmed districts of England, so that more grass-
land, (not permanent, but for a few years), is seen in
the districts, strictly speaking arable, than was former-
ly kept; and a greater breadth of ground is under the
plough, in many of those counties, which formerly
were almost exclusively under grass.

Wheat is by far the most important, and the most
tightly cultivated crop in England: from what has
been already said, it will appear that it is sown after
clover, fallow, tares, and cabbages: it is also sown
after beans and potatoes, but never in the best farmed
districts of England after any white crop. As it is a
crop on which the farmer mainly depends, the prepa-
ration for it, in whatever rotation it comes, is managed
with great labour and attention. If it is to be sown
after fallow, the land is ploughed and harrowed re-
peatedly, and well manured. After one ploughing is given, and seldom more after beans; where
tares have been previously sown, they are got off the
land in sufficient time to plough it more than once for
the succeeding crop of wheat. The drill husbandry,
with respect to this crop, is by no means common in
England; and it is still less frequently put in with the
dibble, by far the greatest proportion being sown broad-
cast.

The usual quantity of seed to an acre is from 2 to 3 bushels. The kinds of wheat sown are very
numerous, but they may be classed under four heads:
concealed or bearded wheat, which however is now little
sown; white wheat, of which the varieties are almost
numberless; red wheat, which is seldom sown where
the climate is very good and early, and the land in
high condition; and spring wheat. The last, in con-
sequence of the high price of wheat, and the desire
which this naturally produces in the farmer to sow
wheat after his turnips in the spring, is becoming more
common, though the real spring wheat is of compar-
atively late introduction. Wheat is seldom sown before
the beginning or middle of September in any part of
England, and seldom so late as the end of April: the
most usual period is between the middle of October and
the end of the year. While growing, not much atten-
tion or labour are bestowed upon it, unless where it is
drilled, in which case it is hoed: where sown broadcast,
it is sometimes rolled and harrowed in the spring. The
wheat harvest commences in the south of England about
the end of July, or the beginning of August; in the
midland counties it is about 10 days later; in the
northern counties, nearly three weeks. There is a stri-
kng difference in the harvest field in respect to this, as well as other kinds of grain, in the
north and in the south of England; in the former, du-
ring harvest, the corn field exhibits a large num-
ber of reapers, perhaps 50, 60, or even 100, all pro-
ceding in their operations together, and presenting
an interesting and animating picture. In the south of
England, and indeed over the greater part of the mid-
land counties, on the contrary, wheat is cut down by
two or three individuals, each of whom contracts to
cut a field, or a certain number of acres. The wheat
field consequently exhibits merely one or two men, per-
haps, with their wives, working in different parts of
it. Wheat is seldom or never cut down with the
cythe, but is either reaped with the common sickle, or,
as is the practice in some of the counties near the
metropolis, as well as in some of the south western coun-
ties, it is bagged, that is, struck down near the ground
with a large and heavy hook. It is universally bound
in sheaves. Perhaps no circumstance marks the dis-
ference of climate in the south and north of England
more strongly, than the difference in point of time du-
ring which it is necessary to keep wheat and other grain
in the field before it is taken home. In the southern
counties, it is generally ready in a week or ten days;
whereas, in the north of England, it is necessary to
let it stand out for two or three weeks. In the south-
erm and midland counties, it is frequently put into
barrels: in the northern counties, it is almost universal-
ly stacked. As this grain is so very extensively cul-
tivated, and consequently on much inferior soil, and
frequently after very imperfect preparation, the produce
per acre varies very considerably in different counties:
as it is also very liable in this climate to be injured by
a bad seed-time, a wet winter, or a blight during the
period of its flowering (which last is here the common
cause of the failure or deficiency of our wheat crop)
its produce varies as much in different seasons in the
same part of England, and under the same manage-
ment, as it does during the same season in different
parts of the kingdom. The lowest quantity of pro-
due, except where an absolute deficiency from blight
occurs, may perhaps be rated at 12 bushels per acre;
the highest at six or seven quarters. The latter have
been reaped on the deep loams near Chichester in
Sussex, on the calcareous loams near Epsom, and in
some of the more favoured and highly cultivated spots
of Kent, Essex, Lincolnshire, and Somerset. A
tabular view of the average produce of the different
counties of England and Wales, in wheat, barley, oats,
&c. will afterwards be given.

The wheat counties of England are Kent, Essex,
Suffolk, Rutland, Hertfordshire, Berkshire, Hampshire,
and Herefordshire; that is, these are most distinguis-
ished for the quantity, as well as the quality, of their
wheat. In the north of England, this grain is of an
inferior quality, being cold to the feel, dark coloured,
thick skinned, and yielding comparatively little flour.
In the best wheat counties, and in good years, the
weight of a bushel of wheat, eight gallons to the bushel,
is from 60 to 62 lbs. In the Isle of Shepey, in Kent,
(where perhaps the best samples of wheat sent to the
London market are produced), this grain, in some fa-
vourable seasons, weighs 64 lbs. the bushel. Where
the climate is naturally colder, wetter, and more back-
ward, or in bad seasons, the weight of the bushel of
wheat is not more than 56 or 57 lbs. It is calculat-
ed that the average weight of the bushel of good En-
lish wheat is 58 lbs., yielding 344 lbs. of flour for stan-
dard wheaten bread; and 573 lbs. for household. Se-
ven bushels of good wheat will make a sack of wheaten
flour.

The culture of rye, which was formerly pretty ex-
tensive in some parts of England, has now nearly en-
tirely disappeared. This has arisen from the operation
of two causes. In the first place, greater experience
and improved skill, have convinced the farmers that a
very large proportion of very light land, which was
deemed fit only for rye, may, by proper management
and due labour and expence, be rendered capable of
producing valuable crops of wheat; and, in the second
place, the increased wages of the labouring classes of the
community has naturally led them to a preference of
wheat bread to bread of any other description. Rye,
however, is still cultivated in some parts of North-
umberland and Durham, either by itself, or along with
wheat; and in the vicinity of the metropolis. In no
other part is it cultivated to any extent for seed: but
it is grown in many counties as green food for cattle,
coming early in the spring to maturity for this purpose,
and afterwards allowing time for a subsequent crop the
same year.

The culture of barley is also on the decline in most Bar-
ley. parts of England, owing, of course, to a diminished
demand for it, and to the increasing demand for wheat,
and consequent high price of this latter grain. The
diminished demand for barley arises from the same
cause which has produced a diminished demand for
rye, namely, the increased wages of the labouring classes,
in conjunction with another cause, the stoppage of
distillation from this grain, which has frequently taken
place in late years. These two causes would probably
have diminished the growth of barley to a still greater
extent than they have done, were it not for its impor-
tance as a crop in the rotation most adapted and bene-
cicial to light lands. The barley counties of England
are principally Norfolk, Suffolk, Cambridgeshire, Bed-
fordshire, Leicestershire, Nottinghamshire, and the upper
parts of Herefordshire, Warwickshire, Shropshire.
The most common preparation for this crop, where its
culture is best understood, and most extensively followed,
is turnips: after these are drawn or eaten off, the land
is ploughed two or three times, and harrowed repe-
tedly. The season for sowing barley extends from the
middle of March to the end of April. It is more
generally drilled than wheat, but this mode of culture is
by no means common; when followed, about two bu-
shels of seed are sown; in the broadcast method, three
or 3¼ bushels. There are two leading varieties of this
grain grown; the common barley, of which there are
several kinds, and big; the latter, however, is almost
totally confined to the lofty parts of the northern
counties. The barley harvest, in the south of Eng-
land, commences nearly about the same time as the
wheat harvest, perhaps a little later: in the north, it
is often cut down before the wheat. The practice of
mowing it, which has long been followed in the south,
is becoming general; but the carrying it home in a
loose state, without being bound into sheaves, is con-
fined to the southern counties, and indeed can only be
practised there with safety, where the climate is so
warm and steady as frequently to render it fit to be
carried to the barn-yard in the course of a few days.
It is seldom housed in any part of England. The pro-
duce varies from three to eight quarters: the most
usual crop is 3½ or 4 quarters: the usual weight of a
bushel of barley is 50 lbs.; the best Norfolk barley,
however, sometimes weighs 55 lbs. This crop is grown
in some places after peas and tares, as well as after
turnips; and where it is sown on strong land, a sum-
mer fallow preparation is sometimes given. The prac-
tice of sowing it after wheat or oats is on the de-
cline.

In consequence of the increased number of horses Oats
kept in England for business or pleasure, within these
few years, the cultivation of oats has been considerably
extended. As, however, they do not suit so well with
a warm and early climate, as with a climate more moist
and backward, the crops of them in the former being
never so abundant nor of such good quality as in the
latter: the cultivation of oats is more attended to in
the north of England and Wales, than in the southern
counties. The counties in which they are most ex-
tensively grown, are Northumberland, Durham, Cumber-
land, Westmoreland, Lancashire; and the fens of Lin-
There are four leading varieties of this grain cultivated in England: the white, the black, the grey, and the brown or red; of the white, the subvarieties are very numerous; but the most common are the common white, the Tartarian, the Dutch, the Polish, and the potato oat: the black and grey are little cultivated: the red is confined principally to Cheshire, Derbyshire, and Staffordshire. Besides these kinds, a species of naked oats, called provincially pillar, are grown in Cornwall.

Oats are almost always, in every part of the kingdom, the first crop after the breaking up of old grass land. They are also sown generally on strong land, after clover ley; and in the north of England, they succeed clover on most kinds of soil. Besides coming in this rotation, they are sown sometimes after turnips; and where the husbandry is bad, they are taken as the last crop before fallow, even when the ground is dirty and exhausted. In the southern counties of England, the end of February, and in the midland and northern counties, the middle or end of March is the usual seed-time. They are very seldom drilled. The usual quantity of seed to the acre is five bushels. Perhaps the produce of no species of grain varies more than that of oats. Where the ground is foul and exhausted, not more than 20 bushels are obtained; but on rich soil well managed, eight, nine, and sometimes ten quarters, have been produced. In most parts of England they are mown, except when the crop is very strong. They are generally, but not always, carried loose into the barn-yard, where they are put up in stacks.

Beans are grown on almost all the strong lands of the kingdom, which are under the plough; and their cultivation probably has not extended, as, according to the old rotation pursued when most of the land was in common fields, they, preceded by wheat and followed by fallow, formed the whole course of the husbandry of our ancestors. But though their cultivation is very general, there are few counties in which it is well conducted. Perhaps Gloucestershire in the west of England, and Kent and Essex in the south, may be pointed out, as the counties where the culture of this plant is conducted with the greatest judgment, skill, and success. In these and some other counties, they are planted in rows or clusters, and carefully weeded, both by the horse-hoe and the hand. They are generally grown after wheat, oats, or clover ley; and are put into the ground as soon in the spring as the weather will permit. The bean harvest, in every part of the kingdom, is late, generally ten days or a fortnight after all the white corn is cut down. The produce varies from 16 to 40 bushels. Pease are very little cultivated in any part of the kingdom, except in the vicinity of the metropolis, as a garden crop. Where grown as a farm crop, they generally succeed clover ley, wheat, barley, or oats. The produce, in consequence of the unsettled nature of our climate, is very uncertain and various.

Tares are principally grown as spring food for sheep, cattle, or horses. In the south of England, there are two kinds: the winter and spring. The former, sown in the autumn, is ready to cut in the month of April or May; but this kind does not come to perfection in the northern counties. The latter kind is sown in March and is cut in the autumn. Buck-wheat is seldom seen in England. A little of it is cultivated in Norfolk and some other counties, where the soil is light and poor, and permitted to remain till it is ripe; in other parts, it is sown and ploughed down, as a winter, white. There are three kinds of clover, red, Dutch, and yellow clover, or trefoil, are very generally grown, but to a greater extent, and with more success in the eastern, southern, and northern counties, than in the western or midland. The cultivation of red clover after barley, and as a preparation for wheat, is considered as one of the proofs of superior husbandry, in those districts where it is extensively and regularly sown in this rotation. In the north of England, rye-grass is commonly sown along with clover, where hay is the object; but in the south, and particularly in the vicinity of the metropolis, clover is sown alone. Dutch or white clover is used principally in laying down land to grass. Sainfoin not thriving well, except where the soil or subsoil is calcareous, is not met with generally. On the Cotswold hills, and on the chalk soils of Dorsetshire, Hampshire, Wiltshire, Hertfordshire, Surrey, Sussex, and Kent, it is extensively cultivated. It generally remains for eight or ten years; a much longer period, according to A. Young, than it is found to do in France. It is made into hay, and the after crop eaten by sheep or cattle. Lucerne, nearly allied to sainfoin in its character, habits, and properties, is not grown to any extent, except in some districts of Sussex and Kent.

The counties into which the culture and use of that valuable root, the potato, was first introduced, and in which it is still grown in the greatest perfection, are Lancashire and Cheshire: in the former, about Altrincham, and in the latter, about Frodsham. Potatoes are also grown to a considerable extent in Yorkshire, particularly on the warland, or the soil on which the sediment of the river is permitted to be deposited, Cumberland, and Cornwall. Their cultivation and use, however, are less extensive and common in the western counties, than in any other part of the kingdom. On the light soils in the low parts of Wales, they are commonly grown. They are planted in the months of April and May, generally in rows; horse-hoed and weeded by the hand while growing, and taken up in the month of October, either by the plough, or by a particular kind of fork. The produce varies from six to ten tons. They are used as a preparation for wheat, instead of a fallow. In Lancashire and Cheshire, however, they are planted on lands broken up from grass for the purpose.

The county of Norfolk was, for a long time, almost exclusively remarkable for the great breadth of turnips sown in it, and for the judgment, skill, and success, with which they were cultivated; but at present this most useful and valuable root is grown in almost every county in England, in a greater or less degree. In a superior manner, however, and to a greater extent in Norfolk and Northumberland, than in any other counties. Perhaps there are fewer turnips grown in Cheshire and Lancashire, in the north-west, and in some of the south-western counties, than elsewhere. In the north part of Northumberland, they are almost universally drilled. The drill husbandry is also used with respect to them partially in other places; but by far the most common mode of sowing them, is broadcast. They seldom suc-
Flax and hemp.

and extend the cultivation of flax and hemp; but the bounties were soon withdrawn, it is said, because they indirectly went to the landlords instead of the tenants, the former expecting an increased rent for their land, in proportion to the bounties given. However this may be, flax and hemp are by no means extensively cultivated in England; chiefly between Bridport and Beaminster in Dorsetshire, about Frome, Crewkerne, &c. in Somersetshire; at Upwell and Chatteris in the Isle of Ely, in some parts of Lincolnshire, and on the strong lands of High Suffolk.

England has long been noted for its hops. They are grown cultivated in the neighbourhood of Canterbury and Maidstone in Kent, where there is a larger extent of ground under this crop than in any other county in the kingdom: about Farnham in Surrey, and the adjoining parts of Hampshire, where, from superior management, or other causes, their quality is so highly esteemed, that they always bring a much higher price than any other hops: in Worcestershire, particularly in the vale of the Severn and in the vale of the Team; in the vicinity of Stow market in Suffolk, and near Retford in Nottinghamshire; but in these two places only, to a very inconsiderable extent: in Herefordshire, particularly on the confines of Worcestershire: in Essex, about Castle Hedingham: and in some parts of Sussex. This crop is so much affected by the climate, and so much exposed to blights and other distempers, that its produce varies more perhaps than that of any other plant cultivated in the fields. This will sufficiently appear, from the following statement of the produce of hops in England during the years $1795$ and $1796$.

In the former year, it amounted only to 5,000,000 lbs., whereas in 1796, the produce was 42,528,587 lbs. The average, ascertained from the produce of a considerable number of years, is found to be 20,543,070 lbs. Hop grounds let at a higher rate per acre than any other kind of land not possessed of peculiar local advantages, bringing from L5 to L10 per acre; and about Farnham, considerably more.

There is scarcely a farm of any extent in the southern and south-western counties, which has not an orchard attached to it, containing apple trees at least sufficiently numerous and productive to supply the farmer's family with cider; but it is exclusively or principally in the counties of Devonshire, Herefordshire, Worcestershire, Gloucestershire, Monmouthshire, and Somersetshire, that cider and perry are made in very large quantities for sale; and where the management of the orchards forms principally or exclusively the concern of the farmer. Perry is made chiefly in Worcestershire; and the cider of Herefordshire and Gloucestershire is deemed of a superior quality to that of Devonshire. The actual quantity of cider made in the cider counties has not been ascertained. Mr. Marshall calculates that the produce of the four counties of Worcester, Gloucester, Hereford, and Monmouth, on a par of years, may be laid at 30,000 hogsheads; of this quantity it is supposed Worcestershire supplies nearly 10,000 hogsheads, besides 1000 hogsheads of perry. Exclusively of these liquors, which are sent into all parts of the kingdom, these counties, which may be considered the principal fruit counties of England, send large quantities of fruit chiefly into the northern counties. The average tonnage of fruit sent out of Worcestershire alone, by the canals, into the north, for three years, amounted to 1500 tons; and in one year it exceeded 2000 tons. The county of Kent is famous for orchards of another description from those of the western counties. These...
are orchards of cherries and filberts. The former are common in most parts of Kent; the latter are principally confined to the vicinity of Maidstone, where they amount to several hundred acres.

**Sect. IV. Grazing Husbandry.**

The principal dairy counties have been already enumerated. Of those appropriated to the making of cheese, Cheshire and Gloucestershire are the most famous. Much cheese is also made in that part of Shropshire which borders on Cheshire, and in North Wiltshire; the former goes under the name of Cheshire cheese; the latter was, till lately, called Gloucester cheese, now it receives its appellation from the county where it is made. A strong cheese, somewhat resembling Parmesan, is made at Cheddar, in Somersetshire. The rich cheese called Stilton, is made in Leicestershire, principally in the villages round Melton Mowbray. A rich cheese is also made at Leigh in Lancashire. The other cheeses made in England, which have acquired a peculiar name, either from the quantity made, or from the quality, are the Derbyshire, Stockton, Cottenham, and Southam cheeses. The last two are new-milk cheeses, of a singularly delicious flavour; the places where they are made are in Cambridgeshire. Bath and York are remarkable for their cream cheese. The county of Warwick, and Banbury in Oxfordshire also are remarkable for cheese: the former for the quantity made in it; about 19,000 tons being sent annually to London, besides a very large supply to Birmingham. The cheese made at Banbury is distinguished for its rich quality. The principal counties in which large quantities of butter are made, are Buckinghamshire, Cambridgeshire, Suffolk, Yorkshire, Dorsetshire, and Devonshire. Cambridge, Suffolk, and Yorkshire, annually supply London with about 60,000 firkins. Epping also is famous for its butter, nearly the whole of which is consumed in London; the quantity is about 20,000 firkins.

The richest grazing lands in England are, the Vale of Aylesbury in Buckinghamshire, the marsh lands of Somersetshire, the fens of Lincolnshire, Huntingdonshire, &c. Romney Marsh in Kent, and the midland counties, Leicestershire, Northamptonshire, &c. The natural fertility of some of these districts, and the fertility bestowed upon them, by the agricultural skill, capital, and industry of the farmer, is astonishing. On the rich grazing lands in Lincolnshire 2½ sheep have been kept on an acre during the summer, besides 1½ bullocks; and during winter, the same ground has kept two sheep per acre.

The hay made in this kingdom is either from the natural grasses, from clover and rye grass, or clover alone, or from sainfoin. The first description, or meadow hay, as it is called, is principally the produce of the western counties, where comparatively little clover is sown, and where meadows are most extensive and numerous. The mode of making this species of hay is carried to the greatest perfection in the county of Middlesex, particularly in the immediate vicinity of the metropolis. Clover hay, either pure, or mixed with rye grass, is most common in the southern, eastern, and northern counties. Sainfoin hay, is confined to those counties which have a calcareous soil, as on such a soil alone this plant can be profitably grown. The usual weight of a crop of meadow hay, is from one to one and a half tons per acre; of clover hay, from one to two tons; and of sainfoin hay, about the same quantity. In those counties, which are peculiarly favoured with an early and dry climate, clover is sometimes permitted, after it has been once cut, to stand for the purpose of procuring its seed; but by far the greatest proportion of clover seed is obtained from Holland and Flanders.

From the sketch which we have given of the arable husbandry of England, it will be perceived, that, with the exception of a few counties, it is by no means generally deserving of a high character for excellence and improvement. Many of the implements employed are constructed on bad principles, and awkwardly made; much labour and expense in the cultivation of the ground is thus needlessly thrown away. Besides, the ground in many counties is imperfectly ploughed and kept clean; and courses of crops are followed, which tend to exhaust it, or at least to prevent the farmer from reaping all the advantages from his expense and labour, which, under more judicious rotations, he could not fail to derive.

**Sect. V. Live Stock.**

But though the arable husbandry of England, on the whole, is thus defective and backward, the agricultural character of the country must be placed deservedly very high, on account of the breeds of its sheep and cattle, and the great improvements which within these few years have been made in them. Respecting the sheep of this country, we shall enter into pretty full and minute details; and we trust our readers will not deem these details too far drawn out, or superfluous, when they reflect, that the investigation and account which we shall afterwards give of our staple manufactory, will be thus rendered more full, satisfactory, and complete. As the same reason does not exist for being so particular respecting the other branches of live stock, we shall bestow on them a comparatively short notice.

Before, however, we proceed to describe and enumerate the different kinds of sheep that are kept in England, and to form an estimate of the quantity of wool which they afford, it may be proper to premise some general remarks respecting their management. Sheep are fed either on the mountainous districts of England and Wales, in the rich grazing grounds, especially in the midland counties, and on the marsh lands, or on arable farms. In the mountainous districts, the chief object is to breed them; where they are kept on grazing grounds, or on arable farms, the principal object is to prepare them for the butcher. In some parts of England they are kept on arable farms, not only for the purpose of being fattened, but also to manure the fallows, by being folded on them. This practice, however, is by no means general. On these farms, the most common mode of fattening them is by means of turnips, oil cake, hay, and corn.

There are great varieties of sheep kept in this country. Varieties

The principal kinds are, the Dishley or New Leicester, the Lincoln, the Teeswater, the Dartmoor, the Exmoor, the Dorset, the Hereford, the South Down, the Norfolk, the Heath, the Hardwick, the Cheviot, the Dunfaced, the Romney Marsh, the Wiltshire, the Bagshot Heath, and the Spanish or Merino. Of these, however, it may be remarked, that the Wiltshire and the Dorsetshire are nearly alike in their form, the quality of their wool, and their general properties; and that the Bagshot Heath sheep are nearly extinct, or, where remaining, are so
nearly allied to the Heath sheep; that they may be classed with them. The following Table will exhibit a clear view of these different breeds, according to their most important and distinguishing properties.

</table>

In our further remarks on the sheep of England, we shall divide them into two classes, the fleece is of which are distinguished from one another, both by the length of the staple and the mode of manufacturing them; the one being adapted to the fabrication of woollen goods, and the other to that of worsted. Long woollen sheep are found in many detached parts of England, but much more commonly on the eastern than on the western side, and often nearer to the coast than the middle of the kingdom. Amongst the larger ranges of long-wooled sheep, the most northern are found near the mouth of the Tees; the next range are found in that district, which comprehends the north-eastern part of Yorkshire, near the whole of Lincolnshire, and the Finlands of Huntingdon, Cambridge, and Norfolk. The same kind of sheep, with respect to their wool, are likewise found in the smaller marshes of Essex and of Kent, which surround the inlets of the sea; but, in the latter county, they are most numerous in the marshes of Romney and Guilford. Long-wooled sheep are also found in the counties of Dorset, Devon, and Cornwall, on the Cotswold hills, in some small and detached parts of Lincolnshire, Oxford, Bedford, and Stafford, through the whole of Leicestershire, Rutlandshire, Northamptonshire, and Huntingdonshire, and among the banks of most of the large rivers in the kingdom.

Having thus sketched out the districts in which the long-wooled sheep are found, we shall now proceed to consider these districts separately, and endeavour to estimate the number of sheep which each district keeps, and the quantity of long-wool which it supplies to our manufactories. To begin with the Teeswater:—in the county of Durham, where we first meet with them in proceeding from the north, the stock of these sheep upon the acres varies very much in different parts; probably, on the whole, there are about two sheep upon every three acres. The extent of land on which this breed of sheep are kept, cannot be more than one third of the county; according to this calculation, the stock of sheep will be 67,200; which, averaging the fleece of each sheep at 9 lbs., will give 2520 packs of wool.

In Yorkshire, the long-wooled breed of sheep are chiefly kept in the districts of Cleveland and Holderness. The former district maintains about 14,300, but their fleece cannot be rated higher than 8 lbs.; thus giving a quantity of wool amounting to 470 packs. The Teeswater breed are seldom seen to the south of Cleveland. The whole quantity of wool produced by them is nearly 3000 packs. The Lincoln breed was formerly very general over the district of Holderness, but latterly they have given way in a great measure to the Dishley; but, although this tract of land is very fertile, and well adapted to grazing, yet, as the breeding of cattle is the main object of the grazier’s attention, the stock of sheep is singularly light, there being probably not more than one to every four acres. According to this calculation, there will be 84,000 sheep, which, at 8 lbs., to the fleece, will give 2800 packs; the whole of which is sent to the manufacturers of the West Riding.

The natural advantages of Lincolnshire, the next district of long-wooled sheep, for the production of this kind of fleece, are great and numerous; and it is probable that they were first attended to here with spirit and profit, since it is known that the looms of Norfolk were supplied for nearly five centuries from the pastures of this county. The native breed of Lincolnshire, though much reduced in numbers, and lowered in fame, by the introduction of the new Leicester, still retain possession of a pretty considerable extent of the county. In other parts, a mixed breed between the new Leicester and the Lincolnshire are kept; by this mixture, the wool is rendered finer and shorter, and its colour is improved; but it has lost a large proportion of that toughness, which is an indispensable quality in good combing wool. The low lands of this county, as has been already remarked, carry a very heavy stock of sheep. Where no cattle are put on along with them, it is said, that eight sheep have been kept on a single acre. Probably, taking in the whole of the low grounds, and allowing for a stock of cattle, the average number of sheep is nearly three on an acre, which will make the number of sheep amount to 1,240,000; and averaging the weight of the fleece so low as 9 lbs., the produce of wool will be about 46,500 packs. As very few sheep can safely be kept during winter on the marsh lands, which extend from the mouth of the Humber along the coast, the stock on them can
not be estimated at more than half a sheep to an acre, which will give 85,700 sheep, and nearly 3000 packs of wool. In the greatest proportion of the other parts of Lincolnshire, short-woolled sheep are kept, which will be considered hereafter. There are, however, a few long-woolled sheep also, the stock being about two sheep upon three acres; the number of sheep is estimated at 505,700, and the quantity of wool 16,900 packs. To the pastures of the eastern and midland districts of this county, the looms of Norwich, Sudbury, Northampton, and Halifax, are indebted for the materials of workmanship.

The long-woolled breeds of sheep are principally met with in the western division of the county of Norfolk, called the Marshland. There are also some sheep of this description in the eastern point of the county, and on the banks of the Yare. The first tract may be regarded as the extreme part of the Lincoln district, on which there are about 11 sheep to eight acres, each yielding a fleece of 7 pounds. The number of long-stapled fleeces in Norfolk may be estimated at 38,500, and their weight at 1120 packs.

Although the Lincoln district of long-wool extends no further to the south-east, it yet stretches into, and comprises a considerable proportion of Cambridgeshire, particularly the fenland, and the isle of Ely. The stock here is very light, probably it does not exceed one sheep to two acres; the weight of the fleece is nearly eight pounds; the number of sheep being 41,700, the wool produced will be nearly 1400 packs.

It is extremely difficult to estimate the number of sheep, producing long-wool, that are kept in Huntingdonshire; the flocks of this county being of such various or dubious characters. Probably of the kind of sheep we are now considering, there are, in this county, 87,500, fed upon as many acres of land, which, taking the average fleece at 7 lbs, will give rather more than 2500 packs. Of these, part is combed and spun in the neighbourhood, particularly on the Northamptonshire border; another part is sent to Leicester, and wrought into stockings; a third portion is used in the manufacture of the Yorkshire woollens; and the remainder is manufactured at Bury St Edmunds, and at Norwich.

The next breed of long-woolled sheep that claim our notice, are the Dishley. In Leicestershire there were formerly two distinct breeds of sheep, known by the names of the old and the new Leiceste; but at present very few of the first are seen. The new Leiceste are principally met with in the county from which they take their name, in Rutlandshire, the inclosed parts of Northamptonshire and Warwickshire, and the richer soils in the eastern part of Staffordshire, and the south of Derbyshire; comprising an extensive tract, the second in point of dimension, which produces long wool. In consequence of the excellent system of sheep-farming practised in Leicestershire, and the natural fertility of the soil, it may be computed that this county maintains 380,500 sheep, which produce more than 11,000 packs of wool. Notwithstanding the very large proportion of common-field land in Northamptonshire, (which of course is incompatible, or at least highly unfavourable to sheep farming,) the stock is estimated at one to every acre, and the weight of the fleece at more than 6 lbs.; the whole produce being 16,000 packs of wool, from 640,000 sheep. In Rutlandshire, the number of sheep is supposed not to exceed 114,000, which, if the average weight of the fleece be 5 lbs., will give, as the produce of the county, nearly 2400 packs of wool. In the south-eastern quarter of Warwickshire, the stock of sheep is considerably heavier than in any other part of the county; and in the north-western quarter it is very light. Even on the richest soils, the number of sheep cannot be estimated at more than seven to eight acres of land; the weight of the fleece does not greatly exceed 5 lbs.; the number of sheep are about 160,000, consequently the annual produce is about 3400 packs. In Staffordshire comparatively few sheep are kept. Large flocks are found chiefly on the rich land near the banks of the Trent, in the south-east angle of the county; and even here the stock is probably not heavier than 7 sheep upon 25 acres; which, supposing that there are 14,000 acres, over which the heavy breed ranges, will give 3700 sheep, producing rather more than 100 packs.

The Romney Marsh sheep are the next species of long-woolled sheep which come under our consideration. They are almost exclusively confined to that part of Kent from which they take their name. In this very fertile marsh, it is estimated, that each acre keeps five sheep. The fleece, on an average does not weigh more than 7 lbs. though particular cases have occurred in which the weight has risen to 12 or 14 lbs. On the marsh there are probably 185,000 sheep, producing 5400 packs of wool. In the isle of Sheppey, some of these sheep are also kept; but though the weight of the fleece is the same, the stock per acre is less; so that on this part of Kent, the number of sheep and weight of fleece is less than might be expected from the natural fertility of the soil. Probably on the banks of the Thames and the Medway there are 108,000 sheep, furnishing nearly 3200 packs. Almost the whole of the wool of Kent is manufactured in the west of England.

In Devonshire there are two kinds of sheep; but the long-woolled are confined almost entirely to the southern division of the county. The fleeces are estimated at 9 lbs. on an average; but this estimate is too high, 8 lbs. being nearer the truth. The number of the long-woolled sheep in this county is about 194,000; which, at an average of 8 lbs. will give 1550 packs. The most singular, as well as the smallest of the districts which produce long-woolled sheep, are the Cotswold Hills in Gloucestershire; from which, it is said, though probably without foundation, that the Spanish flocks derive their origin. On the Cotswold Hills, the fleece, on an average, weighs about 8 lbs. The stock may be estimated at one to each acre, and the produce at about 6700 packs, there being about 200,000 sheep. Thus we have gone over all the districts that contain long-woolled sheep, and, from the statements we have given, it will be seen, that the total number of this kind of fleeces which England produces, is nearly 4,200,000, from about 4,000,000 acres of land; and the weight of the wool amounts to 131,000 packs, of 240 lbs. each. To this quantity must be added the weight of skin-wool procured from slaughtered sheep, which will probably bring the whole quantity of combing wool up to 187,228 packs.

The short-woolled sheep are not so easily arranged or short-wool-estimated as the long-woolled kinds. There are six different kinds of them; the Norfolk, South Down, Wiltshire, Reyeland or Herefordshire, the heath sheep, and the Cheviot or mountain sheep. The Norfolk sheep is found chiefly in that county, in Norfolk and Suffolk, and in parts of Cambridgeshire and Essex. In Norfolk, it is calculated that there are about 684,000
sheep, which at 52 sheep upon 59 acres of land, and at the average weight per fleece of 2 lbs. will give 5700 packs of wool. In Suffolk, where rich loams and clays abound more than in Norfolk, the sheep afford rather a heavier fleece, weighing probably nearly 2½ lbs. The stock is about 490,000, and the quantity of wool amounts to nearly 5000 packs. The Norfolk breed was formerly confined to the eastern part of Cambridgeshire, while the southern and central parts were occupied by the Wiltshire breed; but at present the Norfolk sheep are gaining ground in that county. The average fleece is rather less than 4 lbs. and the number of sheep is estimated at 47,000; these, with the sheep in the fens, which produce short wool, will make the entire quantity about 1120 packs.

A very small proportion of Huntingdonshire is devoted to the grazing of short-woalled sheep, and on the ground where they are kept, there is not a heavier stock than three-fourths of a sheep per acre; so that the whole number is not more than 108,000, producing about 2000 packs of wool. In Bedfordshire, the most careful and accurate observations make the stock of sheep to be at the rate of 52 sheep upon 97 acres; the average fleece is about 5 lbs.; the number of sheep 204,000; and the produce of wool about 4000 packs.

In Essex there was formerly a breed of sheep (probably native) which produced a fleece of long and coarse wool, usually weighing about 4 lbs. At present, the Norfolk, South Downs, Wiltshire, Dorsetshire, and Welsh sheep are kept in the centre of the county, while the Dishley breed are found along the coast. The Norfolk occupies the borders of Suffolke, and the Wiltshire the north-western part of the county. The Welsh, or at least sheep resembling the Welsh, are kept on Epping Forest. The number of sheep kept in Essex, (reckoning all the kinds which produce short wool,) may be at the rate of two upon three acres of land, and the average fleece at 3½ lbs.; the whole number of sheep at 519,000, and the quantity of wool at 6500 packs.

The next breed of short-woalled sheep which claim our notice, are the South Down sheep, which were first cultivated with success on that part of Sussex from which they derive their name. In this district it is usual to shear lambs; the quantity obtained from each being about 8 ounces; the sheep producing about 2 lbs. The whole stock, on their native soil, may be estimated at 316,500, and the wool which they produce at 2630 packs. If the rest of the county of Sussex is taken into the account, where the South Down sheep are kept, the whole number will probably reach 547,000, and the fleece 6800 packs. Most of the wool goes into Yorkshire, and a small part into the west of England. In the county of Kent, the flocks of short-woalled sheep amount to about 7000 packs, shorn from almost 324,500 sheep; each full grown sheep being estimated to produce 3½ lbs. of wool, and the lambs about 8 ounces. The manufacturers in the north of England take off most of the produce. The native breed of Hampshire are something between the sheep of Dorsetshire and those of Wiltshire, producing a fleece better than the former and worse than the latter; but the South Down have gained a considerable footing in this county. The stock is estimated at two sheep upon three acres; the weight of the fleece is about 3 lbs. and the total produce of wool is about 6500 packs, from nearly 517,000 sheep. In the isle of Wight are the Hampshire, Wiltshire, and Dorsetshire breeds, intermingled with the South Downs. The whole island is supposed to support about 61,000 sheep, producing nearly 300 packs of wool.

Suffolk is the last county in the southeastern district of short wool; it maintains the Dorset, Wiltshire, South Down, and a few Hampshire and heath sheep. On the strong lands, the stock is nearly five sheep on six acres, which gives 273,000 sheep. If to these be added the stock of the heaths, which may amount to about 16,000 sheep, and take the average fleece at 3 lbs. the produce of the county will be somewhat more than 3300 packs of wool, which is manufactured principally in Yorkshire and Lancashire.

In Wiltshire we enter on a new district of short wool. The management of the flock is well understood here, and the fold is the chief object for which it is kept; for this purpose the Wiltshire sheep are peculiarly well adapted. On the chalky division of this county their numbers are very great, the South Down sheep having, within these few years, gained admission along with the native breed. This district of Wiltshire is supposed to support 583,500 sheep, which yield, at 2½ lbs. each, a produce of nearly 6700 packs of wool. In the north-western part of the county a much lighter stock is kept, generally about three sheep to four acres, or perhaps, on an average, not more than one sheep to two acres. The number of sheep is estimated at 117,500; which yield, at three pounds of wool each fleece, 1490 packs. Nearly the whole of the wool is wrought in the western manufactures.

In Berkshire, the Bagshot-heath, Wiltshire, Dorset, in Berkshire and South Down breeds are kept. The average weight of wool produced by these different breeds, is about 3½ lbs. The stock about three sheep upon four acres; the total number 306,000; the whole produce 150 packs of wool,—part of which is wrought by the western manufactures, and the remainder used by those in the north of England.

In the southern division of Oxfordshire, the Wiltshire sheep are kept; about four on five acres; the fleece averaging 3½ lbs. while in the northern division it averages 4 lbs. In the whole county there are probably 804,000 sheep, and 5300 packs of wool. Of this quantity one part is used at home, in the manufacture of blankets at Witney, and of worsted slags at Banbury; a second portion is employed at Leicester, in the stocking trade; and a third is sent to the Yorkshire clothiers.

The wool of Buckinghamshire, with the exception of that which is produced on the chalk hills of that county, is fit for the use of the clothier. It is derived principally from sheep of the Dorset and Wiltshire breed, though in some parts the Dishley breed has been introduced. The stock in this county is about six sheep to eleven acres; the total number 283,000; the fleece, on an average, 3 lbs. and the whole wool produced 2800 packs: a small proportion of which is used in Leicester, by far the greater part going into the Yorkshire clothing country.

The sheep in Hertfordshire are chiefly of the Wiltshire breed, though the South Down are rapidly making progress in that county. The fleece of both kinds may be averaged at 3½ lbs.; the total number of sheep at upwards of 277,000; and the whole produce of wool at 5300 packs. Nearly the whole of it is wrought up in the north of England, some little at Leicester, and some in Suffolk, at Bury St Edmunds.
The vicinio of the metropolis, and the peculiar demands on agricultural produce which it creates, render Middlesex by no means remarkable, either for the number of sheep which it supports, or for the judicious nature of their management, or the quality of their wool. The stock here is extremely light, not being more than 19 sheep upon 22 acres; and as not half the ground supports this animal, the total number cannot be reckoned at more than 45,000; the average weight of whose fleeces being 4 lbs. the whole wool produced in this county is 750 packs.

In Dorset.

The sheep of Dorsetshire, it has been already remarked, resemble those of Wiltshire; in one respect, however, they are more valuable, at least to the sheep farmers in the vicinity of the metropolis, as they lamb very early in the season, and thus supply the London market, at a time when this kind of food is in great request, and consequently very dear. In the county from which they derive their name, they are, however, in some measure driven out by the introduction of the South Down. In the isles of Portland and Purbeck, and about Wareham and Poole, a small kind of sheep prevails, different from the native breed, and resembling the Welsh sheep. The stock of Dorsetshire is about 652,300, or 28 sheep to 51 acres. The average fleece is 3 lbs. and the whole produce of wool is 9900 packs. In this county the lambs are shorn, and the wool from them is about one-third of the quantity obtained from the dams. Most of the wool is employed in the manufactures of the west of England.

In Devon.

In Devonshire, besides the long-wooled sheep already noticed, there are several kinds which carry short wool; the average fleece of which may be estimated at 4 lbs. According to which, from 437,000 sheep, there will be produced about 7500 packs of wool, which is manufactured within the county.

In Cornwall.

Cornwall, both on account of the moisture of its climate and the nature of its soil, is ill adapted to sheep-husbandry. It is extremely difficult to form an estimate of the stock kept in this county; it is very light, probably not more than one sheep to four acres; the weight of the fleece is about 4 lbs.; the number of sheep about 200,000; the quantity of wool they afford, nearly 3400 packs. The yarn produced from it is partly wrought into the common serge of the county, and partly sent to Devonshire.

In Somerset.

In the east of Somersets the Wiltshire sheep are kept, and in the west the Dorsetshire breed. Besides these, there is a peculiar breed in Exmoor, and a sheep of very small size on the Mendip Hills. The weight of the fleece in this county varies very much; some not being more than 2 lbs. while others rise to 14 lbs. the average, perhaps, is about 4 lbs. The stock is light, not more than 10 sheep upon 17 acres; the number, 500,700 sheep; the produce about 9400 packs of wool; a small quantity of which is sent into Yorkshire, and the principal part manufactured within the county.

The sheep on the Cotswold Hills have already been noticed. On the hills in the eastern parts of Gloucestershire the Wiltshire breed are kept; in the vale of Gloucester, the same kind as on the Cotswold Hills; and to the west of the Severn the Herefordshire breed. The fleece of the first kind is about 5 lbs.; that procured from the vale 5 lbs.; and that from the Herefordshire about 2 lb. The whole stock is about 355,000; the produce in wool above 5400 packs; part of which is wrought in Yorkshire, and part in the home manufactury. The limits of the western district of short wool are accurately defined by the ocean, the Severn, and the chalky soil, which bounds that river towards the east.

In Herefordshire, another variety of the short-wooled In Herefordshire, another variety of the short-wooled sheep is found, which afford about 2 lbs. of very excellent wool; they are generally known by the name of Ryeland sheep. In this county, the practice of cutting their sheep is very common. The stock kept may be estimated at three sheep upon four acres; the number of sheep at 500,000; the produce about 4000 packs of wool, which is sent to the clothiers both of the north and the west of England.

Upon one-third of the land in Monmouthshire, a stock of one sheep to five acres is kept, each producing 1½ lbs. of wool; on the remainder of the soil there may be three sheep to four acres: the whole number being about 177,000 sheep, which yield 1400 packs.

The sheep of Worcestershire are in general small, in Worcestershire, particularly in the southern portion of the county, the farmers of which display great spirit in the improvement and extension of the best breeds; but the flocks of this county are in general light, by far the greater number weighing only from 1½ to 2½ lbs.; in the level country they sometimes weigh 4 lbs.; on the average, the whole may be calculated at 2½ lbs. The stock is nearly 17 sheep to 30 acres; the number of sheep 422,000, and the whole quantity of wool 4400 pack. The whole produce is manufactured in Yorkshire.

The greater part of Staffordshire supports short-wooled sheep. Here 21 occupy 150 acres of ground. The fleece weighs about 2 lbs. The total number of sheep is estimated at 183,000; and the packs of wool amount to 1520: the greater part of which is sent into Yorkshire, the remainder being wrought up in the county itself.

In the counties of Warwick, Lincoln, and Leicester, there are a few sheep bearing short wool kept. In the first mentioned county probably 183,000, producing 2500 packs of wool. In Lincolnshire, principally on the Wolds, and on the drier soils of the heaths of Ancestor and Lincoln, there may be kept of these kinds of sheep 123,000, producing 2800 packs of wool; the stock being two sheep upon five acres, and the fleece weighing nearly 3 lbs. Short-wooled sheep are found on the forest land of Leicestershire, where the number may perhaps consist of 20,000, and the whole fleeces 250 packs.

On the sandy soil of Nottinghamshire, to the west of the Trent, there is a small breed of sheep, producing nearly 2½ lbs. of fine wool. The enclosed land in the same part of the county contains a heavier stock, the fleece being 4 lbs. Over the whole of Nottinghamshire there may be about 27 sheep on 40 acres. The forest breed yields about 700 packs, the heavier breed nearly 2120, and the Dishley breed, which is also kept here, 1820; the whole number of sheep being about 255,200. Part of the wool of Nottinghamshire is wrought within the county, but by far the largest quantity is sent into Yorkshire.

In Derbyshire we meet with a new district of short...
wool, which extends from the high peak to the borders of Scotland, and from the moorlands of Yorkshire to the Irish sea. The sheep have black faces and legs; their fleeces are loose and coarse. Other kinds, however, are kept in this county. The average stock is about 21 sheep on 19 acres; the whole number kept 362,400; the fleece averages 3 lbs.; and the total quantity of wool may be estimated at 4530 packs, the market for which is in Yorkshire.

In Cheshire very few sheep are kept. They, in general, are small, producing short and fine wool. The stock is heaviest on the high grounds, on the eastern part of the county, and on the forest of Delamere. It is calculated that the whole number in the county does not exceed 15,000, which, yielding an average fleece of 4 lbs., give 380 packs of wool. In Cheshire, the skin-wool bears a much larger proportion to the fleeces than in most other parts of England.

Lancashire also supports few sheep. The return of stock in this county, made by order of government in the year 1803, includes 80,930 sheep; but this return is evidently grossly erroneous. It is much more probable, that, as there is nearly one sheep to three acres of ground, the whole number may amount to 310,000; and as the fleece averages 3 lbs., the quantity of wool produced in Lancashire may be estimated at 4520 packs, which is wrought either in the manufactures of the country, or in those of Yorkshire.

In considering Yorkshire as supporting short-wooled sheep, it may be proper to take the three Ridings separately. In the West Riding a great variety are met among others, the Dishley and the Cheviot. In the more fertile parts, the fleece probably weighs 4 lbs., and is at the rate of four sheep on seven acres; while on the hills, where the mountain breed are kept, the stock cannot be calculated higher than one sheep to eight acres, and the average fleece at 3 lbs. The produce of the whole of this Riding, therefore, is nearly 5000 packs of wool, obtained from 261,700 sheep. The long-wooled sheep of Holderness, in the East Riding, have been already noticed. On the Wolds, a great number of the short-wooled kind are kept; according to the best accounts, about 53 upon 40 acres; the fleeces weighing nearly 5 lbs.; the total number of sheep 366,240; the packs of wool 6400. In the North Riding, averaging the stock and fleeces of the eastern and western moorlands and the vale of York, the former may be one sheep to two acres, and the latter may weigh 6 lbs.; affording 4660 packs from 280,000 sheep. Most of the wool from the North Riding is sent into the west of England.

In Westmoreland, the breed of sheep is of the mountain kind. On the low lands of this county there is about half a sheep to an acre of ground, but on the mountains not half that proportion. It is calculated that the total stock may amount to 225,700 sheep, which afford 3260 packs, at 3 lbs. each; the greatest part of which is wrought by the manufacturers of Kendal, and the remainder sent into Yorkshire.

On the mountains of Cumberland, the Herdwick and the mountain breed are kept; and other varieties in the vale lands. Part of this county is very thinly stocked, on 200,000 acres there not being more than 50,000 sheep; on the remainder of the land there may be nearly half a sheep per acre. Over the whole county, perhaps, there are 378,400 sheep, producing 5000 packs of wool, at the average of 23 lbs. the fleece.

The Teeswater district of Durham, on the which the long-wooled sheep of that denomination are kept, has been already described. Over the rest of the county short-wooled sheep are generally kept; the average fleece may be estimated at 5 lbs.; the number of these sheep at 159,400; and the whole produce of wool at 3300 packs.

On the mountains of Northumberland the black-faced heath sheep are kept; but in other parts of this county a better stock prevails, namely, the Cheviot breed. On the mountains the stock is light, not amounting to more than 179 sheep on 277 acres; in the other districts it is heavier. Probably in the whole county there may be 558,000 sheep; and as the average fleece is about 4 lbs., the total quantity of wool will be 12,330 packs. The greatest proportion of this wool is sent to Yorkshire; a part of it to Aberdeen, and other places in Scotland; and the remainder is manufactured within the county.

Over nearly the whole of Wales the sheep are singularly small, with horns, white faces, and white legs; but the influence of different kinds of manufactures is visible on the flocks of the principality, especially on the flocks of Montgomery, over which the influence of the market at Welshpool for Welsh flannels extends. And in Glamorgan, a breed somewhat similar to those on the Cotswold Hills is kept. In North Wales the stock is light, five acres supporting not more than a single sheep, exclusively of cattle. In this division of Wales it may be estimated that 683,000 are maintained, producing nearly 5300 packs of wool, the fleece being reckoned, on an average, at 2 lbs. The principal marts for it are the fairs of Llanreost and Bangor.

On the mountains of South Wales, the same kind of sheep are met with, which occupy the mountains of the northern division of the principality; but they are more numerous in general; the fleeces are reckoned at 1 pound, and give as their total weight 5570 packs, the produce of 571,000 sheep: the home manufactures take off the whole of it.

Besides the various kinds of sheep which have been Merino described, the Merino or Spanish sheep must not be passed over unnoticed; they were introduced into this country about 14 years ago, and for some years were a very favourite breed; but it has been ascertained, that though the fleece does not much degenerate here, yet the carcase, which is naturally very ill formed, and affords comparatively little weight of meat, does not improve; and as the farmer, in the kind of sheep which he keeps, must look not only to the produce of wool, but also to the butcher market, he has found it his interest rather to return to the native breeds of his own country, and to give up the Spanish sheep; they are, however, been of considerable service to the flocks of England, having been judiciously and successfully crossed, in many instances, with the South Down, Ryeland, &c.

It may be proper, as well as useful and acceptable to General readers, before quitting this most interesting and important branch of our subject, to give the general results of the details into which we have entered.

In the first place, with regard to the long-wooled sheep of England, from the details which we have given, it appears that the number of sheep of this kind, kept in this country, amount to 4,153,308.

That the total number of acres on which they are maintained is 3,939,563.

That the average fleece of the long wool, varying in
ENGLAND.

From the data which have been given, the important and difficult point respecting the number of sheep in this country may be ascertained, with as near an approximation to the truth as can be expected on such a subject; the following table will exhibit the result:

<table>
<thead>
<tr>
<th>Description</th>
<th>Number</th>
</tr>
</thead>
<tbody>
<tr>
<td>Number of long woolled sheep</td>
<td>4,158,508</td>
</tr>
<tr>
<td>Number of short woolled sheep</td>
<td>4,221,748</td>
</tr>
<tr>
<td>Total number of sheep</td>
<td>19,007,607</td>
</tr>
</tbody>
</table>

The grand result of these investigations, that the number of sheep in England and Wales does not much exceed 26 millions, and that the produce of wool is not annually 400,000 packs, we must acknowledge is at variance with the general opinion on this most important subject, which estimates the produce of England and Wales at 600,000 packs, and increases the number of sheep nearly in the same proportion; but this opinion either rests on no specific and particular data, or it is grounded on an erroneous estimate of the quantity of land in England and Wales, and, in the next place, on an overcharged calculation of the quantity of stock kept per acre. We have already had occasion to point out the error in the estimate of the quantity of land in this kingdom, which reckons it considerably above 40 millions of acres. The number of acres capable of supporting sheep certainly cannot be supposed much to exceed 32 millions of acres; the quantity of stock per acre has been averaged from the average stock of the different counties, by Mr Luceock, in his "Treatise on English Wool," whom we have followed through all these details, with great confidence, from a well-founded opinion of his minute and extensive knowledge on this important subject; and, with him, we have no doubt, that the estimate of 600,000 packs of wool, as the annual produce of England and Wales, is far above the truth, and that it does not reach 400,000 packs.

The original and established breeds of cattle, with their permanent varieties at present in England, are the following: First, the Devonshire; from these are derived the Herefordshire, the old red cattle of Gloucestershire, and the Sussex. The Devonshire are admirably calculated for draught, and faten easily; they are a most beautiful and well-formed animal: they are chiefly found in the county from which they take their name. The Herefordshire are rather larger than the Devonshire, but similar to them in most of their qualities; the cows yield a large portion of rich milk; they also are princi-
pally met with in the county from which they derive their name. At this time, it is difficult to find any specimens of the old variety of the Gloucestershire reds, which seem to have been a mixed breed from the Devonshire and Welsh cattle. The Sussex cattle are in high estimation for beef and labour; and with respect to milk, they excel the Devonshire and Herefordshire. They are a mixed breed, having been produced by a crossing of Welsh cattle. They are principally found in Sussex and Kent; in the former county, oxen are more used for draught than in most parts of England; great numbers of them are fattened in the marshes and meadows. In Kent are also found a different kind of cattle, called the Kentish home breed, which are well adapted for the dairy; they are of a mixed breed, the Sussex being most predominant, crossed with the Welsh, Alderney, &c.

The next breed consists of the Welsh mountain and lowland cattle; those of Glamorganshire are in high repute for draught; they resemble the cattle of Normandy. The Pembrokeishe somewhat resemble those of Glamorganshire, but they are not equally valuable. The next Welsh county in which the best breed of the principality occur, is Cardigan; but varieties of this breed are found all over Wales, and in most of the southern counties of England; they are in general quick feeders.

The next are the Lancashire, and north-western and midland country long horns: they were originally confined to Lancashire, Westmoreland, and Cumberland, from whence they spread to the south, into the counties of Derby, Nottingham, Leicester, Stafford, Warwick, Northampton, and Buckingham. It is rather a singular circumstance, that the neck of land, containing Lancashire and Cumberland on the western, and Yorkshire, Durham, and Northumberland, on the eastern coast, should have been the parent country, both of the long-horned and short-horned cattle; the latter extending from Northumberland southward, to the county of Lincoln. It was on the Lancashire long-horned, that Mr Bakewell made his experiments for the improvement of cattle, and the result was the new Leicester variety, which are calculated solely for the grazer, the old breed retaining their superiority in the dairy. The former are in great request in almost all parts of the kingdom.

The northern short horns, which include the Teeswater, Lincoln, Holderness, and Tweedside varieties, are the largest breed in England; the Hereford being next to them in that respect: their peculiar advantages are that they fatten kindly, and yield large quantities of milk and tallow; but their milk is not rich, and the cattle themselves are coarse and ill formed. They are principally found in the eastern counties.

The extreme coarseness and size of this breed led to the introduction of Norman and Alderney bulls, which were first imported into Holderness in Yorkshire; the mixture of these seeds has produced that useful and valuable variety, from which the stock generally kept by the London cow keepers is supplied. The pure Alderney breed, which are of a very small size, and are distinguished for being very rich milkers, are chiefly found in the south of England in the possession of gentlemen.

The northern, or Yorkshire polled cattle, are very similar in their qualities to the short horned, amongst which they are found.

The Norfolk home breed, formerly the principal stock in the county whence they derive their appellation, when attention was given to breeding in it, are now seldom met with, though they are still in much repute where they are kept, and bring high prices from the Smithfield salesmen.

The Suffolk dums, which are polled and small sized, are most excellent for the dairy, yielding abundance of rich milk: they are chiefly found in Suffolk and the adjoining counties, and are generally supposed to have originated in the polled Galloway breed of Scotland, with which Suffolk and Norfolk have been supplied during the last century.

There are no data, on which to found an estimate nearly approaching to the truth, respecting the number of cattle kept in England; though, as the English nation consume a much greater proportion of meat than most other countries, the number must be very considerable. Mr Arthur Young, in his Tour to the North of England, estimated the value of beasts at L. 36,480,000; and as at that period, the average value of cattle could not be more than 10, the whole number kept then was probably between three and four millions; the stock of cattle, since that time, has not increased much. By another mode of calculation, we may arrive at nearly the same conclusion: we have already seen that the annual slaughter of sheep is not quite one fourth of the total number kept in England and Wales; but the annual slaughter of sheep for the kingdom is about ten times as great as it is for London. Now the average annual supply of cattle for London is rather more than 100,000, which, for the whole kingdom, would be about 1,000,000; and if we reckon the annual slaughter of cattle for the whole kingdom as about one-fourth of the stock kept, we shall have about 4,000,000 cattle. It is evident, however, that in all this calculation, there is too much conjecture for the result of it to be regarded as a near approximation to the truth. It may be remarked, that Gregory King estimated the beoves, stirsks, and calves, in his time, at 4,500,000.

The rearing of calves forms an important branch of Rearing of husbandry, in some parts of this country, particularly calves in Essex, and in the vale of Aylesbury in Buckinghamshire. In Cheshire, more calves are fed during the months of March and April, than in any other part of England; but, as the milk cannot be long spared, they are killed very young. The suckling of calves, for the London market, is carried on to a considerable extent at Cottenham, in Cambridgeshire, (already mentioned as celebrated for its rich cheeses,) as well as in Essex.

There are several kinds of horses bred and kept in this country, well adapted for the saddle, either as road horses or as hunters; and for working, as well as for the race-course. In the midland counties, particularly in Northamptonshire and Leicestershire, a very large breed is kept. They are generally a dark black colour, and well adapted for the cart. It is said, that the improvement in this breed, which were originally ill-compacted in their make, took its rise from six Zealand mares, sent over by the late Lord Chesterfield, during his embassy at the Hague. The improved breed began in Derbyshire, at his lordship’s seat. It afterwards spread into Leicestershire, where Mr Bakewell, so deservedly celebrated for his improvements in the breed of sheep and black cattle, turned his attention, experience, and judgment to them, and still further improved them. The great demand for this breed is in London, where they are seen in full perfection in the dray-carts, &c. Yorkshire also has long been celebrated for its breed of horses, both for the saddle and for draught, but especially for the former. A variety of Bred of horses, which are of large and strong size, and are known in the market as “Yorkshire.”
of this animal, extremely well adapted for the plough, has lately been bred in the district of Cleveland. Suffolk also produces a breed of these animals, short, well compacted, and active, which are very valuable as farm horses. The Welsh horses are small, but active. In no country in the world has so much attention been paid to horses, for hunting and the race course, as in England; and this attention has been rewarded by the excellence of the animals reared. Foreign stallions of the most esteemed species, such as those from Barbary, Turkey, &c. have been procured at a very great expense; and, according to Buffon, the English horses, in respect to figure, nearly approach those of Arabia and Barbary. It has been said, that an Englishman is naturally fond of his horse; and this popular saying is confirmed by the very superior and attentive manner in which horses of nearly all descriptions are kept, of whatever class of people their owners may be. The fondness of the English for horse-racing has undoubtedly contributed to improve the breed, at least in respect to symmetry of form and speed. The best race-horses run 22½ fathoms in one second, or nearly a mile in a minute.

The number of horses employed in agriculture has never been very accurately ascertained. Mr. Marshall supposes that each square mile employs 20 horses, which is about 3 to 100 acres; if this supposition be correct, and we reckon that, in England and Wales, there are 80 millions of acres of cultivated ground, the number of horses would be about 900,000. The following facts will render this calculation still more probable: In 1804, the number of horses for which duty was paid in Great Britain, was 1,178,000; but, besides these, there were a great many others; and from the communications made to the Board of Agriculture on this subject, it was calculated, that at this period there were 200,000 pleasure horses, 40,000 cavalry horses, 1,200,000 employed in husbandry, and 850,000 colts and mares. Now, if we deduct from the 1,200,000 horses employed in husbandry in Great Britain, the number we may suppose to be employed in this way in Scotland, which is probably between a fifth and a sixth of what are employed in the whole island, we shall have between 900,000 and one million for the horses used in husbandry in England and Wales. In 1806, the number of horses was estimated at 919,924, of which about 20,000 were supposed to be employed in stage-coaches, post-chaises, and hackney-coaches. In the Appendix to the Report of the Committee on Broad Wheels and Turnpike Roads, it is calculated that 100,000 horses are in constant employment, in waggons, carts, &c. on the roads, for 300 days in the year. By the 13th George III. the load allowed to each horse is 16 cwt.; but let us suppose each horse carries half a ton, and goes 20 miles a day. The expense of carriage varies from 1s. to 2s. per ton per mile. On the 16 principal roads, the average is rather more than 1s. If we take it at 1s. and allow each horse to draw half a ton, two miles, the annual value of the labour will be L.150; and for 100,000 horses, L.15,000,000. The quantity of hay and oats necessary to keep pleasure horses cannot be reckoned at less than five acres; and the same quantity for cavalry horses. Perhaps four acres may be sufficient to keep horses employed in husbandry, on the roads, &c. while breeding mares and colts will not consume the produce of three acres. The expense of keeping each horse, on an average of all the kinds kept in this kingdom, even at the low price of 32s. per quarter for oats, cannot be estimated at less than L.52 per annum.

Mules and asses, especially the former, are not very abundant in England; and are scarcely, if at all, used in husbandry. They are in general larger than those of other countries, Spain, Portugal, and Malta excepted.

There is a great variety in the breeds of swine kept in this country, of which the following are either the most common, or the most valuable.

The Berkshire, which is small boned, and disposed to fatten quickly. It has extended from the district, from which it derives its name, over most parts of the island. It is the sort mostly fattened at the distilleries, and is good either for pork or bacon.

The Chinese breed, the size of which is small, and the flesh delicate, is also to be met with in almost every county. It is the best adapted for using as pork, but is seldom cured into bacon, being too small for that purpose.

The Gloucestershire breed, which Mr. Marshall supposes to have been formerly the prevailing breed of the island, is large, but ill formed. Its colour in general is white. It is a very unprofitable sort; and is chiefly confined to Gloucestershire, Shropshire, and the west of Devonshire.

The Hampshire breed is very large; but not so compact as the Berkshire. They are white, well disposed to fatten, and come up to a great weight when properly managed.

The Herefordshire is a large useful breed, but not by any means superior to either the Berkshire or Hampshire.

The Rudgwick breed, so called from a town of that name in Sussex, on the confines of Surrey, is supposed by Mr. Middleton to be the largest in the island; feeding to an extraordinary size, and, at two years old, weighing nearly double or treble the weight of other sorts of hogs of that age.

The Northampton breed, which are reared chiefly in that county, are of a large size, but they do not fatten very kindly. The breed of Shropshire is nearly similar to that of Northamptonshire.

The swing-tailed breed are not very numerous. Their size is small; their form well proportioned. They are very hardy, and fatten to a good weight.

A new variety of swine was introduced by the late Duke of Bedford, called the larger-spotted Woburn breed, which are very prolific, hardy, and well disposed to fatten, attaining nearly twice the size and weight of other hogs, within the same period of time.

The counties in England most remarkable for the quantity and quality of their hams, are Westmoreland and Yorkshire; and those in which bacon of the best quality is cured, are Wiltshire, Hampshire, and Berkshire. At Farringdon, in the last named county, upwards of L. 4000 worth is sold in the course of the year. Very little either of bacon or hams are exported; but they form a considerable branch of internal commerce.

Goats are reared in the mountainous parts of the north of England, particularly on the Cheviot Hills; but in much greater abundance in Wales. The breed of English and Welsh goats is large, and their skins valuable. Their milk also yields a profit.

Rabbit warrens are kept only on such kind of land as is not fitted for any more lucrative and valuable purpose. These are more numerous and extensive per-
It is calculated, that in the county of Worcester alone, there are in the inclosures, between 300,000 and 400,000 trees, principally oak, ash, elm, and willow, which might be removed, without any sensible injury either to the proprietor or the occupier of the soil.

Oak is by far the most important, though not the most abundant of English trees. It flourishes in great perfection on the Wealds of Kent, Surrey, and Sussex; in the hedge rows of Cheshire, in Monmouthshire, Flintshire, and several other parts of England and Wales; but there are some counties that produce very few oaks indeed, considering their size, perhaps not more than may be sufficient for their own consumption, such as Middlesex, the greater part of Hertfordshire, Oxfordshire, Wiltshire, Dorsetshire, Devonshire, Somersetshire, Gloucestershire, (with the exception of the forest of Dean,) Lincolnshire, Cambridgeshire, Norfolk, Suffolk, and several others.

But the principal supply of oak is derived from the Royal Forests, of which the following statement will exhibit the extent of the land, in which the timber belongs to the crown:

Besides the timber in these forests, the crown possesses much of it in Windsor Forest, and in the lands belonging to it, in the Duchies of Cornwall and Lancaster.

It is a generally received opinion, that the growth of oak timber is on the decline in this kingdom; and this opinion is confirmed by the result of two investigations, which were made at different and very distant periods, into the state of the oak timber in several of the Royal Forests. In the year 1608, a survey was made of all the timber that was fit for felling in the Royal Forest, and other estates of the crown. The whole, however, was not completed, neither the Forest of Dehsh, nor that of Whichwood, being comprised in the surveys; but the result appears to have been, that on the part of the Crown's estate that was surveyed, there must have been then growing about 649,880 loads of timber fit for the navy, and 1,148,650 loads of what was decayed and decayed. In 1783, another survey was taken, by order of the House of Commons, from which it appeared, that in New Forest, Aicholt and Woolmer, Bere, Whittlewood, Salcey, and Sherwood, there were only 50,445 loads of timber fit for the navy; whereas, in 1608, in these forests, there were 234,229; and that, in 1783, there were in these forests only 33,554 loads of decayed trees; whereas, in 1608, there were 265,145; so that the quantity of timber in 1783, in those forests, was little more than the sixth part of what it was at the former period. The general fact of the decrease of oak timber in nearly all the counties of England was further confirmed in 1791, by the answers which were returned by some of the principal timber merchants and land-surveyors, as well as by the chairman of the Quarter Sessions of the several counties in England and Wales, to questions sent to them by the commissioners of the land revenue.

Besides oak, elm, ash, beech, alder, and willow are elm, ash, common in the hedge rows, &c. of several of the counties. It is impossible to form an estimate of all these kinds of trees. Mr. Malcolm, in his survey of Surrey.
supposes, that of oak there may be five trees in every 20 acres; but this is evidently a random conjecture. An attempt was made some years ago, to have a survey taken of all the timber growing on private estates in England; but the surveys were interrupted by the proprietors before they got through the second county.

Sect. VII. Statistical Branch of the Agriculture of England.

We now come to the statistical branch of our present subject, which includes many curious, important, and highly interesting particulars; but, like all statistical enquiries, our investigations on this subject cannot be expected to proceed on data absolutely certain, or to give results quite conformable to the truth. The principal points to be ascertained, are the number of cultivated acres in England and Wales; the distribution and application of these acres; the value of their several kinds of produce; the rental of the land; the capital employed in agriculture; the profits arising from his labours and capital to the farmer; the number of people employed in agricultural pursuits, &c.

1. We have already endeavoured to show that the quantity of land in England and Wales is about 35,000,000 acres; it may be proper, however, to add, that by the accounts depended on by Mr Rose, the total acres are 37,334,400; and by the reports returned to the Board of Agriculture, the amount is 37,900,455, exclusive of Wales, which contains about 5,000,000 acres. The first point to be ascertained, whichever of these numbers we take, (and considering the impossibility of obtaining accuracy on this subject, as well as the total amount, the difference in these statements is not very considerable or important,) respects the quantity of waste land. In 1795, the Board of Agriculture referred the subject of the waste lands in the kingdom to a committee, who seem to have taken considerable pains in making enquiries and gaining information; from their report it appears, that at that time the number of acres of waste land in England was 6,259,470, and in Wales 1,659,093, making a total of 7,918,777. Dr Becke, who reckons the total number of acres to be less than the statements of the Board of Agriculture, or Mr Rose makes them, considers the number of acres of waste land to be also fewer; not estimating them higher than 6,477,000; to these, however, he adds, 1,310,000 for roads, water, &c. In consequence of the enclosure bills that have passed since the Report of the Board of Agriculture in 1795, the number of acres of waste land must be somewhat decreased: probably if from 38,500,000 acres, the total in England and Wales, 7,500,000 acres for waste land, roads, water, &c. are taken, we shall leave nearly the amount of the number of acres, either cultivated, or covered with useful timber, that is, 31,000,000 of acres.

2. The next point relates to the distribution and application of this quantity of land. There can be no doubt, both from particular enquiries in the agriculture of the several counties, and from the general and acknowledged fact of the great consumption of animal food in this kingdom, combined with another fact, as indisputed, that land under grass will not support nearly so many inhabitants as under the plough; that the proportion of pasture land is much greater than that of arable land. Dr Becke, in his pamphlet on the Income Tax, supposes that there are 17,881,000 acres in pasture, meadows, &c. while there are only 11,491,000 that are arable; according to other statements, the quantity of pasture ground is 17,479,000 acres. The Board of Agriculture calculates that there are 12,000,000 acres set apart as grass land for meat, and 4,000,000 acres for the dairy. The ground employed in the culture of hops, or for nurseries, is supposed rather to exceed 40,000 acres. The pleasure grounds, and fruit and kitchen gardens, may amount to 50,000 acres.

Taking the arable land at 11,500,000 acres, our next enquiry respects the distribution and application of it. It is probable, that notwithstanding the improvements in husbandry by the abolition of fallow on light soils, the old system of wheat, spring corn, or beans and fallow, is still followed on nearly six-tenths of the arable land of England and Wales, including the common field lands: three-tenths are probably under a rotation similar to that pursued in the county of Norfolk, of wheat, turnips, barley or oats, and clover; and the remaining tenth is under various rotations. According to this statement, 10,000,000 acres of arable land would be cropped in the following proportions: Wheat, 2,750,000 acres; oats and beans, 2,500,000; barley and rye, 750,000; roots, that is turnips, cabbages, &c. 1,000,000; clover, 1,000,000; and fallow, 2,000,000. If this statement, and the ratio on which it is founded, be correct, the number of acres under wheat may be estimated at about 3,200,000 acres; the oats and beans at about 2,800,000 acres; the barley and rye, at about 890,000 acres; the roots, at about 1,100,000 acres; the clover the same; and the acres of fallow at rather more than 2,200,000 acres. We must confess, however, not only that this estimate, like all estimates on this subject, is founded on insufficient data, but also that with respect to the number of acres which it assigns to barley and oats, it falls much below the estimate of Mr Arthur Young. According to him, there are 3,990,926 acres employed in the cultivation of wheat, and barley and oats occupy half as much land again as wheat, consequently the number of acres under these species of grain amount to 3,098,890.

The value of the produce of the cultivated land in England, it is evident, must vary very much, not only according to the different degrees of productiveness in various years, but also according to the price of corn, &c. On this subject, also, there are various conjectures and estimates. Before we proceed, it will be proper to endeavour to form some idea of the average quantity of the different kinds of grain, &c. raised on an acre of land, throughout the different counties of England and Wales. In this we shall be much assisted by the result of the enquiries of a committee of the House of Lords, on the scarcity in 1800. By their directions, the Board of Agriculture investigated the subject with considerable attention and minuteness; and in the Appendix to the Report, Tables were drawn up, from the answers sent to the Board, of the average produce of wheat, barley, &c. in nearly all the counties of Britain. These tables we have compared with the various agricultural reports published by the Board; and having supplied the deficiencies, and corrected them where they appeared to be erroneous, we shall lay, in one Table, the general results before our readers.

</table>

Were the counties of England and Wales all of the same size, and did the proportions of wheat, barley, &c. cultivated in each county nearly correspond, we should be at little loss from this Table, to ascertain the average produce of the whole kingdom in wheat, barley, &c. Even as it is, we may from it infer, with tolerable accuracy, that the average produce of wheat cannot be rated higher than two quarters and a half per acre; of barley, four quarters; of oats, four quarters and a half; of rye, three quarters; of peas, two quarters and a half; of beans, three quarters and a half; and of potatoes 250 bushels. We shall not go into the details of all the calculations which may be formed from these average produce; but confine ourselves to the most important. The number of acres in wheat we estimate, at 3,200,000, which at 2½ quarters per acre, will give 8,000,000 quarters as the total product of England and Wales. That this is nearly the truth, will appear from this consideration: the quantity of wheat used annually by each individual may be estimated at six bushels; taking the population at the gross number of 10,500,000, this will give 63,000,000 bushels, or nearly 8,000,000 quarters. It may perhaps be objected, that the population of England and Wales is fed partly by imported wheat; but in answer to this we observe, that in estimating the produce we have not taken credit for seed-wheat, which, at one-ninth of the produce, is much more than we have imported on the average of some years. The value of this produce it is not so easy to ascertain, the price of wheat having varied so much of late years; but if we take it at L4 per quarter, the total value of the wheat crop, will be L32,000,000. Of the remaining 5,850,000 acres, (exclusive of fallow,) we may suppose that the average produce is about half the value per acre of the average produce of wheat; that is L5 per acre, which will give L29,150,000. The produce of the pasture land is probably worth L4 an acre on an average, which will give L60,916,000. The produce, therefore, of wheat, barley, oats, &c. and of pasture ground, will stand thus:

<table>

Exclusive of the value of the produce of hops, nursery, garden grounds, orchards, &c. Mr Arthur Young, in his Agricultural Report of Essex, estimates the rental of England at L30,000,000, and the value of the produce, (taking all kinds of it into the account,) at L145,800,000. Mr Middleton, in his Survey of Middlesex, enters into very minute and laborious calculations on this important and difficult subject; and the result of his enquiries is, that the whole agricultural produce of the agricultural capital of England and Wales is L126,690,000; and this result he arrives at, notwithstanding he rates the total number of acres in the kingdom much higher than we do, by estimating the average crop of all kinds of produce of arable land at only L5 per acre, which is certainly at present much below the truth. 4: On this subject, however, we shall probably be enabled to come nearer the truth, if we can determine the rental of the lands in England and Wales; since it is well known, that the produce bears a certain proportion to the rental. Formerly, land-surveyors in valuing land, or giving their opinion respecting the rent which it ought to afford, considered that the average produce should be equal to three rents; but at present, in the opinion and practice of the most intelligent and experienced, it is calculated that the rent ought to be only one-fifth of the produce. The actual rent of England and Wales is impossible to ascertain exactly; but the rack-rent, or the rent at which the lands are valued in the opinion of judicious and experienced men, was returned to the House of Commons in the year 1810, by the commissioners of taxes: This return we lay before our readers in the following Table.

\[ L.29,509,073 \times 4.5 = L.132,763,928 \]

In calculating the value of agricultural produce by means of it, it seems fair, as it exhibits the rack-rent (though where the lands are let at their full value, the rack-rent and real rent must correspond, and in some cases, the real rent would be above the fair rent, or that rent which would be quintupled in the produce,) to consider it as \( \frac{4}{5} \), instead of \( 5 \) times the value of the rent. If we go on this supposition, then the value of the agricultural produce will be exhibited thus, \( L.29,509,073 \times \frac{4}{5} = L.132,763,928 \), which differs very inconsiderably from the result on this point, which we obtained by the former mode of calculation. It may,
perhaps, be thought, that as we before averaged the rent of land at 20s. per acre, we over-rated it; since, at this estimate, the total rent would be greater than this Table proves it to be; but in our estimate, we took into account only such pasture land as is let by the acre; and of course excluded all the downs, sheep-walks, &c.

5. About twenty-four years ago, Mr Young estimated the capital employed in agriculture in L.4 the acre; since that time it has increased very much; probably it is more than doubled; so that if we take every thing into account, it will now require L.10 per acre, or at least L.8. The number of cultivated acres has been estimated at 31,000,000, which, at L.8, would require a capital of L.248,000,000; and, at the latter rate, of L.310,000,000: Let us take the medium, and the agricultural capital will amount to L.279,000,000. On this point Dr Hooke's statement is very much at variance with ours; for he estimated the farming capital in 1800 at L.125,000,000, taking it on an average at 5 clear rents, viz., pasture 2 to 3, and arable 5 to 7 rents; but, as he estimates the average rent of England and Wales only at 1½s. the acre, this would be making the capital only L.4 the acre; a sum, even at that period, much too small. Besides, he estimates the net profits of the farmers at L.15,000,000, which we shall immediately prove is little more than the amount of half their profits; and consequently, as the profits must always bear a certain proportion to the capital employed, if the statement respecting the profits is only about half of the truth, the statement respecting the capital must be erroneous in much the same ratio.

6. The same Table (No. 2, p. 736.) which exhibits the amount of the annual value of the land in England and Wales at rack-rent, gives also an account of the annual amount of profits arising from farming land, drawn up from the returns made to the tax-office respecting the income-tax, and presented to the House of Commons. From this column of the Table it appears, that the farming profits are L.294,476,852, or nearly the amount of the rent. Now, in order to arrive at the amount of the capital employed in agriculture, from the amount of agricultural profits, it will be necessary, in the first place, to fix the rate per cent. of the profit. This certainly cannot be reckoned at a lower rate than 10 per cent., which would make the agricultural capital amount to L.294,768,520, which, considering the magnitude of the sum, and the imperfection of the data on which we are obliged to proceed, does not differ very considerably from L.279,000,000, the amount of agricultural capital at which we arrived by calculating it at L.9 per acre.

7. The next enquiry into which we shall briefly enter, respects the absolute value of the landed property in England and Wales. Having ascertained the amount of the rack-rent, we shall have little difficulty in elucidating this point, provided we can determine the number of years' purchase at which land is sold; that is, how many rents ought to be given for the fee-simple of land. Mr Arthur Young, in his Enquiry into the progressive Value of Money, estimates the rate at which land was sold in the year 1811, at 28 years' purchase. As this, however, must have been on the real, and not on the rack-rent, some deduction must be made on that score; while, on the other hand, no addition ought to be made to the rate since 1811, as the value of land certainly has not increased since that year. Assuming, therefore, that L.28,000,000 was the amount in that year, either of the actual rent, or of the rent of such estates as were within a very short period of the expiration of their leases, we shall have the total amount of the value of the landed property of the kingdom, if we multiply this sum by 28; this will give L.784,000,000 as the result.

8. By the returns under the population act in 1811, it appears that the number of families employed in agricultural operations in England was 697,358; and in Wales 72,846, making a total of 770,199. The average number of people in a family is about 4·5; which will make the whole number of people employed in agricultural operations 3,465,895. The number of farmers, or persons occupying farms, is supposed to be about 200,000. On this supposition, if we take the amount of their profits at the round sum of L.30,000,000, the average profit of the farmers will be about L.150 per annum.

It is scarcely necessary to repeat the observations which we have already made more than once, that the result of all these calculations must be considered as merely approximations to the truth. We are also sensible, that, with respect to some of the statements of which we have made, they differ from those given by statistical writers. This difference is accounted for, we trust, favourably to the superior accuracy of our statements, by our grounding them on the results of Table No. 2, p. 736; which must be regarded as resting on more minute, careful, and extensive enquiries, than any private individuals could make. In defence of the accuracy of our statements, we would likewise observe, that they are at variance with statements made 10 or 15 years ago; and we need not remind our readers, that, even within that short period, the advance on the value of every thing (from whatever cause proceeding) has been great. There is only one point on which we feel hesitation and doubt; and that is, respecting the capital per acre required in agriculture. Yet if Mr A. Young came near the truth in estimating the English capital employed in agriculture in 1789 at L.4 an acre, whoever reflects on the increased price of all the expenses attendant on a family and a farm, as well as on the different manner in which farmers now live, will not deem L.9 per acre as an overcharged estimate of the capital which a farmer, who expects to do justice to himself and his farm, ought to possess for every acre on which he enters.

Before we conclude this branch of our subject, for the length of which we must apologise on the ground of its extreme importance, we shall offer a few historical notices on English farming at various periods. This will enable our readers to judge of its progress, and to compare its former with its present state; for statistical enquiries, which are confined entirely and exclusively to the present state of a country, are neither so interesting, instructive, nor so intelligible and connected, as those that also embrace some notice of its former state.

The first decided and important epoch in the history of English agriculture may be fixed in the reign of Henry VII, when a notion began to prevail among the nobility and gentry, that their estates might be rendered much more valuable to them, by being employed in grazing than in tillage. In consequence of this opinion, which was acted upon for this and the two succeeding reigns, there was much discontent among the lower classes of the people; till at length in Elizabeth's time, acts were passed for promoting and encouraging tillage, which were supported by Lord Bacon, and opposed by Sir Walter Raleigh, who thought it impossible to
England.

render grain a staple commodity of this country. His speech exhibits a striking picture of the state of English agriculture at that period. According to him, the poor farmers could not purchase seed to sow the land, which the law required to be sown; and France offered the Queen to supply Ireland with corn at two shillings a bushel, at which price our farmers would be beggars. It would seem that the tillage laws passed by Elizabeth were found to be inefficient, if not injurious, for by an act of the 39 Eliz. they were repealed.

There does not seem to have been any regular mode of conducting the husbandry of this kingdom, or any essential improvements introduced into it, till the restoration of Charles II. At this period, many of the landlords, who had assumed the cause of that monarch, and retired to the continent, on their return introduced several of the principles and modes of practice which they had observed abroad, particularly in Flanders. There is, indeed, good reason to believe, that clover, saffoin, the folding of sheep, and perhaps turnips, (though the introduction of the last is generally fixed at a much later period,) were brought into this country about the time of the restoration of Charles II.

After this time, agriculture advanced slowly but gradually, being in some instances benefited, and in other instances rather obstructed, by the works of some fanciful writers. We allude particularly to the writings of Tull, which have been of essential service in contributing to introduce the row culture at least for green crops, but which had a tendency to do mischief, by insisting on the uselessness of manures.

Hitherto, whatever improvements had taken place in arable husbandry, little attention had been directed to the improvement of the stock of the island. At last Mr. Bakewell turned his thoughts to this subject, and his example being followed by several spirited and judicious farmers in various parts of England, more particularly in the north, this branch of husbandry, as we have already remarked, has, in by far the greatest portion of the kingdom, advanced considerably before its arable husbandry; and indeed the principal and most important improvement in this latter branch may very fairly be traced to the great improvement in stock; for the zeal and anxiety of farmers with respect to their stock, led them to cultivate green crops on a larger scale, and with more attention and judgment, than they had previously done; and by means of these crops, not only was their ground kept clean, but it was also enriched, by the additional quantity of manure, which the consumption of them supplied.

The last epoch in the history of English husbandry was the establishment of the Board of Agriculture; from which perhaps not all the benefit has been derived which was expected, and which might have been obtained, had their proceedings been more cautious and judicious; but which nevertheless has contributed greatly to spread agricultural information, to make each part of the country acquainted with the implements and practices of the other parts, and to soften and break down agricultural prejudice, of all prejudices the most stubborn and long-lived.

Still, whoever has formed his opinion of the excellence of English agriculture, from the high character which this nation bears for enterprise and success in other branches of industry, and particularly in manufacturing and commercial industry, will be much disappointed. Over the whole kingdom, and even in the immediate vicinity of the largest towns, where the demand for agricultural produce must be great and regular, and where the means of improvement are ample and easily acquired, wastes and commons are found, many of them consisting of a soil by no means naturally unfertile, and all of them capable, at little expense, of being rendered in some degree productive and beneficial to the inhabitants. Besides these wastes and commons, what are called common fields (where the ground, though cultivated, is so much subdivided, and the property so much intermixed, that it is absolutely impossible to practise good husbandry, or to derive from it the produce it might yield) are numerous. While these things are so, the agricultural industry and enterprise cannot be rated very high. At the same time it is fair to state, that within these last 50 years, numerous acts of parliament have been passed to inclose and improve these commons and common fields; while before his present Majesty came to the throne, these acts were very few. The first inclosure by act of parliament took place in the reign of Charles II.; the next in Queen Anne's reign. From 1719 to 1759, 249 acts were passed; from 1764 to 1779, the number was 941, averaging 58 annually; from 1780 to 1794, there were 445, averaging 30 annually; in 1795 and 1796, there were 146; and from 1797 to 1805, there were 704; making in all 2,991 inclosure acts. In the ten years from 1785 to 1796, the average number per annum sunk considerably; but in the nine years, from 1796 to 1805, it rose again higher than ever. In the first 40 years of his present Majesty's reign, there were 1213 inclosures, containing 1,990,189 acres, which gives an average for each inclosure of 1616 acres. If we estimate the total number of inclosures at this average, the quantity of land inclosed since the reign of Queen Anne, (for the inclosure in Charles II.'s time related to Malvern Chase,) will amount to 4,187,056 acres, up to the end of 1805. Since that period, the acts for inclosing commons and common fields have not been less numerous. We have entered on this statement, in order to shew, that, though these commons and common fields are a disgrace to the agricultural character and enterprise of the English nation, yet that disgrace is in the course of being wiped away.

It has been more than once noticed, that our agriculture has improved more with respect to farming stock, than with respect to the principles or practices pursued on arable land. Perhaps the truth of this observation cannot be placed in a stronger point of view, than by the following comparison between the weight of bullocks, &c. as it was one hundred years ago, and as it is at the present time.

Horticulture.

The horticulture of England is so justly celebrated, and is so closely connected with its agriculture, that we may be permitted to say a few words on the subject. When we consider the general coldness and moisture, as well as the extreme uncertainty and variability of our climate, it must be regarded as no unequivocal proof of our skill and success in horticulture, that by any means we are enabled to supply ourselves with as many

3
kinds as we do possess, of the fruits of more favoured and warmer countries. Nor are our kitchen gardens less distinguished for the variety and excellence of the vegetables which they produce. From the very great and constant demand that the fruit and vegetables which the most tropical regions of the world produce, the gardens in its vicinity are superior to any others, in the attention and skill with which they are cultivated, and in the returns that they make for the money and labour expended on them. The fruit gardeners near London not only stock their ground with apples, pears, cherries, plums, &c. which they call the upper crop; but they have also an under crop, consisting of raspberries, strawberries, &c. On these garden grounds it is supposed that a population is supported at the rate of ten persons per acre. We have particularly specified the gardens in the neighbourhood of London, as exhibiting proofs of English skill, enterprise, and success in horticulture, beyond what the gardens in the country exhibit. But in the vicinity of most of the large towns in England, and even at the distance of 15 or 20 miles from some of them, the excellence of our horticulture is apparent.

In ornamental gardening, and the laying out of grounds, England is also celebrated, being deservedly regarded as the parent country of real taste in this respect. Nowhere is so much attention, and, if the expression may be allowed, deference paid to nature, in the laying out of grounds, as in England. Such is the picture of this country, with respect to the result of the application of the capital, industry, and skill of its inhabitants, to the cultivation of the soil.

CHAP. VIII.

Of the Produce of Mines and Quarries.

The next branch of industry which we are to consider and investigate, is that which is employed in the mines and quarries of the kingdom. In the remarks which we offered on the mineral geography and geology of England, the produce of the mines was noticed in so far as it was connected with that branch of our subject: but it is now to be considered in another point of view. In what we are about to offer, we shall, as far as our materials enable us to do it, in the first place, enumerate the principal mineral productions of this country, on which the industry and capital of its inhabitants are employed, (so far as regards their unmanufactured state); in the second place, we shall point out the parts of the kingdom in which they are found; and, lastly, we shall endeavour to form an estimate of the quantity produced, the value of the produce, and the number of people employed, as well as particularize the uses to which the various substances are respectively applied. We must premise, however, that on the last head, our information must necessarily be either very loose and conjectural, or limited and partial, since there are not data on which to ground results, not only accurate but complete. In this alternative, we shall prefer giving what we know to be correct, though thus we must unavoidably pass over some part of our subject, to offering vague and unfounded conjectures and speculations.

I. It has been truly and justly observed, that "it seldom or never happens that countries abundant in the productions of agriculture should, at the same time, present an opulent mineralogy: yet England is far from being deficient in this respect." The author of this remark might have been justified in going farther, and in asserting, that England, with respect to those treasures which she draws from the bowels of the earth, holds a distinguished place among European nations, not so much perhaps on account of their very great abundance and natural richness, as on account of the industry, skill, and enterprise, with which she has availed herself of these treasures, and of the capital at first produced by these qualities, and afterwards brought to bear in conjunction with them, so as to raise her, in point of national prosperity, power, and wealth, to the exalted situation in which she now stands. In another point of view, also, may her mineral productions be, honourably for herself, distinguished from those of most other nations: with them, industry, or capital, or both, are in general merely sufficient to procure the minerals in their natural state, or at most, to change them into their rudest and least valuable form; but in England, the various minerals which are found in the bowels of the earth are, for the most part, by the skill and industry of her inhabitants, either converted into the most precious and exquisite, or the most useful and important articles, that the taste, the luxury, the comforts, or the wants of man demand; or they are made the instruments and means of producing those articles in the greatest abundance, and with the smallest application of capital and labour. The truth of these observations will be abundantly apparent, when we enumerate the principal mineral productions in this country, scarcely one of which will not call up to the mind of the most ignorant and careless observer, the rude material of what he daily uses, or the means of producing that rude material.

In point of importance, not only on account of its great abundance and utility here, but also on account of its comparative rarity in most other countries, coal must be mentioned: then perhaps tin, as another mineral, by which England is distinguished from most other nations: black lead, also, (though found here only in a very few places, and only in one place in abundance), claims our notice as an almost exclusive mineral possessed by England. After these, may be mentioned iron, lead, and copper; of what are called the inferior metals, (which are rare everywhere), zinc and manganese may be mentioned as the most important in our manufactures. Of the productions of our quarries, as distinguished from the productions of our mines, marbles and freestone, or calcareous sandstone, of various colours and textures, are in many parts of the kingdom abundant. There are also mines of rock salt, pits of fuller's earth, potter's clay, &c.

II. With respect to the counties in which the mineral productions just enumerated are found, to begin with coal, it may in general be remarked, (as has indeed already appeared from our account of the mineral geography of England), that it abounds in all parts of the kingdom, except the eastern, southern, south-eastern, south-western, and a few of the midland counties. In the following counties, it is found in greater or less abundance: Northumberland, Durham, Yorkshire, Cumberland, and Lancashire, in the north of England; in this northern district, Westmoreland is the only county destitute of coal; in all the rest it is very abundant. To the south of these counties, coal is found in Derbyshire, Staffordshire, and Shropshire: it is wanting in Cheshire on the west side, and Nottinghamshire and Lincolnshire on the east side of this district. Of the midland counties, Leicestershire and Warwickshire are the only two which possess this valuable mineral, none being found in Northamptonshire, Rutlandshire, Oxfordshire, or indeed to the south of
ENGLAND.

Statistics.

east of these counties; so that, besides the counties enumerated in these directions, Huntingdonshire, Cambridgeshire, Norfolk, Suffolk, Essex, Middlesex, Kent, Surrey, Sussex, Hertfordshire, Hampshire, Buckinghamshire, Bedfordshire, and Berkshire, are destitute of coal. As we incline to the west, it is also wanting in Wiltshire, Dorsetshire, Worestershire, Herefordshire, Devonshire, (with the exception of the bovey coal), and Cornwall; Gloucestershire, Somersetshire, and Monmouthshire, being the only counties that possess coal mines in this portion of England. With respect to North Wales, coal is found in Flintshire and Denbeighshire; and in South Wales, in Pembroke, Caermarthen, and Glamorganshire. Iron is found in Cornwall, Cumberland, Derbysire, Devonshire, Durham, Gloucestershire, Hampshire, Kent, Lancashire, Monmouthshire, Northumberland, Shropshire, Somersetshire, Staffordshire, Sussex, Warwickshire, and Wiltshire; but it is most abundant in Shropshire, Gloucestershire, Derbysire, the north of Lancashire, and Wales. Lead is found principally in Derbyshire, Cumberland, Northumberland, Somersetshire, Devonshire, Yorkshire, Durham, Westmoreland, Carlignan, Flint, and Montgomery. Tin is found in Devonshire, and the adjoining parts of Devonshire; and black lead to a small district in Cumberland. Mines of copper are wrought in Cornwall, Devonshire, Derbyshire, and Anglesey, and partially in Yorkshire, Staffordshire, &c. zinc is met with in Derbyshire, Cornwall, &c.: manganese on the Mendip hills in Somersetshire: rock salt in Cheshire and Worcestershire: alum slate in Yorkshire: gypsum or alabaster in Derbyshire and Nottinghamshire: fuller's earth in Berkshire, Bedfordshire, and Surrey: potter's clay principally in Dorsetshire: — and the stone quarries the most celebrated for the abundance and excellence of their stone, are those of Portland, Purbeck, Bath, Yorkshire, Northamptonshire, &c. The most extensive quarries of slate, (as has been already mentioned), are in Westmoreland, Yorkshire, Leicestershire, North Wales, Cornwall, and Devonshire.

Copper.

III. It is extremely difficult to form an estimate of the quantity produced, of the most important of these minerals, of the value of the produce, or of the number of people employed. The consumption of coal in the kingdom must be enormous: in private families, its course depends on the nature of the climate, the condition of the family, and the price of the coals. The following facts may perhaps supply data, by means of which we may arrive near the truth, respecting the consumption of coal for domestic uses. In London, the consumption is nearly about a ton annually for each individual, or perhaps more correctly about three chaldrons (Winton measure, or 28 cwt.) for each house. This appears from the amount of the quantity brought into London from Newcastle, and by means of the Paddington canal. In Manchester, where the climate is colder, and the coals cheaper, it is calculated that each individual uses two tons annually; or, supposing each family to consist of 4.5 individuals, this will give 10 tons for each house, or about seven chaldrons, Winton measure. In Newcastle, where the weather is still colder, and the coals cheaper, the mean consumption is one third of a Newcastle chaldron (nearly 18 cwt.) per month for every constant fire, equalizing the kitchen fire with the rest, which is as much for every fire as is consumed by each family in Manchester; and reckoning one and a half fire through the year, will give 10.5 chaldrons as the annual consumption. This perhaps may be taken as the extreme consumption of coals in families in the kingdom; and supposing the consumption in London to be at the lowest rate, the medium will be 6.75 chaldrons for each house in the kingdom in the course of the year; let us suppose it to be six chaldrons, the number of houses in England is 1,797,504: the total consumption of coals, therefore, for domestic use, will be 1,797,504 x 6, or 10,782,924 chaldrons, or rather more than one chaldron for each individual. This, it must be confessed, is mere conjecture; but it is probably not far from the truth. We shall not even offer a conjecture of the quantity of coals used in our manufactories, but content ourselves with stating the following facts. If the medium of the steam engines consist of 30 inch cylinders, they will consume 18 bushels of coals per day, which is equal to three chaldrons per week, or 156 chaldrons per annum. The salt-works in Cheshire consume 150,000 tons of coals annually. The smelting of the copper ore of Cornwall consumes nearly 200,000 tons of coals per annum; and it is calculated, that in the brass and copper manufactories, there are used nearly as many. In the Coalbrook-dale district of Shropshire, about 250,000 tons are raised annually — a great proportion is used in the iron works. The extensive iron works of Messrs Ferraday in Staffordshire, are said to consume 1000 tons per week. In two blast furnaces in Sheffield, from 600 to 800 tons of coals are used per week: and in the large iron works 1200. Indeed, when we consider that there are nearly 200 furnaces in which coke alone is used, the consumption of coal in the iron works of England must be regarded as immense.

In addition to these proofs of the very great supply and consumption of coal, the following miscellaneous facts may be stated: The quantity of coals raised yearly in Northumberland and Durham, is estimated by Mr Bailey at 1,000,000 chaldrons, Newcastle measure, (which contains 68 Winchester bushels, and weighs 53 cwt.) and he supposes that in those counties there are 200 square miles, or 128,000 acres of coal proper for exportation. In the year 1800, a committee was appointed by Parliament to inquire into the state of the inland coal trade; and from the evidence adduced, it was proved that in the neighbourhood of Dudley, very thick and rich seams of coal were wrought; that at Swansea, upwards of 500 vessels were annually employed in the trade, besides that the copper works there consumed from 1500 to 2000 tons per week; that in Leicestershire, there are many beds of coal very imperfectly and partially wrought; that a supply of coal to the amount of between 50,000 and 100,000 tons might be brought from Newport in Wales to London annually; and that not less than from 150,000 to 200,000 acres of coal are found in the neighbourhood of Leeds, Wakefield, &c. Besides our internal consumption, it is calculated, that in time of peace, nearly 150,000 Newcastle chaldron of coals are exported, principally to Holland, Hamburgh, the Baltic, Spain, and Portugal; and that between 300,000 and 400,000 chaldrons (Winton measure) are sent from Whitchaven, Workington, &c. in Cumberland.

The number of people employed, either directly or indirectly, in the coal trade, must also be very great: In 1792, it was calculated, that on the rivers Tyne and Wear, there were 64,724 men and boys employed; it has also been estimated, on tolerably good data, that in Durham and Northumberland, the proportion of men is as 10,650 to 1,480,080 chaldron of coals:— in both these estimates, however, it is proper to remark, that the seamen who navigate the colliers are taken into the account.
It appears that the iron mines of this country were wrought at a very early period, since iron works are known to have existed in the Forest of Dean in Gloucestershire, before the year 1066. In 1581, in consequence of the great consumption of wood which they occasioned, they were restrained by act of Parliament. In 1624, a patent for smelting iron with pit-coal was exempted from the law against monopolies; but the use of wood for this purpose seems still to have continued; for in 1719, complaints were made that the waste and destruction of the woods in the counties of Warwick, Stafford, Worcester, Hereford, Monmouth, Gloucester, and Salop, by the iron works, was not to be imagined. At this period, about 20,000 tons of iron were annually imported into England from abroad; and subsequently, when our manufactures increased, and before our own mines were properly wrought, the importation was still greater. In 1737, it was computed that England made annually at home about 18,000 tons of bar iron, which, at the rate of three tons of pig iron for one of bar iron, would give 54,000 tons as the produce of our mines. In 1783, a method was invented of converting pig iron into bar iron, superior to the Swedish bar iron; by which improvement it was given in evidence before the House of Commons, in the year 1812, when application was made for a parliamentary reward for the invention, that whereas, about 30 years before, the importation of foreign iron averaged about 50,000 tons, in 1810 it was reduced to 20,500 tons; and that our export of iron, which at the former period was only a few hundred weights, in 1810 amounted to 24,500 tons. From other documents laid before Parliament, it was ascertained, that our average import of foreign iron (principally bar iron) from 1800 to 1805, was 38,218 tons, of which 4590 were exported, leaving 33,628 tons for home consumption; and that the average of British unmanufactured iron exported from 1800 to 1805, was of bar iron 91,797 cwt., and of pig iron 40,186 cwt.: the increase between the beginning and end of that period was considerable, since in 1800 there was exported only 36,892 cwt. of bar iron, and 32,407 of pig iron; whereas, in 1805, there was exported of the former, 131,806 cwt., and in the latter 65,520. The average real value of pig iron exported from 1796 to 1805, was upwards of £14,000; and of bar iron, upwards of £29,000. At present, the iron mines of England are supposed to supply ore sufficient to produce considerably upwards of 150,000 tons of pig iron: 10,300 tons of which are made in Derbyshire, the remainder in Yorkshire, Staffordshire, Shropshire, Lancashire, Monmouthshire, &c. In the last county, there are nine furnaces, each of which makes about 2000 tons of pig iron yearly. At Mynythyr Tydvel, also, in Glamorganshire, there are furnaces for making pig iron, which produce 250 tons weekly, and consume 240 tons of coal daily.

Copper mines were first wrought in England in the year 1189: in 1561, mines of this metal were discovered in Cumberland; and, 1629, they were wrought in several counties. In 1690, copper was discovered in Wales, but it would appear, that during all this period, little attention was bestowed on working any of these mines; nor was it before the commencement of the 17th century that the valuable copper mines of Cornwall were properly and effectually wrought: and in a few years, the quantity produced had attained to a considerable amount. From 1726 to 1735, there was produced 64,800 tons of ore, which afforded the annual quantity of about 700 tons of fine copper. From 1736 to 1745, the ore amounted to 75,520 tons, producing 830 tons of fine copper. From 1746 to 1755, the produce of the former was 98,790, and of the latter 1080. From 1756 to 1765, 169,699 tons of the former, and 1800 tons of the latter; and from 1766 to 1775, 264,273 tons of the former, and 2650 of the latter;—thus exhibiting an increase in the produce of copper in 50 years, from 700 tons per annum, to 2650. About the year 1775, new copper mines were discovered in Derbyshire, which circumstance, added to the discovery of the famous copper mine in Anglesey, forms an important era in the history of this branch of English mining. As long as this latter mine continued productive, it furnished from 5000 to 10,000 tons per quarter, exclusively of what was obtained from the Mona mine, which probably was nearly as much; both together employing 1200 miners, and 90 smelters. But both the Parys and the Mona mines in some years produced comparatively little copper ore. In the mean time, the Cornish and Derbyshire ores were wrought with great spirit and success; so that the produce of them, and of the other mines in England and Wales, about the year 1791, had rendered this country one of the principal sources from which the world was supplied with this useful metal, instead of her depending, as formerly, upon foreign mines for a supply of it. It has already been shewn, that the Cornish mines in 1775, produced about 2650 tons a year: in 1798, the produce had increased to 5427 tons. At this time, the average annual cost of working them amounted to £313,589, of which the labour was £197,640, and the materials employed about 115,950: the number of men employed was about 5000, or perhaps nearer 6000. Within a very few years afterwards, the copper mines of Devonshire began to be wrought with spirit and success: in 1800 they did not produce more than 100 tons of fine copper: in 1804, the produce had increased to 300 tons. In 1805, owing to great exertions made in consequence of the high price of copper, the produce of the Cornish and Devon mines reached 7000 tons of fine copper, producing the amount of £1,260,000. At present, according to Mr Grenfell's Observations on the Copper Coinage, the Cornish and Devon mines yield 80,000 tons of ore annually; and the metal thus obtained being on an average from 5 to 15 in the 100th part, may be stated at 8000 tons of copper: almost all the ore is smelted in Wales. The consequence of this great increase in the produce of our own mines, notwithstanding the increased demand for copper, was visible in the diminution of our importation of this metal from foreign countries. In 1806, we imported, chiefly of copper ore, 43,600 cwt.: in 1807, upwards of 96,000: in 1808, 91,000: in 1809, 49,000: in 1810, 50,000: and, in 1811, only 20,000;—the ore itself having fallen from 73,800 cwt. which it was in 1807, to about 7000 cwt. in 1810.

In giving a historical sketch of the produce of the tin-mines in England, we shall not go farther back than the commencement of the 18th century. At this period, the mines, which had been neglected during the civil wars, were again wrought with effect and success, producing, one year with another, rather more than 1600 tons: From 1720 to 1740, the annual average...
produce was 2100 tons; from 1740 to 1750, 2500; from 1750 to 1760, 2658; from 1760 to 1770, 2728; from 1770 to 1780, 2750; from 1780 to 1790, 2958; from 1790 to 1800, 3245 tons. From the last period the mines seem to have been on the decline.

There is undoubted proof, that the lead-mines of this country, at least those in Derbyshire, were wrought in the time of the Romans, this metal having been exported A.D. 11; and at the time of the Conquest it was used to roof churches. In 1169, the exportation of it was carried to a considerable extent. During all this period, however, it would seem that no mines of this metal were known, or at least wrought, except those in Derbyshire. In the year 1299, lead-mines were discovered and wrought in Wales; and the circumstance being ascertained, that the ore of these mines produced some silver, increased attention and alacrity were given to the working of the mines of this metal. The produce of the lead-mines at present wrought in England cannot accurately be ascertained; those of Derbyshire are supposed to produce annually an average of between 5000 and 6000 tons, but to be on the decline; those on the borders of Cumberland and Northumberland are calculated to produce 150,000 pigs of 14 cwt. or 11,250 tons annually. The Cumberland employ upwards of 1000 men. The other metals which are found in England do not require any particular notice, except the black lead of Cumberland; the manganese of the Mendip Hills, and the zinc of Derbyshire. The first is of excellent quality, and in great demand for pencils, crucibles, &c. No more is wrought than is absolutely necessary to supply the demand, without lowering the price. The manganese of the Mendip Hills is become much more valuable than it formerly was, in consequence of the mode of bleaching by the oxidymuriatic acid, in which it is largely employed. The quantity of ore of zinc produced in Derbyshire, is about 500 tons annually. It is inferior in value to the calamine of Mendip. Besides calamine, blend, or black jack, another ore of zinc, but less valuable than calamine, is got in Derbyshire.

Salt pits.

The salt-pits of Cheshire and Worcestershire appear to have been wrought at a very early period; those of the former county are supposed by Mr Pennant to have been known to the ancient Britons; and the salt pits in Worcestershire were certainly wrought before the Conquest. In 1689, a license was given for making salt at Middlewich; but nearly 150 years after this, salt appears to have been so rare an article in England, that it was stipulated, that a quantity of it should be delivered annually by the king of France to this country. It is rather a singular circumstance, that though the brine pits were known so early, the pits of rock salt were not discovered in Cheshire prior to the year 1670. The quantity of rock salt made in Cheshire, seem rather to have declined within these few years. The annual delivery from the pits is between 50,000 or 50,000 tons, while the brine pits supply about 45,000 tons. At Droitwich, in Worcestershire, the salt made and sold in one year averages upwards of 600,000 bushels; of which, about one-sixth is sent abroad. The duty paid by the pits near this place, into the salt-office in London in the year 1771, was £61,457; at that time nearly one-third of the whole revenue from salt in England. The revenue from the salt made in Cheshire, however, is of so much more consequence, that a particular board is appointed for its collection and management, independent of the boards of customs and excise. It is estimated, that the home consumption of Cheshire salt is 16,000 tons, and the quantity exported about 140,000 tons. The following particulars will further illustrate the nature and extent of the produce of the salt pits in Cheshire and Worcestershire. In the year 1798, 816,731 bushels of rock salt were exported; of which, 651,820 were sent to Ireland, 54,900 to Germany, 49,800 to Russia, and 37,542 to Denmark. In the same year, 4,188,417 bushels of white salt were exported; of which, 910,782 were sent to Prussia, 895,430 to the United States of America, 676,629 to Russia, 407,152 to Denmark, 401,464 to Ireland, 306,103 to Germany, and 298,671 to British America. In 1799, the exportation of rock salt had considerably increased, the quantity being 1,336,025 bushels; of which, 394,975 were sent to Ireland, 167,600 to Denmark, and 163,317 to Prussia. This year the exportation of white salt had rather declined, the total exportation amounting to 4,192,182 bushels; of which, 1,234,027 were sent to Prussia, 1,036,617 to the United States, 549,560 to Russia, and 368,565 to Ireland. In the year 1800, the exportation of rock salt had again rather increased, the total quantity amounting to 1,977,571 bushels; of which, 760,549 were exported to Ireland, 510,582 to Prussia, and 173,098 to Russia. The exportation of white salt in 1800, was greater than it had been in either of the two former years, the total quantity being 4,538,542 bushels; of which, the United States took 1,436,085, Prussia 980,250, British America 551,958, and Russia 481,601. About 70,000 bushels are usually sent to Africa. It must be remarked, however, that the white salt includes what is made at the salt-pans, the principal of which are at Lymington in Hampshire, Sandwich in Kent, and on the coasts of Essex, Durham, and Northumberland. These we have mentioned here, from their connection with the subject of the salt mines, though not strictly in their place. The total number of salt works in the kingdom is between 180 and 190; and there are upwards of twenty refineries for rock salt. The salt sent coastwise during the year above specified, was as follows: British white, 5,631,562 bushels; of which, 3,827,510 were sent from Liverpool, 933,654 from the port of Gloucester, 293,512 from Bristol, 149,839 from Lymington, 146,983 from Hull, 116,948 from Sunderland, and 95,593 from Newcastle. During these years, 165,985 bushels of rock salt were sent coastwise, all from Liverpool. During the same years, 61,785 bushels of foreign white, and 32,50 of foreign rock salt were sent coastwise. The total consumption of salt by the inhabitants of England and Wales, is supposed to be 60,000 tons annually, besides what is used in the fisheries, for curing meat, &c. The statistical particulars connected with the quarries of this country are comparatively so minute and trifling, that we should not be disposed to enter upon them here, even if we had access to the requisite information; but, before concluding this part of our subject, it may be proper to add a few words respecting the pits of fuller's earth, from the immediate and important relation which this substance bears to our staple manufacture. We have already mentioned, that they are found in Bedfordshire, Berkshire, and Surry; a pit also has lately been opened at Maidstone in Kent. Although the demand for fuller's earth is not now nearly so great as it was formerly, in consequence of many of the clothiers using soap instead of it, yet there is still a considerable demand for it, especially for that which is procured in Surry. Mr Malcolm, in his agricultural account of that county, says, that he endeavoured to ascertain the annual consumption of the kingdom, and that, as nearly as might be, he found it to be about
ENGLAND.

Statistics. 6,300 tons; of which quantity, about 4,000 tons were sent from Surry. The price at the pit, in 1805, was about 5s. or 6s. per ton, whereas, in 1744, the price was 4d. per bushel, which is after the rate of 8s. per ton; a proof either that the supply had increased, or that the demand had diminished. Fuller's earth was deemed by the legislature of so much consequence to our woollen manufactures, that a special act was passed in the 28th year of the reign of his present Majesty, prohibiting the exportation of fuller's earth and fuller's clay, under a heavy penalty, and obliging the dealers and buyers of it to enter into bonds, to prevent its exportation; and certainly, whatever may be the opinion and practice now, the great and acknowledged superiority of English cloth was formerly ascribed, both at home and abroad, to the use of fuller's earth.

In estimating the amount of the national profit which is derived from our mines, &c. it is evident, that the mere profit derived by the individuals to whom they belong, even added to the net profit of those who lease and work them, will give us a very imperfect and inadequate notion of the increase which they bring to the stock of national wealth. In order to do this, we should be able to trace the raw produce of our mines through all its stages, till, by the wonderful effects of the unparalleled industry, skill, and capital of this nation, it appears in the form of the most useful or the most expensive articles of life. This, however, in most cases, it would be in vain to attempt, and, at any rate, where it is practicable, it would here be irrelevant, in a great measure, to our subject. We shall, therefore, conclude our account of the mining products of this country, with a tabular view of the profits from quarries, mines, and iron-works, derived by the proprietors, as returned to the House of Commons by the commissioners of taxes. It may be proper to mention, that though the report on the produce of the income-tax, accompanied with a particular statement of the profits from lands, &c. on which this tax was levied, was laid before parliament in 1812, it does not bring the details which we have extracted lower down than the 5th of April 1811.

CHAP. IX.

Manufactures.

CAUSES OF THEIR SUPERIORITY.

Before we proceed to the consideration of the manufactures of this country, it may be proper to premise some remarks on the principal causes which have contributed, either directly or indirectly, to advance and extend them to their present state. This inquiry will not only be in a high degree interesting, but also important and useful; since, undoubtedly, if we can open up the causes which have produced the flourishing state of our manufactures, we shall, at the same time, explain and detect the causes of our national wealth and prosperity.

In the first place, much must be ascribed to the freedom of our constitution; for it would be in vain to attempt the regular and permanent establishment of any manufacture, where the lives and property of those who were to be engaged in it were not secure. At the same time, this position must be taken with some limitation, since the love of wealth with some, and the spirit of industry and enterprise with others, is so strong and overbearing, as to urge them on to risk their property, and the fruits of their industry, even under an unstable and tyrannical government. But certainly a free constitution, though not absolutely essential to a limited and trifling degree of manufactures and commerce, is a necessary requisite for their flourishing and permanent condition.

In the second place, the British government, though it is not by any means free from the charge of an interfering spirit with regard to commercial legislation, has, perhaps, less than most other governments, interfered in an abrupt and improper manner; and, indeed, it may justly be doubted, whether the interference of government, in all cases of trade and commerce, is so necessarily and clearly prejudicial to their interests and flourishing state, as has generally been imagined. There can be no doubt, that the protection and encouragement of government, like the protection and encouragement of individuals, may be beneficial to the exertion of human industry. It is not essentially and necessarily fatal to it, but only, so far as it is exerted in an improper manner, or at an improper time, or continued when circumstances render it expedient that it should be withdrawn. At any rate, whatever may have been the consequences to the nation at large, of the duties on foreign manufactures, and the bounties and drawbacks on home manufactures, which the British legislature has at various times, and on various occasions, enacted, in obliging them to purchase the latter when they could have procured the former at a cheaper rate, there can be no doubt, that these enactments have contributed to the present flourishing and extended state of our manufactures and commerce.

MACHINERY.

In the third place, infinitely more must be ascribed to our improvements in machinery, and our consequent saving of labour, than to either of the preceding causes; though, if we trace this cause up to its source, we shall find, that these improvements in machinery, and this saving of labour, would not have taken place, unless the manufacturers had been protected by a free government; and probably not unless they had been further protected by duties on foreign goods, and bounties and drawbacks on their own. But whatever may have been the disposing causes of these improvements in machinery, by which so much labour is saved, there can be no doubt, that to them we should mainly ascribe the flourishing state and extent of our manufactures at present. It is sufficiently obvious, that men will prefer those articles, whether of necessity, comfort, or luxury, which are offered to them at the best quality, and at the cheapest rate; and it is equally obvious, that cheapness of price must depend, in a great measure, on the smallness of the quantity of labour by which they are produced, or on the low rate of wages or mercantile profit. The low rate of mercantile profit will afterwards be considered; but with respect to the low rate of wages, it may be remarked, that where it exists, the workmen are dissipated, and by no means disposed to exert themselves with that industry, attention, and skill, which are requisite to produce articles of a superior quality; but, by the introduction of machinery, though the rate of the workmen's wages is high, the actual sum of wages which enters into the price of any article is very low: Thus machinery at once enables the manufacturer to sell his goods cheaper, and to continue the same rate of wages, or perhaps to increase it, to his work people.

In the fourth place, the immense capital possessed by the manufacturers of this country must be regarded as one cause of the flourishing state of our manufactures. This acts, in many respects, in the same manner as machinery; by enabling the possessor of it to buy his raw material cheaper than he could otherwise do, it enables him to sell it cheaper. He can also afford to give longer credit, which is, in fact, to sell goods cheaper. But the most striking analogy between the effects of large capital and of machinery, remains yet to be pointed out and explained. We have just seen, that where machinery is used in the manufacture of goods, the value of the labor which enters into the price of these goods is much diminished, though the wages of the labourers continue the same; in like manner, when a manufacturer is possessed of a large capital, the rate of profit which he derives from the sale of his goods may be diminished, and yet his actual profit may remain the same; so that he can, by means of his capital, afford to sell his goods cheaper, and yet derive the same pecuniary benefit from his trade, which he did before his capital was increased. It is obvious also, that as the possession of a large capital is necessary to the erection and maintenance of machinery, and to the payment of the numerous labourers which it requires, capital, in this view of it, may be regarded as contributing to a diminution of price, and to superiority of quality, and consequently to an extension of demand, of trade, and of profit.

In the fifth place, the division of labour is carried much further in this country than in any other part of the world; on the consequences of this, so far as regards dispatch and dexterity (whatever may be its effects on the mind,) it is unnecessary to enlarge.

Lastly, besides these causes of the present flourishing state of the manufactures of this nation, all of which have been frequently pointed out and explained, there seems to us to be another cause which has not been sufficiently attended to and appreciated, in considering this subject. It is, we believe, generally admitted, that an English labourer will work with much greater and longer continued exertion than the labourers of most other nations. In two respects he is superior to them: in the first place, he possesses more activity and energy, both of body and mind, than the labourers of those nations who can plod at their work with equal steadiness, and for an equal length of time; and in the second...
place, he more than compensates for that superior quickness and agility of body and mind, which the labourers of France and some other countries display, by the steady and unremitting nature of his exertions. Such is the character of the English labourers in general; but it is obvious and natural, that this character will not display itself fully and permanently in action, unless there are circumstances sufficiently powerful to bring it forth; or, in other words, that the English labourer, like all other men, requires a powerful stimulus to induce him to work, with all the activity, energy, and steadiness of which he is capable. It was therefore desirable that his reward should be in exact proportion to his services; but in the case of his being paid by the day, this could not be the case, as his reward then was in proportion to the time he was employed, not in proportion to the quantity of work which he performed. Accordingly it was the interest of the master to pay his workmen by the piece; nor was it less their interest to accede to this proposition, since thus they were enabled to acquire more wages than they could possibly do when paid by the day. This system of task work, so common in almost all the branches of our manufactures, must therefore be considered as one of the causes of the cheapness, if not of the excellence, of the articles they produce; since, where a master pays his workmen in this manner, he is certain of getting a greater quantity of work done for the same money than if he had paid them by the day, and consequently can afford to sell his goods at a cheaper rate; while the workmen, feeling a more direct and deep interest in what they are about, will work with more spirit and enterprise.

Such appear to us to be the principal causes of the superior quality, the cheaper rate, and the wonderful variety, extent, and prosperity of our manufactures. Other causes may, and do undoubtedly exist and operate, but they are either partial, and confined to some particular branches of manufactures, or they may be traced up to those which we have just enumerated and explained.

Sect. I. The Woollen Manufacture.

Having premised these remarks, we shall now enter on our view of the manufactures themselves, beginning with the woollen manufacture, as the most ancient, and probably even yet, notwithstanding the rivalry of the cotton manufacture, the most extensive and valuable.

The introduction of the fabrication of woollens was undoubtedly owing to the Romans, who persuaded the rude and savage inhabitants of this island, not only to exchange the skins in which they had hitherto been clothed for the more comfortable attire of their conquerors, but also to turn their attention to the art of weaving. A manufacture was established at Winchester of sufficient magnitude to supply the Roman army; and there is reason to believe, that, while the Romans remained in possession of this island, this manufacture was continued. From the period of their quitting it till the commencement of the tenth century, there are not any evidences, either direct or indirect, by means of which we can judge of the state of the woollen manufacture; but at the latter period, from the prices of wool which are mentioned as the current rate of the fleece, there is reason to suppose that the article was cultivated with considerable attention. About the year 925, a fleece was valued at two-fifths of the whole sheep; a proportion much greater than that which it bears at present, and which proves, either that the demand for the carcass was much smaller, or that for the fleece much greater than it is in our own times. The value of the sheep continued nearly the same for some hundred years, while wool at the same time advanced in price, and continued to do so through the space of two centuries. The difference in value between them was very striking in the year 1135, at which time the price of sheep had declined 50 per cent, and the price of wool had advanced nearly as much. The demand for fine cloth, which seems to have been pretty general among the nobility in Henry II. time, led to the introduction of Spanish wool; but this was soon prohibited by a statute, which was framed for the encouragement of the British farmer, and the improvement of his wool. About the year 1240, the importation of fine cloth began to be encouraged, the consequence of which was, that English wool, being in some measure deprived of the home market, was sent abroad to Flanders, where it was manufactured. This kind of traffic subsisted about 100 years without interruption; till about the year 1330, the English began seriously to encourage the manufacture of woollens among themselves; and the mode which they adopted for that purpose displays a liberal and sound policy, very creditable to the times.

Sensible of the superior expertise of the Flemings, they tempted them to come over and settle in this country; their success and the improvement of the English was so great, that the legislature very soon began to imagine that the English fabrics were extensive enough to consume all the wool in the kingdom, and a law was accordingly passed totally prohibiting its exportation. The consequence was such as might have been anticipated and expected. Our fleece, which the regular demand from the Netherlands had increased in quantity, and greatly improved in quality, suffered in both respects. The surplus of wool appears from the time of Henry II. to that of Edward III. to have constantly increased, and the exportations as regularly took it from the hands of the grower, who, finding that he obtained a higher price in proportion to the goodness of the quality, turned his attention to the improvement of his fleece. Afterwards, when the woollen manufacture was established at home, it also exerted its natural influence on the quantity and quality of our wool; for the flocks in the southern part of the island, where the manufacture was most attended to, were in the best condition, and the quality of the staple most desirable.

Having thus briefly traced the woollen manufacture of England to the time of Edward III. when it may be said to have gained a firm footing in this country, we shall now content ourselves with giving some few detached historical notices concerning it, previously to entering on an account of its present state. It does not appear that the original seat of this manufacture was either in the west of England, or in Yorkshire; by some, Kendal is supposed to have been the first town where it was established; but the more probable opinion is, that the Flemings, brought over by Edward III. were fixed at Cranton, in Kent. In the beginning of the 16th century, however, the north of England was distinguished for this manufacture; for in 1520, it is recorded, that there were three famous clothiers living in the north country, viz. Cuthtbert of Kendal, Hodgskins of Halifax, and Martin Brian of Manchester, each of whom kept a great number of servants at work, spinners, carders, weavers, fullers, dyers, &c. Towards the middle of this century, Manchester, Lancashire, and
England.

Cheshire, are mentioned in an act of Edward VI. as famous for their cotton goods, which were, at that time, a species of woollen cloths. We have only a traditionary account of the place from which the woollen manufacture was introduced into that part of Yorkshire where it now flourishes; and this tradition reports, that it was brought thither out of Devonshire, where it had been settled by some workmen from Flanders. Rippon seems to have been one of the towns in Yorkshire, into which it was first introduced; but, according to Wright, in his History of Halifax, it was removed to the latter place for the sake of the advantage of the coals and water. During the infancy of this manufacture, the legislature interfered in it, not only by prohibiting the exportation of the raw material, but also by limiting and expressly naming the particular towns, both in the north and west of England, in which it was to be carried on. In 1534, the woollen manufacture in Worcestershire was conferred to five towns. In 1551, if we may credit the accounts, the Hanse merchants exported from this country 44,000 pieces of cloth, and the English manufacturers 1400 pieces; and a very few years afterwards, above 200,000 pieces were sent to the Netherlands. In 1614, a great improvement took place in the woollen manufacture of the west of England, by the invention of what is called medley or mixed cloth, for which Gloucestershire is still famous. At the end of this century, the total annual manufacture of woollen was estimated at L.8,000,000. In 1739, the author of Considerations on the running of wool, gives an estimate of the number of people employed in the woollen manufacture, rating them as high as 1,500,000, and, "if these earn, (he adds,) one with another per day, for 313 working days in the year, their wages will amount to L.11,757,500." This author, however, must have greatly overrated the number of people employed, since the wages of labour in this manufacture, at present, when the price of labour is at least four times as high as he takes it at, will not reach that sum. In the year 1770, it was proved, by documents laid before Parliament, that the official value of the woollen goods exported, amounted to more than L.4,000,000. From 1772 to 1776, the exportation seems not to have increased, as it appears from an account of the value, as rated in the inspectors' books, of all the woollen goods of all sorts, viz. bays, cloths, cottons (coating), flannels, serges, says, stuffs, stuffs mixed, carpets, and worsted stockings, that the amount of the whole of these articles exported from England, in 1772, was L.4,436,783; in the year 1773, L.3,975,929; in the year 1774, L.4,333,583; in the year 1775, L.4,280,173; and in the year 1776, L.3,868,053. At this time, as is the case at present, a much greater value of woollen manufactures was shipped from London than from all the other ports of England. In the year 1775, when the export of London was much less than in some other years, the value of woollens shipped from London was L.2,947,570; and from the exports, only L.1,978,602. As far as we are able to judge of the increase in our woollen manufactures from the quantity exported, it does not appear to have been considerable from the end of the 17th century till the year 1777, as will appear from the following statement of the value of the exports of it, at the former period.

In 1698, from London, L.2,102,634; and from the outports, L.1,017,981; total, L.3,120,615.

In 1700, 2,021,145; ... 903,018; ... 2,989,108.

In 1701, 2,045,961; ... 1,082,414; ... 3,128,365.

In 1789, a pamphlet was published, containing an estimate of the annual produce and condition of the principal manufactures of this country, in which the woollen manufacture was rated at L.16,500,000; but the data on which the author builds this calculation are not given. About this period, the demand for fine cloths seems to have been increasing, for in an account of the quantity of the principal articles imported and used in the manufactures of Great Britain, on an annual medium of five years, commencing 5th January, 1772, laid before Parliament, it appears, that from the year 1772 to the year 1776, the annual medium quantity of Spanish wool imported was 1,578,605 lbs.; and in the period of five years, ending 1787, the annual medium quantity was 1,975,327 lbs. The account was continued down to 1799, and it proved a greater rate of increase in the quantity of Spanish wool imported, during the two next series of five years, than before, on an annual medium from 1787 to 1792, 3,174,429 lbs.; and on an annual medium from 1792 to 1799, 3,880,583 lbs.

In the year 1799, an account of the total value of the woollen manufactures exported, agreeable to the estimate of the inspector-general's books, (and consequently at least 50 per cent. below the real value,) during the ten years preceding, was laid before Parliament; from this account, it appears, that the official value of these manufactures, during 1790, was L.5,190,637; during 1791, L.5,605,034; in 1792, L.5,510,668; in 1793, L.3,806,536; in 1794, L.4,399,920; in 1795, L.5,172,884; in 1796, L.6,011,133; in 1797, L.4,926,555; in 1798, L.6,499,399; and in 1799, L.6,860,939. The effect of the first year of the war is very visible in the diminution of the value of the exports for 1793. As this account gives the value of woollen manufactures exported to each different country, it affords a further insight into the state of the export woolen trade during this period. By far the greatest quantity every year appears to have been exported to the United States; in 1790, the value of the exports this year was L.1,481,376, and in the year 1799, L.2,933,490. Before the commencement of the war, Spain and Portugal seem each to have taken, to the amount of between L.500,000 and L.400,000, and Holland nearly an equal quantity. Ireland, in 1790, took to the value of L.1,894,790, which increased till the year 1793, when the value was only L.178,071. In the year 1794, the value again rose nearly to what it was in 1791; and continued to increase to the end of the period, it being in 1799 as high as L.916,190. The value of the woolen goods exported to India, (probably nearly all the manufacture of the west of England) varied, during this period, between L.892,500 and L.668,161. France, before the war, does not appear to have taken, on an average, woolen goods to the amount of L.100,000 official value.

In the month of April 1800, the principal manufacturers of woolen goods in Yorkshire, and in the West of England, were examined before a committee of the House of Commons relative to the state of that manufacture: We shall, in the first place, give the results of their evidence on this occasion, and afterwards offer some remarks upon it; premising, that where no prejudices or interests intervene, to conceal, exaggerate, or distort facts, more information is to be got, on the ma-
manufacturing and commercial state of the kingdom; from evidence given before Parliament, than from any other source, or by any other means; since no otherwise can access be had to the information, experience, and opinions of so many persons, who must necessarily be so extensively, accurately, and minutely informed, on the subjects on which they give their evidence.

The first point to which the evidence of the manufacturers examined before the committee of the House of Commons relates, is the number of sheep kept in England and Wales; these they estimated at 28,020,000; and the produce of the fleece from these sheep, they rated at 600,000 packs, of 240 lbs. each pack. Some of the witnesses, however, were of opinion, that the number of sheep, and consequently the produce of wool, had diminished between the year 1784 and the period of their examination. On the supposition that the number of packs was 600,000, they rated the total value of the wool in the kingdom at £6,600,000, being at the average price of £L.11 per pack. The next point to be ascertained respected the increase of the value of the raw material, after it was manufactured. This increase evidently varied very much; in some kinds of goods it was double only, while in other species of goods, the increase was ninefold. As the quantity of goods, in which the former rate of increase took place, consumed a much greater proportion of the raw material than the latter, the increase was supposed, on an average, to be threefold. According to this supposition, the total value of woollen goods manufactured in the kingdom amounted to £L.19,800,000. Having thus ascertained these points, or at least gained the opinion of intelligent and experienced manufacturers respecting them, it next became a question of considerable importance to determine the number of people engaged in this extensive manufacture. On this head, the evidence is not so distinct and satisfactory; we are merely informed, without any detail being entered into, or any satisfactory calculations given, that the woollen manufacture was supposed to give employment to three millions of men, women, boys, and girls: this astonishing number was given in evidence, as being actually employed, though at the same time, it was admitted, that, by the use of the machinery in the various processes previous to the weaving, 35 persons were enabled to do the work, which about the year 1785, when machinery had not been introduced into the woollen manufacture, required the labour of 1694 persons. It is evident, that, through the introduction of this machinery, the quantity of human labour necessary to manufacture the woollen goods was diminished, yet the capital requisite to carry on the manufacture must have been considerably increased; and it was given in evidence, that the capital vested in machinery and buildings appropriated to the woollen manufacture, was, in the opinion of the witnesses, supposed to be nearly equal to the value of the raw material, or £L.6,600,000.

Such was the evidence given respecting all the various branches of manufacture in which wool was employed; with regard to the woollen manufactures of the West Riding of Yorkshire, which at all times have been the most important and extensive in the kingdom, it was given in evidence, that there were employed in it 78,734 packs of wool, at that time worth £L.11 a pack, and consequently, on the whole, worth £L.800,074; and that from this quantity of wool, there was manufactured 278,755 pieces of broad cloth, which, at about £L.13, 18s. the piece, were of the value of £L.3,795,157. It was further stated, that there were 38,028 packs used in the woollen manufacture of the West Riding of Yorkshire, of the average value of £L.14 per pack, which were manufactured into 180,168 pieces of narrow cloth, the average value of which was £L.6 a piece, and consequently the total value of this species of cloth was £L.1,081,008, making the total value of broad and narrow cloths to be £L.3,876,165. The value of the kerseymeres, blankets, and other goods, was rated at £L.1,000,000; and the value of the stuffs, or worsted goods, at £L.1,400,000; the whole woollen goods manufactured in the West Riding being thus estimated at £L.7,876,165; or about 10/11 of the value of the woollen goods manufactured in the whole kingdom.

Now, with respect to this evidence, so far as it relates to the woollen manufacture of England and Wales generally, we are afraid that it is erroneous on two of its principal and leading points. In the first place, it appears to us, that the number of sheep is over-rated, and consequently the quantity of wool. On this mistake we need not enlarge, since we have already endeavoured to prove, by enquiring into the number of sheep, and the produce of the wool in each separate county in England and Wales, that the number of the former is rather more than 26,000,000, and the quantity of the latter rather more than 393,000 packs. In the second place, it appears to us that the number of people stated to be employed in the woollen manufacture of the whole kingdom, is also greatly over-rated. We have seen that the value of the woollen goods manufactured in the West Riding of Yorkshire, was about 1/11 of the value of the woollen goods manufactured in the whole kingdom; now, if we suppose that the number of hands employed in the West Riding at that time, bore the same proportion to the hands employed in the whole woollen manufacture, that the value of the goods did, there must have been upwards of 1,100,000 people employed in this part of Yorkshire, that is nearly twice the number of inhabitants which it then contained. But let us try this point another way: the value of the whole raw material was estimated at £L.6,600,000: the value of the whole manufactured goods, at £L.19,800,000, leaving £L.13,200,000 for interest of capital, manufacturing profit, and the wages of labour. We cannot estimate these at less than 20 per cent. on the sum thus reduced, which will make them amount to the sum of £L.2,640,000; leaving the sum of £L.10,560,000 for manufacturing wages, which, if there were 3,000,000 of people among whom it were to be divided, would give, as the wages of each individual, little more than £L.3 per annum; but as we cannot average the wages of men, women, boys and girls, at less than 6s. 8d. a week, or about £L.17 per annum, we must suppose that the number of people employed did not amount to more than 550,000, a number much more probable than the former. It may also be remarked, that the calculation is made at too high a price of wool; the average price for three or four years preceding 1800, being not more than from ten pence to ten guineas. For these reasons, some authors who notice the result of this evidence, not only reduce the quantity of wool from 600,000 packs to 500,000, (a quantity which we have shewn to be still too great,) but also form the calculation of the value of the wool manufactured in 1800, at £L.10,10s. per pack, making the total value £L.5,250,000. But, if the manufacturers examined on this occasion, erred in estimating the quantity and value of English wool too highly, they also erred on the other hand, in not taking into their account the value of Spanish wool imported, which
at least amounted to £500,000; this, added to the former sum, will make the total value of the raw material £2,750,000 and supposing the manufactured value to be thricefold, the total value of woollen goods will be £1,175,000.

Mr Grellier's statement examined.

We should not have thought of dwelling longer on the state and extent of the woollen manufacture at this period, had we not observed, that the late Mr Grellier, who was deservedly celebrated for the attention he paid to statistical enquiries, differs from us in various points respecting it. This circumstance, joined to the consideration, that if we can determine the state of the woollen manufacture in 1800, we shall be the better able to ascertain its state at present, or at least to form a comparison between its state at the two periods, induces us to add a few observations, which, in our opinion, will point out the instances in which Mr Grellier is mistaken. In the first place, he gives it as his opinion, that the real value of the woollen goods exported is only about 38 per cent. above the official value; but this is certainly a mistake, and we observe in the report on the state of the woollen manufacture, in 1805, that the committee, mentioning the very great national importance of this manufacture, state the official value of the exports to be £6,000,000; and expressly add, or £9,000,000 actual value. In the next place, Mr Grellier deduces from the gross amount of the value of the manufactured goods only 10 per cent. for the profits of the manufacturer, including the interest of his capital; but a little reflection must serve to convince us, that 10 per cent. on the gross value, is too small a sum; and that 20 per cent. on the sum which remains, after subtracting the price of the raw material from the gross value of the manufactured articles, is nearer the truth. In the last place, Mr Grellier, taking all classes of work people, in the woollen manufactures, together, estimates their wages at 8s. per week; and by this high rate of wages, and a reduction in the value of the whole manufactured goods, notwithstanding he allows less to the master manufacturer himself, he reckons the whole number of persons employed only at 440,330. But when we reflect on the large proportion of women, boys, and girls, that are employed in this manufacture, and at the lowness of the wages, especially of the two last, we shall be disposed to consider his average rate as too high, at least for the year 1800; and moreover, when we consider, that in many of the manufacturing parishes in the West Riding of Yorkshire, one-half or two-thirds of the people are employed in the woollen trade; that the population of the whole Riding, in 1800, was upwards of 560,000; and that the amount of the value of the woollen goods manufactured there was only ½ of the whole goods manufactured in the kingdom, we shall be disposed to estimate the number of people employed in this manufacture at considerably more than 440,330. At the same time it must be admitted, that on this as well as on many other points of statistical enquiry, the data are too few, or too questionable, on which to ground accurate and perfectly satisfactory results.

Having thus brought the historical sketch of our woollen manufacture, considered generally, down to the commencement of the present century, we shall now proceed to consider the principal branches of it; the districts or towns in the kingdom which they occupy; and their actual state.

Under the general head of manufactures of wool, we comprehend not merely what are strictly and properly denominated the woollen manufactures, but also all manufactures in which wool is the raw material employed; these are naturally divided into the manufacture of woollen and of worsted goods; or into those goods in which the card or the comb are employed in the preparation of the raw material.

The principal seats of the former kind are the West Riding of Yorkshire, and the western counties of Wales, Somersetshire, and Gloucestershire; and of the latter kind, the county of Norfolk; for we shall omit the consideration of the stocking manufacture at present, and consider it by itself, as stockings, being made of worsted, cotton, and silk, seem properly to fall under none of these heads. The woollen manufactures of North Wales will also be considered; they are principally situated in the counties of Merioneth, Denbigh, and Montgomery.

The length of the manufacturing district of the West Riding of Yorkshire, from north to south, may be estimated at 40 miles, and its mean width at 20 miles, giving together an area of 200 square miles; but this space includes the hardware manufacturing district about Sheffield, as well as the clothing district: the latter commences below Craven, and extends over a tract, of which Leeds, Bradford, Halifax, and Wakefield, are the principal centres. The most important manufacture in this district is that of woollen cloth, the greatest part of which is made in the neighbourhood of Leeds, Wakefield, Huddersfield, and Saddleworth. Leeds is particularly the mart for the coloured and white broad cloths. The former are sometimes called mixed cloths, and are made of dyed wool. The mixed cloth manufacturers reside partly in the villages belonging to the parish of Leeds, but chiefly at Morley, Guisborough, Adwalton, Dudlington, Pudsey, Parsley, Calverley, Eccleshall, Idle, Baildon, Yendal, Gisley, Rawdon, and Horsforth, in or bordering upon the vale of Aire, principally to the west of Leeds; and at Batley, Dewsbury, Osset, Horbury, and Kirkburton, west of Wakefield, in or near the valley of Calder. Very few mixed cloth manufacturers are to be found to the east and north of Leeds, and there are very few in the town itself. The white cloth is manufactured chiefly at Alverthorpe, Osset, Kirkheaton, Dewsbury, Batley, Birstall, Hopton, Merfield, Kirkheaton, Little-town, Bowling, and Shetley, a tract of country which forms an oblique belt across the hills that separate the vale of Calder from the vale of Aire, beginning about a mile west of Wakefield, leaving Huddersfield and Bradford a little to the left, terminating at Shipley on the Aire, and not coming within less than six miles of Leeds on the right. The districts of the mixed and white cloth are in general distinct and separate, but in some places, particularly at their south-east and south-west extremities, they run into each other. The principal manufactures of woollen in and near Halifax, are flannels and baizes; though cloth, especially of that kind which is used for the army, is very generally made. The blanket and flannel lines lie between Leeds and Huddersfield; and the manufacture of stuffs, principally in the neighbourhood of Bradford and Halifax: narrow cloths are made in and near Huddersfield. At Saddleworth, the manufacture of broad cloths, nearly equal in fineness to those of the west of England, and of kerseymeres, is carried on. At Wakefield some white cloths are made; but this place is principally distinguished for its wool market, and for the excellence of its mode of dyeing cloths.

The county which first claims our attention in the west of England, for its woolen manufacture, is Gloucestershire.
esteshire; here broad cloths of various sorts are made, but chiefly superfine, of Spanish wool; and of fine narrow goods, in the fancy way, to a very great extent. This manufacture is carried on in that district— which, by way of distinction, is called the Bottoms, including parts of the several parishes of Avening, Painswick, Pitcomb, Randwick, Minchinhampton, Stroud, Bisley, Rodborough, Stonehouse, King's Stanley, Leonard Stanley, Wood Chesters, Horseley, and Eastington; extensive works are also carried on at Durley, Can, Uley, Alderley, Wickwar, and Wooten-under-Edge. Stroud may be considered as the centre of the manufacture in this part of the country, all the surrounding valleys exhibiting a range of houses or villages, inhabited by persons engaged in this business.

In Wiltshire, the principal manufactures of woollen cloth are Bradford, which is considered the centre of the greatest fabric of superfine cloths in England, which it shares with the surrounding towns of Trowbridge, Melksham, Corsham, and Chippenham; besides these places, woollen cloth, of a thin texture, is made at Wilton; and cloths of various qualities, but all fine, are made at Warminster, Calne, and Devizes.

The principal places in Somersetshire, where this manufacture is carried on, are Taunton; here the woolen goods are principally of a coarse fabric: Frome and Shippon Mallet; the former is famed for its manufacture of second cloths, the latter for superfine, of which it generally makes annually between 150,000 and 200,000 yards. The woollen cloths made in the west of England are commonly arranged into five classes, according to their thickness: the thickest are double superfine milled; the finest and thinnest cloths are for the Turkey trade; ladies cloths are rather thicker than these; cloths manufactured for the East and West Indies, a degree thicker; and the superfine are, in point of thickness, next to the double superfine already mentioned. The woollen manufacture of the west of England also extends into parts of Dorsetshire, Sturminster Newton in that county being famous for its broad cloths and flannels.

In these two grand seats of the woollen manufacture of England, the West Riding of Yorkshire, and the counties of Gloucestershire, Wiltshire, and Somersetshire, there are three different modes of carrying it on: 1st, That of the master clothier of the west of England; 2d, That of the factory system; and 3d, That of the domestic system. The last was undoubtedly the original, and formerly the most prevalent and extensive system, though the state and circumstances of society, and especially the improvements in machinery, have at present confined it within narrow limits. It is to be found principally a few miles below Leeds, and 14 miles to the south of it. It does not extend far from Leeds in the other directions. It is also found nearly at the same distance round Huddersfield. The factory system, however, is daily encroaching on the limits of the domestic system, and, without doubt, will in time totally extinguish it.

Through the whole of the west of England, as well as in the north of England, there are factories; but the master clothier of the west of England buys his wool from the importer, if it be foreign, in the fleece, or from the wool stapler if it be of domestic growth; and in all the distinct processes employs distinct classes of persons, who work either at their own houses, or in the factories of their master. None of those workmen go beyond their own peculiar branch of the manufacture. From this circumstance, and the necessary consequence of it, that each is excellent and perfect in his own line, it is superseded that the superior excellence of the west of England cloth arises. Previously to the introduction of machinery, it was common for the north country man to come into the west of England, purchase wool, work it up in Yorkshire, and sell it in its manufactured state in its native country. This circumstance was supposed to arise from the north country man being at liberty to work himself, and employ his family and others as he pleased. In the factory system, the master manufacturer, who sometimes possesses a large capital, employs a number of workmen in one or more buildings or factories under his own inspection, or that of his superintendents. It is evident that, both in the system of the west of England, where the master clothier gives the raw material to workmen, who manufacture it either in their own houses or in factories, and in the factory system of the West Riding of Yorkshire, the workmen have no property in the goods which they manufacture. This circumstance marks the essential difference between these systems and the domestic.

The domestic system, as we have already mentioned, still exists in Yorkshire, though not to nearly so great an extent as formerly. It is also found in Devonshire, and in the manufacture of woollen cloth, in Wales, and in a small village in Cambridgeshire; but it is with it as it exists in Yorkshire that we are now interested. According to this system, the manufacture is conducted by a number of master manufacturers, generally men of small capital, who, besides carrying on their manufacture of woollen cloth, have small farms of a few acres, partly for the support of their families, and partly for the convenience of their manufacture. The domestic clothiers have sometimes one loom, sometimes two or three, but seldom four looms in their houses, at which they themselves, their wives and children, and from three to seven journeymen, are generally employed: during harvest, their wives, children, and servants, are sent out to work. They buy their wool of the dealer, and formerly used to carry it through all the stages of its manufacture, and even dye it; but at present they make use of the mills and machinery, which may happen to be in their neighbourhood, for many of the processes, as there are public mills near every manufacturing village. If the distance of the domestic clothier from these mills be considerable, or if he is obliged to go farther for a market for his cloth, he generally keeps a horse, which is supported on his little farm. As there is coal in all the district where the domestic system is principally carried on, which may be about from 20 to 30 miles long, and from 10 to 15 broad, the domestic clothier easily and cheaply obtains this article, so necessary for his own comfort, and for the conducting of his business.

By the natural operation of very obvious causes, the domestic clothiers are gradually forced from the vicinity of large towns, since near them land rises in price much sooner, and to a greater degree than at a distance from them; and it is a great convenience, if not absolutely necessary, for the domestic clothier to have a small portion of land attached to his cottage.

The establishment and extension of the factory system naturally excited the fears and jealousy of the domestic clothiers; and, in order if possible to put a stop to it, in 1806 they applied to parliament to put in force the laws respecting apprentices, and the number of looms. The first law was passed in the time of Queen Elizabeth, at a time when the number of our distinct trades was not above 100, whereas now they are between 600 and 700. The factory system creating a
great demand for manufacturers, induced the proprietors of large factories to take many who had not served the legal length of apprenticeship; whereas the system of apprenticeship being more congenial to the domestic system, those who followed this system had no temptation to break the law. The other law, which, in their petition to parliament, the domestic clothes wished to be enforced, is commonly called the weaver's act. It was passed during the 2d of Philip and Mary, and in certain cases, and parts of England, limits the number of looms in one building; but on their application to parliament, it was shown that this act does not extend to Yorkshire, Northumberland, Cumberland, or Westmoreland. The petitioners also wished, that the statute of the 5 and 6 of Edward VI, which they contended applied to the gig mill, should be put in force. Of this statute, the committee, in their report on the evidence, recommended the abolition.

From the report and evidence on this occasion, the following facts and circumstances may be selected, as illustrating the state of the woollen manufacture in general, and especially in the West Riding of Yorkshire.

The acts of parliament relating to this manufacture, which are still on the statute book, amount to nearly 70, and may be divided into three classes: 1st, Laws for regulating the conduct of masters and workmen, and for preventing fraud and embezzlement by journeymen, &c. These in general are wise and salutary, particularly one passed in the 29th Geo. II. by which masters are prevented from paying their workmen in goods, 2d, Laws prohibiting the exportation of certain materials and implements, all of which have been passed in the reign of his present Majesty; and 3d, Laws which control the manufacturer in making and selling his cloth, particularly those which prohibit the use of certain articles of machinery. Among those may be included the law respecting apprentices, and the weaving act already mentioned.

The committee, in their report, pointed out what in their opinion were the advantages and disadvantages of the domestic system, as distinguished from, and contrasted with, the factory system. According to them, one peculiar recommendation of the domestic system is, that a young man can always obtain credit for as much wool as will enable him to set up as a small master manufacturer, while the public millenable him to command the use of very extensive machinery. Another advantage of this system is made manifest, on the failure of a market for any particular kind of goods; since where this system prevails, it does not throw a multitude out of employment, as it does when the stroke falls on the capital of a great individual. In the domestic system the losses spread much, and it is remarked, that the domestic clothiers seldom turn off their journeymen. On the other hand, the domestic clothiers necessarily waste much time in carrying their goods to the fulling mills, &c. which might be saved, if the factory system, in which all the operations are carried on under one roof, were adopted.

Perhaps, however, the most important point of view in which these systems can be contrasted, respects their influence on the morals and habits of the people; and there can be no doubt, that if the distinguishing excellence of the English character results in a great measure from their domestic habits, or if domestic habits are favourable to propriety and steadiness of conduct, the domestic is preferable to that of the factory system. Viewed in this light, which however is more the object of the moralist than of the statistical enquirer, the domestic system of Yorkshire, in which the manufacturer not only works at home in the midst of, and in company with, his family, but also on goods entirely his own property, is undoubtedly the most valuable and useful. Next to this must be placed the system, common but not universal in the west of England, according to which the workmen work at their own houses, but on goods not their own property. Here the domestic habits and their consequences may be the same as are produced by the first system; but that feeling which arises from the consciousness of the possession of property, which not only stimulates to industry, but also keeps up regular habits of conduct and independence of mind, must be wanting. In the scale of the moralist, the factory system must stand lowest, though, as applied to the woollen trade, it is not so dangerous to the best interests of society, as when applied to the cotton trade. The causes of this we shall afterwards attempt to point out, when we come to compare the state of the manufacturing population of the woollen and cotton districts.

Besides the difference in the mode of conducting the woollen manufacture, which we have explained at considerable length, there is also a difference between the Yorkshire and the west of England mode of disposing of the goods when manufactured. In the latter, they are principally sold at markets or fairs; in the former, they are principally sold in what are called cloth-halls, and which towns have three or four cloth-halls at Bradford, Halifax, Huddersfield, Wakefield, &c. We shall confine our observations to those of Leeds, and to the mode of conducting business in them.

The two principal halls in Leeds are for mixed and white cloth. They are principally distinguished from the third hall, (which was erected about 1795,) by not admitting any manufacturers to expose their goods in them, who have not served an apprenticeship to the woollen trade. Formerly a regular apprenticeship of seven years was insisted on; but now five years are deemed sufficient. The mixed cloth-hall was erected in the year 1758. At first they were only 1557 stands, but afterwards 171 were added, making the total number 1728. The original price was £3, 5s. 6d.; but they have advanced greatly since. The price, however, varies according to the state of the trade. There are seldom fewer than 7000 pieces of cloth, and sometimes nearly 20,000 weekly in the coloured cloth-hall.

The white cloth-hall was built in 1773. The number of stands is upwards of 1200; but there are many manufacturers who have two stands each. In the district round Leeds, it is computed that there are 3500 masters who attend both halls; but there are many who have no stands in either hall, but pay 6d. for every fresh cloth; when a cloth has once paid, it does not remain, but may be removed to any other part of the market. There are 15 districts belonging to the coloured, and 17 to the white hall, over each of which there is a trustee, who manages the affairs of the district; and in all of whom is lodged the power of directing whatever concerns the halls. These trustees are elected for three years.

These halls consist of long walks or galleries, throughout the whole length of which the master manufacturers have their stands in double rows, each behind his own little division; his goods being exposed to sale on the stands. Between these rows, the merchants pass along, and make their purchases. At the end of an hour, a bell rings, and the market closes. Such goods as are purchased, are carried to the merchants' houses; the goods that are unsold, remain in the hall till they find a purchaser. Lately, however, the system is in some degree changed; some merchants give samples

By the same stamping acts, three sets of officers were appointed to superintend the woollen manufacture, both in Yorkshire and in the west of England; but in the west they perform their duty in a very negligent manner, and in Yorkshire they are by no means very strict or careful. These officers are, 1st, the searchers, who measure the cloth at the fulling-mill, after it is full, stamp it, and put their seal on it, with the length and breadth, which are entered in a book. After this, the clothier may take it away. The second set of officers, are the inspectors, who go among the dressers, in order to see that they do not overstretch the cloth, and restamp them, if materially short or narrow. They also inspect the tenters, and observe that improper cards are not used in dressing the cloths. The last set of officers are the supervisors, who superintend the others. In purchasing cloth, however, the merchant does not consider himself bound to take the pieces at the length which the searcher has stamped upon them.

Norwich was the first seat of the worsted manufacture in England, or rather perhaps Worsted, a small town in the county of Norfolk, from which the manufacture took its name. About the end of the 14th and beginning of the 15th century, this species of manufacture extended itself, not only over the county of Norfolk, but even through Suffolk and Cambridgeshire; and, in process of time, sent its colonies into Essex, the midland and southern counties, and even into Yorkshire. In the time of Henry VIII., the sale of stuffs made in Norwich only amounted to 100,000 annually, besides stockings, which were computed at 60,000 more. During the two succeeding reigns, new articles of manufacture were introduced; and, in 1575, the Dutch, who fled hither from the persecutions of the Duke of Alva, introduced the making of broadsaxes, a manufacture for which this city has been long famous. At this period, however, and for a considerable time afterwards, its trade did not depend so much upon foreign demand as it does now. As long as Sir Robert Walpole continued in power, he encouraged its manufactures of crape, then a staple article, by using his influence for orders to be given, that the public mournings should always be in Norwich crape. The most fatal blow to the home trade of this city was given by the prevalence of cotton manufactures, which began to be sold cheap, after the invention of Sir Robert Arkwright. It then became absolutely necessary for the Norwich manufacturers to seek a market abroad; and this they succeeded in obtaining. There was scarcely a country in Europe, in which their goods were not to be seen, and the demand for them increased so much, and so rapidly, that it became necessary to increase the imports of raw yarn from Ireland. Before, however, the commencement of the first Frenchrevolutionary war, the manufactures of Norwich began to show symptoms of decline, and the war completed its ruin. It has since revived a little, but probably will never regain its former prosperity. While the trade was tolerable, it was estimated that about 50,000 tods of wool were combed and spun in the county of Norfolk, which employed about 500 combers, and furnished spinning work for most of the poor women and children in the county. During its flourishing state, the returns of the manufacture were estimated to be about L1,200,000 per annum; and even in 1805, when it was deprived of many of its foreign markets, the returns were nearly L800,000. Of this sum it was calculated that the price of labour took off L685,000, while the value of the raw material, dying stuff, oil, soap, and coals, was only L115,000; thus shewing its great importance. It furnished employment for about 50 distinct occupations. The staple articles of manufacture in Norwich may be said to be its fine camblets, of which the East India Company take off annually a considerable quantity, and its worsted damasks, shawls, &c.

Before proceeding to the consideration of the woollen manufacture of North Wales, it may be proper briefly to notice the districts, or places in England, where other species of goods made from wool, than those already noticed, are manufactured. It would be tedious, however, even to name all the kinds of these goods, or the various places in which they are made; we must, therefore, content ourselves with noticing the most considerable. In Devonshire, and the adjoining part of Cornwall, as well as in some parts of Somersetshire, a variety of woolen goods, little consumed in England, are made, such as druggets, long-ells, &c. These are sold as they come from the loom to the merchants of Exeter, where they are milled, dyed, and finished, and afterwards exported. The East India Company take off a large proportion of the long-ells: while this manufacture was in a flourishing state, the average annual value exported to all parts was valued at L600,000. In other parts of Devonshire, there are also branches of the woolen manufacture; of which the manufacture of plush, at Modbury, deserves notice, on account of the ingenious construction of the machines used for this purpose.

A large manufacture of baize was formerly carried on in the towns and neighbourhood of Colchester, Bocking, Braintree, and Coggeshall, in the county of Essex. This article was exported to Spain, Portugal, and Italy; but the manufacture has greatly declined here, having passed to other places, especially to Rockdale, in Lancashire, on the borders of Yorkshire. This, indeed, is one of the most flourishing places in the kingdom, for the manufacture of baize, serges, flannels, &c. The population of the district, in which this manufacture is carried on, is about 36,000; and it is calculated that one half are employed in it. Baize and flannels are also manufactured at Bury, in Lancashire, and the former article, with coarse cloth and blankets, at Chichester in Sussex. Salisbury is noted for its flannels. Blankets are made at Leeds, Witney, Dulverton, &c. With respect to Witney, however, it may be observed, that since the introduction of machinery, the chief part of the blankets (though they still retain the name) are made in Glamorganshire, and sent to Witney. Carpets are manufactured at Kidderminster, Wilton, Cirencester, Worcester, Axminster, &c. These made at the last place are deemed equal to any imported from Turkey or Persia.

At Kendal, Ambleside, and Keswick, there are made considerable quantities of coarse woolens, druggets, &c. At Andover, Basingstoke, and Alton, in Hampshire, the latter article, and shawls, serges, and a variety of worsted articles. At Banbury and Coventry, worsted shags. At Burford, rugs. Fleecy hosiery at Godalming, in Surrey. It has already been mentioned, that the Norwich manufacture extended itself into Suffolk; but the articles now made there rather differ from those made in that city, consisting of light stuff, butting, crape, &c. The manufacture of these articles is carried on at Sudbury, Bury St Edmund's, Needham Market, and Lavenham. In this county,
The woollen manufactures of North Wales, as has been already mentioned, are carried on principally in Montgomeryshire, Merionethshire, and Denbighshire. They consist of webs, flannels, stockings, socks, wigs, and gloves. As the stockings made in Wales are all worsted, we shall consider them here apart from the stocking manufacture of England. The webs manufactured in North Wales are distinguished into two sorts; strong cloth, or high country cloth; and semi-cloth, or low country cloth. The first kind is made in Merionethshire, principally on the domestic system, but in some parts there are factories. Almost every little farmer makes webs, and few cottages are without a loom. In some cases, the manufacturing farmers employ wool of their own growth; but it is principally bought from the wool staplers and skinners: all kinds are sold indiscriminately. The quality of the manufactured article is of various degrees. There is a market for strong cloth at Shrewsbury; but it is customary for the drapers of that town to go up into the country, (as they term it,) and buy goods, wherever they can get them. It is likewise a custom with the principal drapers to keep servants the greater part of the year in the vicinity of the manufactures, who get acquainted with the persons who make cloth, assist the poor ones probably with money to purchase wool, and superintend the making and dressing of the goods. Most of the strong cloth is exported from London or Liverpool, to Holland, Germany, and America — a very considerable quantity being used at home for workmen's jackets, ironing cloths, blankets, &c.

Strong cloth.

The small cloth is manufactured in Denbighshire, entirely in a large tract of country, which includes Llangollen and Corwen. The factory system has not yet been applied to this article. The raw material is procured from the neighbourhood of Oswestry, and is sorted into two kinds. The finer part is manufactured into a sort of flannel, called Oswestry flannel; while the coarser part is made into small cloth. Most of this is sent abroad; and the purposes to which it is there applied are various. The clothing of the slaves in the West Indies and South America, creates a large demand. Stockings are made to be made of it in Germany, and other parts of the Continent.

Flannels.

Flannels form the most important and valuable of the manufactures of Wales: they are principally made in Montgomeryshire; but not entirely so, being made in various places within a circle of about 20 miles round Welshpool. The manufacture of flannels is chiefly of the domestic kind, there being very few factories in which it is carried on. In Shropshire, however, into which this native manufacture of Wales has spread itself, machinery in general is substituted for manual labour. The market for flannels is Welshpool: formerly, each manufacturer used to bring his own goods; but now a set of middle-men go about the country, and buy all the flannel they can lay their hands upon. At the Pool-market, nothing is bought on credit, every piece being paid for as soon as measured: it is the same with the rest of the woollen manufactures of the principality. There is no accurate calculation of the number of yards manufactured, nor indeed can they be conjectured with any probability. Mr Pennant, in the year 1781, says, that there were annually brought into Salop, 700,000 yards of webs; and to Welshpool, between 700,000 and 800,000 yards of flannel; but it is not known on what data he grounds his calculation. Stockings, socks, wigs, and gloves, are made principally in the town and neighbourhood of Bala, where they are sold. It is said, that on a market-day, from L.200 to L.500 worth of stockings alone are sold.

Having thus given a pretty detailed account of the state of the various branches of the woollen manufacture of England and Wales, introduced by some historical sketches of its state formerly, we shall conclude this branch of our subject with an attempt to ascertain, as nearly as we can, the following points; viz. the value of the manufactured article; the value of the raw produce from which it is manufactured; the amount of the profits of the master-manufacturers, including interest for the capital, and an allowance for machinery, &c.; the amount of the sum paid in wages; and the number of people employed in this branch of manufacture. For these calculations, the data we take are the amount of the value of the woollen goods exported, and the proportion which their value bears to the value of the woolen goods kept for home consumption. We have already seen, that the manufacturers examined before the House of Commons in the year 1800, estimated the total value of the woollen manufactured goods, at the sum of L.19,800,000; but, as we observed, they erred in supposing that the stock of wool in the kingdom was 600,000 packs, whereas, in fact, it does not reach 400,000. They probably were mistaken, also, in the price they put upon the wool at that time. Making deductions on these accounts, and, on the other hand, allowing for the Spanish wool employed, it is probable that the total value of the woolen goods, at that time, will be, as we have already stated, about L.17,250,000. The official value of woollen goods exported in 1799, was L.6,435,423; and, in the year 1800, L.6,918,175: the real value, therefore, must have been above L.9,000,000; but let us take it at L.5,000,000; and the value of the whole manufacture at L.18,000,000: on this supposition, which is sufficiently near the fact for our purpose, the real value of the woolen goods exported, will be about one half the value of the whole goods manufactured in this kingdom. Circumstances, however, did occur, which necessarily varied this proportion; since, in consequence of our disputes with America, and the state of the European continent, the official value of woollen goods exported in 1808, was only L.4,883,580; in 1809, L.5,416,151; in 1810, L.5,773,214; in 1811, L.5,376,445; and, in 1812, L.5,084,991. But we must not conclude, because the value of the exports was diminished, that therefore the total value of the goods manufactured was lessened in the same proportion; for, however it might be with respect to other manufactures, or with respect to some branches of the woollen trade, the demand for woolen goods for the army was increased, at the time when the foreign demand was diminished. We may therefore safely suppose the total value of the woolen goods manufactured in England and Wales, to be now what we have supposed it to be in the year 1800, viz. about L.18,000,000; of this we must deduct a third, or L.6,000,000, for the value of the raw produce, which will leave the sum of L.12,000,000 for produce the master manufacturer and his workmen. On the average, the following points; viz. the value of the manufactured article, the value of the raw produce, and the wages paid to the workmen.
ENGLAND.

The next branch of the manufactures of England that we shall notice, is that of cotton. This exhibits a more surprising instance of rapid and extensive progress, than can perhaps be shown in any country, with regard to any species of manufacture. There is no evidence that any article was made of cotton in this country prior to the middle of the 17th century. In the year 1641, cotton was imported from Cyprus and Smyrna, and made into fustians at Bolton, in Lancashire. As this species of goods passed under the name of Augsburg and Milan fustians, it is not improbable that the mode of manufacturing them was introduced from Germany or Italy. About 20 years afterwards, cotton was imported from our North American colonies; and, as a law was passed in the year 1660, prohibiting it from being landed anywhere but in the English dominions, it is probable that its value and utility, as an article of manufacture, were beginning to be understood and experienced. The cotton trade, however, must have been for several years afterwards conducted on a very narrow scale; since, on an average of five years, ending 1705, the total quantity of cotton-wool imported into England was only 1,170,881 pounds. In the year 1765, the cotton-trade could scarcely be said to be known here; and a considerable quantity of the cotton-wool which we procured from our colonies, we exported to Holland. Two years afterwards, however, an invention took place, which, though it is rude and imperfect, compared with the machinery at present used in the manufacture of cotton, was of the greatest importance in establishing and extending the trade: we allude to the invention of the jenny. Some years previous to this, however, the preparation of the cotton for spinning had been facilitated by the invention of a rude carding machine. The jennies, or spinning machines, were first used by the country people in Lancashire, on a very confined scale, few of them having more than 12 spindles. The awkward posture required to spin on them, was discouraging to grown up people, who saw, with surprise, children from nine to 12 years of age, manage them with dexterity. The consequences of this invention were beneficial, not only to the master manufacturers, but also to the labouring classes of the community; for the younger branches of their families, who previously had been without regular and full employment, now gained considerable wages, while the weavers, by employing their own children at the spinning machines, were no longer at the mercy of the spinners. But, notwithstanding the manifest utility of this invention, and the benefits it produced to the weavers, some risings of the people took place, and the jennies were destroyed by the uninformed populace. By degrees, their fears and jealousy of this invention diminished; and a general acquiescence in their use, to a certain number of spindles, was brought about, by the prudent and sensible conduct and admonition of some respectable people in Lancashire. The labouring classes were not long in reaping such general and undoubted benefits from them, that the spindles were soon multiplied to three or four times the original number; and the demand for twist for warps increasing in proportion as the quantity of weft supplied by the spinning jennies became more abundant, new machines were invented, for the purpose of manufacturing twist, and a new impetus was given to the cotton trade.

These machines were the invention of Sir Richard Arkwright: by means of them, thousands of spindles per minute are put in motion by a water-wheel, and managed mostly by children, without confusion; and with less waste of cotton than by the former methods. Soon after the invention of Sir Richard Arkwright's machines, the people of Lancashire were incited against them, and some of them were demolished before protection could be obtained: this arose from their producing such excellent twist for warps, that they soon outrivalled the warps made on the larger jennies, which had yielded good profit to the owners. But experience soon convinced the people, of what, indeed, a little reflection might have taught them, that if more warps were made, there would be a greater demand for weft from their jennies, and a better price for it. Upon these machines, twist could be made of any fineness proper for warps, but it was not so proper for weft. On the introduction of fine calicoes and muslins, which took place in the year 1781, another machine was invented, called a mule, being a mixed machine between the jennies and the machines for twisting, and adapted to spin twist as fine as could be desired.

As this invention, by creating the necessity and advantage of large cotton manufactories, and by destroying what may be called the domestic system of the cotton trade (at least so far as respects the spinning of cotton), has altered not only the state of the trade, but, in our opinion, the moral character and habits of the manufacturing labourers engaged in it, it may not be
unimportant or uninteresting, to take a retrospective view of what were their condition and habits previous to this invention.

From the time that the original system in the fustian branch, of buying pieces in the grey from the weaver, was changed, by delivering them out work, the custom of giving them out woof in the cops, which obtained for a while, grew into disuse, as there was no detecting the knavery of spinners till a piece came to be woven; so that the practice was altered, and wool given with warps, the weaver answering for the spinning. The weavers, in a scarcity of spinning, have sometimes been paid less for the woof than they gave the spinner, but durst not complain, much less abate the spinner, lest their looms should be unremunerated; but when spinning jennies were introduced, and children could work upon them, the case was reversed. At this period of the cotton manufacture, the cottage of the weaver presented an interesting and amiable picture: while he was engaged at his loom, his children were employed in spinning the woof; the feelings and habits of domestic life were entire; and that link of affection between a father and his children, which secures each very frequently from vice and misery, and which is closely and intimately connected with the best interests of society, was sound and unbroken. Lower wages were obtained than are now got under the factory system, but as methods, regularity, economy, and sobriety, prevailed, what they earned procured them more of the necessaries and comforts of life, than they can now obtain with their increased wages. At that period, Lancashire, which has always displayed, in a conspicuous and peculiar manner, the wealth and the vices of the cotton trade, was not disgraced and degraded by those instances and scenes of vice and misery which now spread over its surface. The relationships of parents and children were not then merely a name; home was not then deserted for the ale-house, or for places of still greater debauchery and vice; health was not then so lavishly sacrificed to the cupidity of the master manufacturer, or so much despised and neglected by the manufacturing labourer, in the pursuit and indulgence of his passions. In short, the manufacturing classes were then respectable, comfortable, healthy, and virtuous, because they spent the greatest part of their time in their own families, and not in crowded manufactories, amidst the contagion of ignorance, vice, and misery. But we forget that our subject and inquiries are statistical, not moral; and that our object is to give some historical notices of the state of the cotton trade, as a source of national and individual wealth, at different periods.

For several years after the commencement of the present reign, the whole value of the cotton manufactures of this kingdom, (including Scotland as well as England,) was estimated to be less than L. 300,000; and in the spinning of cotton yarn, for this amount of cotton goods, not above 50,000 spindles were employed. In the year 1781, when, as we have already noticed, muslins were first made in this kingdom, only 5,101,929 pounds of cotton wool were imported. In 1782, in consequence of the increased demand for muslins, the quantity of cotton wool was more than doubled, and the amount of cotton goods was estimated at nearly L. 4,000,000. During the years 1783 and 1784, there was no increase in the importation of cotton yarn, and consequently no increase in the value of cotton goods. In the year 1784, the patent which Sir Richard Arkwright had obtained, for his invention of water-mills, expired, and they were immediately erected in all parts of the kingdom; and although the mode of spinning wool by machinery was yet scarcely known, yet the spinning of it by the hand engines nearly kept proportion with the increased supply of warp. This year, the importation of cotton yarn amounted to 11,280,238 pounds, and the estimated value of the cotton manufactures was L. 3,950,000. In the following year, a great increase was visible; the quantity of imported raw material having been L. 17,992,888, while the value of the goods had risen to the sum of L. 6,000,000. In 1786, the quantity of cotton wool imported, amounted to 19,151,877 pounds, which was manufactured into goods of the value of L. 6,500,000. And in the year 1787, the quantity of cotton wool was 22,176,887 pounds, which produced goods of the value of L. 7,500,000.

A writer, who investigated the subject of the cotton manufactures at this time, estimates the supply and expenditure of cotton in the year 1787, in the following proportions:

<table>
<thead>
<tr>
<th>Imported from</th>
<th>Pounds</th>
<th>Worked up in</th>
<th>Pounds</th>
</tr>
</thead>
<tbody>
<tr>
<td>British West Indies</td>
<td>6,600,000</td>

<td><strong>22,600,000</strong></td>
</tr>
</tbody>
</table>

This estimate, however, is not correct, with respect to the quantity imported from the British West India colonies; since it appears, from the report of the committee of the privy council on the slave trade, that the cotton imported from Jamaica, Grenada, and Barbadoes, in the year 1783, exceeded the quantity here stated as imported from all the British West India Islands. In order to reconcile this with the estimate of the quantity of cotton, which is stated above, to be used in the manufactures of this kingdom, in the year 1787, viz. 22,176,887 pounds, it must be observed, that there was always a certain proportion re-exported; so that, probably, the quantity actually retained for home consumption was very near what it is here said to have been. It may be proper to point out the view of the state of the cotton manufacture at this period, which is afforded by the comparative quantities of the cotton wool employed in its different branches. Fustians, as we have seen, were the oldest cotton manufactures in the kingdom, whereas muslins and calicos had only been introduced six years before, viz. in the year 1781; and yet, the quantity of cotton wool employed in the latter, in the year 1787, was, according to this statement, very nearly double the quantity employed in the manufacture of fustians. The same author gives an estimate of the number of water-mills, or machines for spinning
twist cotton yarn for warps, both in England and Scotland. We shall lay before our readers his estimate for both countries, in order that they may be enabled to take a comparative view of the state of the cotton trade in them both.

In England and Wales 123

The whole number being 143, the cost of which was estimated at L 715,000. There were at the same time 550 mule jennies, or machines of 90 spindles each, and 20,700 hand jennies of 80 spindles each, for spinning yarn for the slube or woof, the cost of which, and of the auxiliary machinery, together with that of the buildings, is stated to have been at least L 285,000, making the total expenditure on the machinery and buildings L 1,000,000. It was, moreover, calculated, that these establishments, when in full employment, produced as much cotton wool, as could be spun by a million of persons, upon single wheels. At this period, it was calculated also, that there were employed 26,000 men, 31,000 women, 58,000 children, in all 110,000 in the operations of spinning; and 153,000 men, 59,000 women, and 48,000 children, in all 250,000 in the subsequent stages of the manufacture; there being, in all, 159,000 men, 90,000 women, and 101,000 children, and a total of 350,000 persons employed in this manufacture; nearly one-third of them in the calico and muslin branches. In these most important branches, at this time, the raw material was advanced in value from ten to fifty fold.

From the data which these statements afford, we may be able to ascertain several particulars respecting the state of the cotton manufacture in England at this time, separately from the state of it in the kingdom at large; taking it for granted that the capital and number of people employed in England, bear the same proportion to the total capital, and number of people employed in the whole kingdom, that the number of water mills in the former did to the number in the latter. Now, as the number of water mills in Great Britain, was 143, and in England 123, we may consider the proportion in the latter as six-sevenths of the whole, which will give us, as the cost of the water mills in England, about the sum of L 600,000, and as the cost of the machines for spinning woof, and the necessary buildings, the further sum of at least L 240,000, making the total expenditure in England to be about L 840,000, the number of people employed in spinning the cotton wool about 35,000, and the number of people engaged in the subsequent stages of the manufacture to be about 405,000, in all about 500,000 people employed in the cotton manufacture in England. About this period, several very large cotton-works were established in different parts of England. The most extensive and considerable of which were those of Sir Robert Peel, at Bury, in Lancashire. By the report of the committee of the House of Commons, in 1785, on the subject of the commercial intercourse with Ireland, it appears, that this gentleman, at this period, employed 6900 people, and several thousands were employed by Mr Smith, and numbers, proportionally great, by other manufacturers of cotton. From the time of the invention of the mule, till the breaking out of the first French revolutionary war, the cotton trade of England flourished in a most astonishing manner; fortunes were made, especially in Lancashire, where it was carried on to the greatest extent, and with the greatest spirit and enterprise, with almost unparalleled rapidity. The improvements in the steam engine seconded the improvements in the machinery for spinning cotton, while improvements equally great and important were made in the mode of bleaching and dyeing the goods. Indeed, it may well be doubted, whether it could have been possible to have bleached, by the old process, all the cotton goods which were now made; so that the discovery which chemistry made in this art, came opportune

The breaking out of the war in 1793, gave a great effect to the shock to this trade; at first it was very severely felt; but after several of the most intelligent and well-informed of those who were engaged in it, having more leisure, by the decreased demand for their goods, than they formerly had, applied themselves to the further improvement of the machinery used in the spinning of cotton. Attempts were also made to work a number of looms together by machinery; and a factory was actually erected near Manchester to weave piece goods in this manner; but it was burnt down before any judgment could be formed how it could have succeeded. We shall afterwards see that the cotton manufacturers attained their object in a considerable degree, by the construction of what are called power looms.

In the year 1795, Dr Aikin published his History of Manchester, from which we have gathered the following miscellaneous information, respecting the state of the cotton district of England, at that period. According to him, the increase of value acquired by the raw material, in the labour expended upon it, in manufacturing, was generally from 1000 to 5000 per cent. At Ashton-under-Lyne, a considerable quantity of twist and warps was made, for the heavy goods that were manufactured in Manchester. At Middleton, the cotton trade was carried on in all its different processes; a large twist manufactory had been established, and very considerable printing and bleaching works: in this place, as well as in many other parts of Lancashire, the cotton manufacture had supplanted the long-established manufactures, the weaves of muslin and needle having taken place of the weaving of silk. Even at Rochdale, which we have already noticed as distinguished at present for its manufacture of flannels, and other woollen goods, the cotton manufacture seems to have gained a footing when Dr Aikin wrote; but though it has spread beyond this place into Yorkshire, it does not seem to have flourished much or extensively here. In 1796, the muslin trade was in a flourishing condition at Bolton; but, in consequence of the want of sufficiently powerful streams, there were but few spinning factories in this town; or its neighbourhood: there were, however, many crofts for bleaching. We have already noticed that Bolton was the original seat of the cotton manufacture; flaxmills having been made there about the middle of the 17th century; from Bolton the cot-
ton trade spread to almost all the places in Lancashire, in which it is at present carried on; among the rest, it spread to Bury, where it was in 1796, and is yet carried on, in conjunction with the manufacture of flannel, &c. The works of Sir Robert Peel, at this place, have been already noticed; they embraced nearly all the stages and processes of the cotton manufacture, spinning, weaving, bleaching, and printing. The first species of cotton goods manufactured at Blackburn were what were denominated Blackburn greys; these were plains of linen, warp shot with cotton. In 1795, this town had gone very extensively into the making of calicoes, and the fields in its vicinity were whitened with the materials lying to bleach. Haslingden has already been noticed, under the head of the woollen manufactures, as being a place in which woollen yarn is made: in 1795, twist for warps was spun in several of the factories in its neighbourhood, the cotton trade having been there lately introduced. We may here observe, that wherever the cotton trade gained a footing, (with very few and inconsiderable exceptions,) it preserved and extended itself; most certainly is the case in nearly all the places in which, or in the vicinity of which, the manufacture of woollens is carried on, as in those parts of the West Riding of Yorkshire, bordering on Lancashire. One of the most obvious and powerful causes of this is, that the workmen can with little difficulty turn themselves to the woollen trade, if the cotton should suffer a partial or temporary depression. Our remarks respecting the prevalence of the cotton over the woollen manufacture, is further confirmed by what had taken place about this period at Colne in Lancashire, where the manufacture of calicoes and dimities had, in a great measure, superseded the original and long established trade of making woollen and worsted goods.

But Dr Akin's account of the places near Manchester, is principally interesting and important in relation to our subject, from the account which it gives of Preston; we shall afterwards have occasion to notice this town as one of the most flourishing seats of the cotton manufacture: but it was only a short time before 1795 that it had gained a footing here; probably the general disposition and habits of its inhabitants, (for it was long known under the name of proud Preston,) presented a more formidable barrier to the introduction of the cotton trade, than would have been offered by any long-established manufacture. There had been here, however, a large mart for the sale of Lancashire linens; a species of manufacture which we may remark the cotton trade has nearly rooted out of Lancashire, or at least out of those parts where it has gained a footing.

In 1795, Chorley was already known for its cotton factories and its bleaching and printing grounds; and this flourishing and flourishing trade had established itself at Wigan, notwithstanding the opposition of its original and celebrated manufacture of checks. But no place in the vicinity of Manchester perhaps exhibited, though on a small scale, such a picture of the extension of this trade, as a small village in the parish of Leigh. In 1780, there were only two farm houses, and eight or nine cottages; in the year 1795, there were 182 houses, and 976 inhabitants, who employed 925 looms in the cotton manufactures, as marseilles quiltings, dimities, corduroys, &c. and this rapid increase had by no means reached its utmost limits. At Warrington, Dr Akin remarks, there had been a curious alternate reverse in the state of the staple manufacture of the place,—sail-cloth, and the manufacture of cotton. After the termination of the American war, the demand for the former necessarily ceased in a great degree, several of the manufacturers introduced the cotton branches; and as the cotton goods made were principally of the coarse kind, the sail-cloth weavers found no difficulty in turning themselves to the new manufacture; but when the French war broke out, the demand for sail-cloth again becoming extensive and pressing, the original trade regained its footing.

The cotton manufacture, which, as we have seen, had its original seat at Bolton, and thence extended itself not only some way into the north of Lancashire, but also to its southern extremity, passed easily from the last into Cheshire. The place where it seems first to have fixed itself, was Stockport; and it is not improbable that the circumstance of there being here mills for winding and throwing silk, which were unemploy-ed, by a decline of this trade, contributed to establish the cotton manufacture at Stockport; for there mills were applied to cotton spinning. Perhaps no town in the whole cotton district of England exhibits more of the active and enterprising spirit of trade than Stockport: at first the inhabitants engaged in the spinning of reeled wool, then in weaving checks, and lastly in fustians; and scarcely had the invention of mules produced a thread sufficiently fine and soft, than they began the muslin trade, which in 1795 was as flourishing as the circumstances of the times would admit of;—the present state of the latter trade in this town, we shall afterwards notice. In 1795, besides a large number of cotton-spinning shops, there were 23 large cotton factories, four of which were worked by steam engines. At this period the cotton trade had been introduced into several other places in Cheshire, adjoining to Lancashire, among the rest into Macclesfield, Mowbray, where there were 12 large machines worked by water, besides a great number of smaller ones turned by horses,—and Duckinhill. In this last place, the pernicious effects of the cotton factories on the health and longevity of the inhabitants, were particularly striking; while the trade had afforded employment to all ages, it had debilitated the constitution, and retarded the growth of many, and made an alarming increase in the mortality. This effect was principally attributed to the custom of making the children in the mills work night and day, one set getting out of bed, when another went into the same; thus never allowing the rooms to be well ventilated. Before we conclude this sketch of the state of the cotton trade in Cheshire in 1795, we shall mention one decided and striking proof of its rapid advancement; in 1788, as we have already seen, there were only eight water-mills in the whole county; in 1795, in Stockport alone, there were 23 large cotton factories, besides a great number of spinning shops.

Derbyshire also, at the latter period, had entered pretty considerably into the cotton trade, not only in and near the county town, but also at Glossop, Chapel-le-Frith, Bakewell parish, (into part of which the manufacture of muslins had been introduced); Cromford, the residence of Sir Richard Arkwright, and the first place in this county in which he established his works; Chesterfield, where a cotton mill had then been very lately erected; and other places.

From these details, a pretty accurate view of the cotton trade in 1795 will be gathered; and when it is re-collected, that at this period mules had not been invented much more than 15 years, and water-mills not 28, and that prior to the invention of the latter there could not properly be said to be any such trade as the,
cotton trade in England, we shall be disposed to admit, that no country can exhibit a more striking instance of enterprising and successful industry.

One of the most obvious and accurate means of judging the progress of any manufacture, and of its comparative state at different periods, is by ascertaining the relative quantity of the raw materials used at those periods. We shall therefore lay before our readers an account of the quantity of cotton imported in Great Britain, on an annual medium of four periods, of five years each, commencing 5th January 1772; premising, that the quantity imported for the use of England may be estimated at six-sevenths of the whole. On an annual medium of five years, from 1772 to 1776, the quantity of cotton wool imported amounted only to 4,414,757 lbs.; during the next period, down to 1787, it had increased to upwards of 16,000,000 lbs.; in the next, down to 1792, the quantity was nearly 29,000,000; and in the last of the series of periods, including five years preceding the 5th of January 1799, on an annual medium it amounted to upwards of 26,000,000 lbs. In the year 1795, there were printed in England and Wales, of English calicoes and muslins, upwards of 24,000,000 yards; in the year 1800, upwards of 23,000,000 yards: the value of the former being about L 3,500,000, and of the latter about L 4,150,000; but as the quantity of white muslins and calicoes made in England and Wales, was probably much greater than that of the printed, they may be estimated at the value of L 3,000,000, even though their price, from not being printed, was not so high as the others. The annual exports of British cotton manufactures, from all the parts of the kingdom, on the average of three years, 1797, 1798, and 1799, was upwards of L 4,000,000. In the year 1801, the import of cotton-wool into Britain was 42,000,000 lbs. and the estimated value of the cotton manufacture L 15,000,000 sterling. In 1802, the importation of cotton-wool was not less than 54,000,000 lbs.; and the particulars of the trade were stated, on good authority, to be as follow:—"The raw material, when delivered on board the merchant ships, costs about L 4,000,000 sterling; upwards of 30,000 tons of shipping, and about 2000 steamers, are constantly employed in bringing cotton-wool to this country, and in exporting the goods manufactured from it. To work the wool into thread, requires a capital in building and machinery to the amount of L 19,255,000; and those buildings and machinery are chiefly composed of bricks, slates, glass, timber, lead, iron, copper, tin, and leather, from most of which, in one shape or other, a considerable duty is collected for the support of the state. This trade gives employment or support to upwards of 800,000 individuals; and the annual return of the manufacture is nearly as follows:—

Of which sum, at least L 13,000,000 sterling are paid in wages to the natives of Great Britain."

Though these particulars relate to the state of the cotton trade in Great Britain, yet we have quoted them, as exhibiting a striking picture of its extent and importance at this period, and of its rapid advance, which proceeded in England in at least an equal degree as it did in Scotland.

In the year 1787, it will be recollected, the number of water mills in the whole of Lancashire was 41; and at different periods, the number of mule spindles, worked both by machinery and hand, in Great Britain, was about 1,700,000. In the year 1804, there were in Manchester alone 93 spinning factories, and at least 1,500,000 spindles in the different factories in the town and neighbourhood. Supposing that 1000 spindles are a fair average for each horse power, and that the steam engines averaged a ten-horse power, these spindles would have required 150 such steam engines to work them; which, at the estimate of a ton of coal per day for each engine, must have consumed about 50,000 tons of coal annually.

In the year 1812, there was laid before the House of Commons an account of cotton-wool imported, containing the average of four periods, of five years each, beginning 1792, which we subjoin, although we have already, in some degree, anticipated the result of the importation during the first series of years.

Average of 5 years, from 1792 to 1796, 27,866,938 lbs. 1797 to 1801, 42,125,865 lbs. 1802 to 1806, 58,776,780 lbs. 1807 to 1811, 87,881,808 lbs.

In order that the increase in the value of cotton goods exported may be compared with the increase in the quantity of cotton-wool imported, we give the two following Tables:
These Tables also serve to show the countries from which we got our cotton-wool, and the countries to which we exported our manufactured goods and our cotton yarn; for, in consequence of the great improvement in the machinery for spinning cotton, there were not weavers enough in the kingdom to manufacture it; while, on the continent, the weavers, who had been accustomed to weave linen and silk, easily turning themselves to the weaving of cotton, the superfluity of our yarn found a ready market there.

We shall conclude this branch of our subject, with a sketch of the present state and condition of the cotton trade in England; an attempt to estimate its value, with respect to the same points which we endeavoured to establish in regard to the woollen trade; and a comparative view of the two trades, as they seem to affect the wealth, the morals, and the general condition of those engaged in them.

The cotton district of England has nearly the same extent and boundaries now that it had 20 years ago, though the manufacture, in some, or all of its branches, may have appeared since that time in distant and insulated parts of the kingdom. Manchester may still be considered as the centre of this district. To the north-west and west of this town it is most widely diffused, having, since the period before alluded to, approached nearer the northern confines of the county. In Lancashire, Bolton, Blackburn, Wigan, and Preston, may be regarded as centres to the smaller divisions of this district, and as still engaged, for the most part, in those branches of the trade which they followed in the year 1795, and which have been already noticed. Stockport, to the south of Manchester, and Ashton to the east, are centres of the division of the districts which lie in these directions; when we pass them, we pass the limits of the regular cotton trade, though it makes its appearance as far to the south as Derby. Since 1795, it has gained a firmer and more extensive footing in the West Riding of Yorkshire, intermixing with the original and staple manufacture of that district. With respect to the places where the different kinds of goods are manufactured, it may be proper to give more minute information: Great quantities of checks are made at Carlisle, and in other parts of Cumberland; the lowest qualities of calicoes are made chiefly at Burnley and Colne in Lancashire, and at Bradford in Yorkshire; the best qualities at Blackburn and Stockport; the muslins are made at Bolton, Stockport, and the surrounding villages; the shirtings at Blackburn, Stockport, Manchester, &c.; the pillow handkerchiefs in the neighbourhood of Manchester; the quiltings and dimities in the neighbourhood of Bolton, as well as the bed-quilts and counterpanes; nankeens and cottonickings are chiefly made within seven miles of Manchester; velvets, thicksets, and cords, chiefly at Warrington; and velveteens principally at Oldham, and in very great quantity in those parts of Yorkshire which border on Lancashire; fustian cutting is almost entirely confined to the town of Manchester; bleaching and printing are chiefly carried on at Blackburn, Bury, &c. and the former at Bolton; calico-printing is also carried on extensively at Carlisle, and in the neighbourhood of London. Most of the mills for spinning cotton are in the neighbourhood of Manchester and Stockport.

The proportion of the population in the cotton district of England employed in that trade, is very great; some estimate it so high as five-sevenths. In Bolton it is supposed to be nearly one-half; in Stockport two-thirds. The proportion of men and women employed in weaving was formerly nearly equal; but, in consequence of the introduction of the power-looms, (to which we have before adverted, and which forms the most recent era in the history of the cotton trade of
this country,) though these looms as yet are but partially applied to weaving, the proportion of women employed in this branch of the cotton trade may be estimated to be greater than the men: the number of children is nearly equal to both men and women. The proportions employed in the preparation of the cotton and in spinning, are nearly four-fifths to one-fifth men: in this branch, also, the number of children is equal to both. The quantity of cotton manufactured in the cotton district, is estimated at about 81,000,000 lbs.

In the examination of witnesses before the House of Commons, in the year 1812, respecting rewarding Mr Crompton, who invented the mule, it was given in evidence, that the rate of increase of the cotton trade in Lancashire and the adjoining districts, within 30 years from that time, was as twenty to one; that four millions of spindles were employed according to Mr Crompton's invention; that two-thirds of the steam engines for spinning cotton turned mules; and that the value of the machinery, buildings, &c., on Mr Crompton's principle, was between L.3,000,000 and L.4,000,000; consequently the value of all the machinery of every kind employed in the cotton trade, must have been at least L.7,000,000.

As the official value of the cotton goods exported from Great Britain in 1809 and 1810 was upwards of L.19,000,000 each year, we cannot estimate the total value of the goods made in the cotton district in England, both for home consumption and exportation, at less than L.29,000,000; allowing the difference between the official and the real value, (which, however, cannot be great,) and the value of the goods retained for home consumption throughout the kingdom, to be equivalent to the value of the goods made in Scotland. But as it may be, said, that the quantity exported during these two years was much greater than the average export, and that the export of cotton manufactured goods in 1811 was only L.11,715,583, and of cotton yarn L.545,927, making a total of L.12,260,770; and of 1812, of the former L.15,672,826, and of the latter L.986,097, making a total of L.16,978,883; we shall suppose the steady average exportation to be only L.15,000,000, and allowing, as before, the difference between the official and the real value, and the value of what is retained for home consumption, to be equal to the value of what is made in Scotland, we shall take L.3,500,000 as the real value of the goods made in the cotton districts of England. As it is probable that 80,000,000 pounds of cotton wool is too high an estimate for the consumption of this district, we shall take it at 70,000,000; averaging the price at 2s. per pound; this will give L.7,000,000 for the total cost of it; leaving 8,000,000 for interest of capital, profit to the manufacturer, and wages of labour. As a very large proportion of women and children are employed in this trade, the average wages cannot be rated higher than L.15 per annum. The rate of profit to the manufacturer, including interest of capital, must be rated at L.20 per cent. since the expense and wear of machinery are very great. Now L.20 per cent. on L.8,000,000, is L.1,600,000, leaving L.6,400,000 for wages. This at L.15 per annum for each person employed, will give 426,666 as the number of people employed. And that this must be pretty nearly the number, will appear from the following considerations. The number of people in Liverpool, and in other parts of Lancashire where the cotton trade is not established, is probably considerably greater than the population of those places out of Lancashire, in which the trade is established; we may therefore take 600,000, which is about 200,000 less than the population of Lancashire, as the population of the cotton district of England; and supposing, as before stated, that five-sevenths of this population is employed in the trade, the whole number will be 428,570, which comes very near the number to which we brought it by the other mode of computation. The statement, then, with regard to the cotton manufacture of England, will stand as follows:

Total value of the manufactured article, L.15,000,000  
Value of the raw material, L.7,000,000  
Interest on capital, and manufacturers profit L.1,600,000  
Manufacturing wages 6,400,000  
Number of people employed, 427,000

In many respects, there is a striking and considerable contrast between the woollen and cotton manufactures, which, in every point of view, may be regarded as the most important manufactures of this country. In the first, the woollen manufacture in general, at least in the West Riding of Yorkshire, is carried on by men of comparatively small capital; whereas most of those engaged in the cotton manufacture are men of rather large capital. There can be no doubt that this point of contrast will soon vanish, both from the natural course of trade, and from the superior advantages which the factory system (so far as regards the grand object, the making of money) possesses over the domestic system. Factories are much more common now than they were formerly in the West Riding, and their number is increasing. In the second place, the cotton manufacture, as has just been incidentally observed, is distinguished from the woollen manufacture, by the mode of carrying on: the most important branch of it, the spinning, is entirely done in factories; and by the late invention of power looms for weaving, it is highly probable that, in the course of a few years, the next important branch, that of weaving, will also be carried on in factories. In the third place, it may be remarked, that in the cotton manufacture, the proportion of women and children, and more especially of the latter, to men, is much greater than in the woollen manufacture. In the fourth place, the cotton manufacture is not nearly so regular and steady a trade as the woollen manufacture. This seems to arise principally from two causes. In the woollen manufacture, the foreign demand and exportation is not more than equal to the home consumption; and the goods manufactured, being less articles of luxury, taste, and fancy, meet with a more regular and constant demand; neither the interruption of foreign trade, nor the vicissitudes of foreign fashion, therefore, can influence the demand so much as is the case frequently with the cotton manufacture. Moreover, in the case of the woollen manufacture, by far the greatest proportion of the raw material employed in it is of domestic growth; whereas in the case of the latter manufacture, the whole of the raw material comes from abroad; consequently the supply and price of it must vary very often, and very much. As, therefore, we depend on foreign countries for the raw material of our cotton manufacture, and on them also for taking off a much larger proportion of it than of our woollen goods, the trade in the latter must be more regular and steady than in the cotton trade.

But the most material and important contrast between the two species of manufactures, consists in the different condition of the people employed in them. Whoever has been in the woollen and cotton districts of England, must have been immediately struck with
this circumstance; and it is peculiarly striking, and almost forces itself upon a person who crosses the country from York to Manchester, and consequently passes immediately from the woollen district of the West Riding, to the cotton district of Lancashire. In the former, he observes much of the comfort and feelings of domestic life; the habits and manners of the manufacturing classes are sober, decent, and regular; they seem to have an interest and a pride in keeping up the respectability of their character, in setting a good example to their children, and in bringing them up in the paths of virtue. But, even before a traveller has time or opportunity to ascertain these facts, he is struck with the cleanliness and neatness of their dress and persons, with the healthiness of their looks, and with their steady and cheerful manners. Let him pass into the cotton district, and the case is most miserably reversed: the manufacturing classes are dirty, squalid, and unhealthy in their looks, having the appearance of debauchery and poverty strongly marked in their persons. Nor will these appearances, on enquiry, be found to be erroneous: the utmost ignorance and dissolution of manners prevail; there is none of that laudable feeling of independence, none of that prospective prudence, without which the manufacturing classes must always be sunk in poverty and vice. Such being the striking contrast, it is important to endeavour to ascertain its causes, and these by no means lie deep; they are sufficiently obvious. Before stating them, however, it may be proper to recall to our readers, that the principal points of contrast regard the health and morals of the manufacturing classes in the two districts: whatever causes will account for their difference in these respects, will also account for their difference in respect to comparative cleanliness, comfort, and pecuniary means. In the first place, then, the factory system being more prevalent in the cotton than in the woollen district, must be looked to as one of the primary and great causes: it is unnecessary to explain how this must operate in giving rise to disease and vice; but it may be remarked, that, in all probability, even if the factory system should become as prevalent in the woollen as it is in the cotton district, it will not produce effects equally prejudicial; and this, from the operation of the second cause of the contrast between the two trades, to which we shall now allude. - In the cotton trade, the number of children employed is very great; and it is easy to conceive how their health must be affected in a crowded factory, where they are obliged to work long before their strength is adequate to the task, and at a period of life when close and long confinement are extremely prejudicial. As they are sent to these factories before they receive any education, they can attain little while they are there, associate, while in them, with depraved characters, and at home meet with no encouragement or example to cleanliness or propriety of conduct; it is not to be wondered that they should almost universally exhibit instances of most disgusting filth, of most pitiable want of health, and of vice, which at any age would be shocking, and at their early age is peculiarly so. But there is still another cause to which we must advert, in order satisfactorily to account for and explain the contrast between the woollen and the cotton manufacturers. It has already been remarked, that in the woollen trade, the demand is more regular and steady than it is in the cotton trade; consequently, in the former, there are not so many, nor so great inequalities in the wages of the manufacturers. Besides, in the woollen trade, when the demand slackens, it is customary to dismiss as few hands as possible, but rather to keep them on at a lower rate of wages: whereas, in the cotton trade, when the demand diminishes in any considerable degree, multitudes of work people are thrown out of employment. Now, no person who is in the least acquainted with the habits and feelings of the labouring classes in England, need be told, that to them, high wages at one time, and low wages at another time, constitutes one of the greatest evils to which they can be exposed. They almost uniformly live up to the maximum rate of their wages; consequently, when they are not employed, or but partially employed, they have no means, or very inadequate means, of supporting themselves. Nor is this the only evil; while trade was brisk, they indulged in various things, which, of course, they cannot acquire when trade is bad: of course, in the latter state of things, they retain all the wants and habits which they acquired in the former state of things, and are no longer able to satisfy them. Thus, with high wages, they are extravagant, debauched, and thoughtless; and with low wages, they are starving. It must be obvious, that the more frequently those fluctuations in trade occur, which produce corresponding fluctuations of wages, the more confirmed and inveterate will all the consequences produced by these fluctuations become; and these consequences of extreme high and low wages, frequently, and often rapidly, succeeding one another, are the more dreadful, as they fall on a set of people not prepared by education or habits of reflection and prudence to avoid them. In the woollen trade, the case is different; wages are much more regular and steady; and the people employed in it are better able, from their education and habits, to withstand the temptation of high wages, and consequently are less exposed to the evil consequences of low wages. Such appear to us to be the chief causes of the difference so visible and general between the condition and morals of the labouring classes in the cotton and in the woollen districts: it may be added, that the cotton factories in the former are generally in large towns, and that at least, so far as respects Manchester, the principal seat and centre of the trade, a great number of Irish people are employed in it, who certainly, from the peculiarities of their national character, are as little able to withstand the temptations of vice, and of alternate high and low wages, as any race of people in the world. On the contrary, the factories in the woolen district are generally not in towns, and the people who work in them are generally natives. It is proper, however, to remark, that the filth, poverty, unhealthiness, and dissipation, which characterize, in such a striking and lamentable manner, the spinning branch of the manufacture of cotton, do not exist, in nearly an equal degree, in the weaving and other branches; many of the weavers, on the contrary, are industrious, sober, and intelligent men; and in the neighbourhood of Manchester, particularly, frequently possess small farms, which they manage along with their weaving business: these farms, it is true, are too often neglected, in consequence of their attention and time being almost exclusively devoted to their other business. (W. S.)
